The human heart is divided by a septum into right and left halves, and each half is further divided into two cavities, an upper termed the *auricle* and a lower the *ventricle*. The heart therefore consists of four chambers, two, the right auricle and right ventricle, forming the right half, and two, the left auricle and left ventricle, the left half. The auricles are receiving chambers, and the ventricles distributing ones. The right half of the heart contains venous or impure blood; the left, arterial or pure blood. From the cavity of the left ventricle the pure blood is carried into a large artery, the *aorta*, through the numerous branches of which it is distributed to all parts of the body, with the exception of the lungs. In its passage through the capillaries of the body the blood gives up to the tissues the materials necessary for their growth and nourishment, and at the same time receives from the tissues the waste products resulting from their metabolism. In doing so it becomes changed from arterial into venous blood, which is collected by the veins and through them returned to the right auricle of the heart. From this cavity the impure blood passes into the right ventricle, and is thence conveyed through the *pulmonary arteries* to the lungs. In the capillaries of the lungs it again becomes arterialised, and is then carried to the left auricle by the *pulmonary veins*. From the left auricle it passes into the left ventricle, from which the cycle once more begins.

The course of the blood from the left ventricle through the body generally to the right side of the heart constitutes the greater or *systemic* circulation, while its passage from the right ventricle through the lungs to the left side of the heart is termed the lesser or *pulmonary* circulation.

It is necessary, however, to state that the blood which circulates through the spleen, pancreas, stomach, small intestine, and the greater part of the large intestine is not returned directly from these organs to the heart, but is collected into a large vein, termed the *portal vein*, by which it is carried to the liver. In the liver this vein divides, after the manner of an artery, and ultimately ends in capillary vessels, from which the rootlets of a series of veins, called the *hepatic veins*, arise; these carry the blood into the inferior vena cava, whence it is conveyed to the right auricle. From this it will be seen that

* The composition of the blood and the structure of the blood-vessels are described in the section on Histology.

the blood contained in the portal vein passes through two sets of capillary vessels: (1) those in the spleen, pancreas, stomach, &c., and (2) those in the liver.

Speaking generally, the arteries may be said to contain pure, and the veins impure, blood. This is true of the systemic, but not of the pulmonary vessels, since it has been seen that the impure blood is conveyed from the heart to the lungs by the pulmonary arteries, and the pure blood returned from the lungs to the heart by the pulmonary veins. Arteries, therefore, must be defined as vessels which convey blood *from* the heart, and veins as vessels which return blood *to* the heart.

The heart and lungs are situated in the thorax, the walls of which afford them protection. The heart lies between the two lungs, and is enclosed within a membranous bag, the *pericardium*, while each lung is invested by a serous membrane, the *pleura*. The skeleton of the thorax, and the shape and boundaries of the cavity, have already been described (page 202).

The cavity of the thorax.—The capacity of the cavity of the thorax does not correspond with its apparent size externally, because (1) the space enclosed by the lower ribs is occupied by some of the abdominal viscera; and (2) the cavity extends above the first rib into the neck. The size of the thoracic cavity is constantly varying during life with the movements of the ribs and Diaphragm, and with the degree of distension of the abdominal viscera. From the collapsed state of the lungs as seen when the thorax is opened in the dead body, it would appear as if the viscera only partly filled the cavity, but during life there is no vacant space, that which is seen after death being filled up by the expanded lungs.

The upper opening of the thorax.—The parts which pass through the upper opening of the thorax are, from before backwards in or near the middle line, the Sterno-hyoid and Sterno-thyroid muscles, the remains of the thymus gland, the inferior thyroid veins, the trachea, œsophagus, thoracic duct, and the Longus colli muscles; at the sides, the innominate artery, the left common carotid and left subclavian arteries, the internal mammary and superior intercostal arteries, the innominate veins, the pneumogastric, cardiac, phrenic, and sympathetic nerves, the greater part of the anterior primary divisions of the first thoracic nerves, and the recurrent laryngeal nerve of the left side. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the level of the anterior end of the first rib.

The **lower opening of the thorax** is wider transversely than from before backwards. It slopes obliquely downwards and backwards, so that the thoracic cavity is much deeper behind than in front. The Diaphragm (see page 501) closes the opening and forms the floor of the thorax. The floor is flatter at the centre than at the sides, and higher on the right side than on the left; in the dead body the right side reaches the level of the upper border of the fifth costal cartilage, while the left extends only to the corresponding part of the sixth costal cartilage. From the highest point on each side the floor slopes suddenly downwards to the costal and vertebral attachments of the Diaphragm; this slope is more marked behind than in front, so that only a narrow space is left between the Diaphragm and the posterior wall of the thorax.

The Pericardium

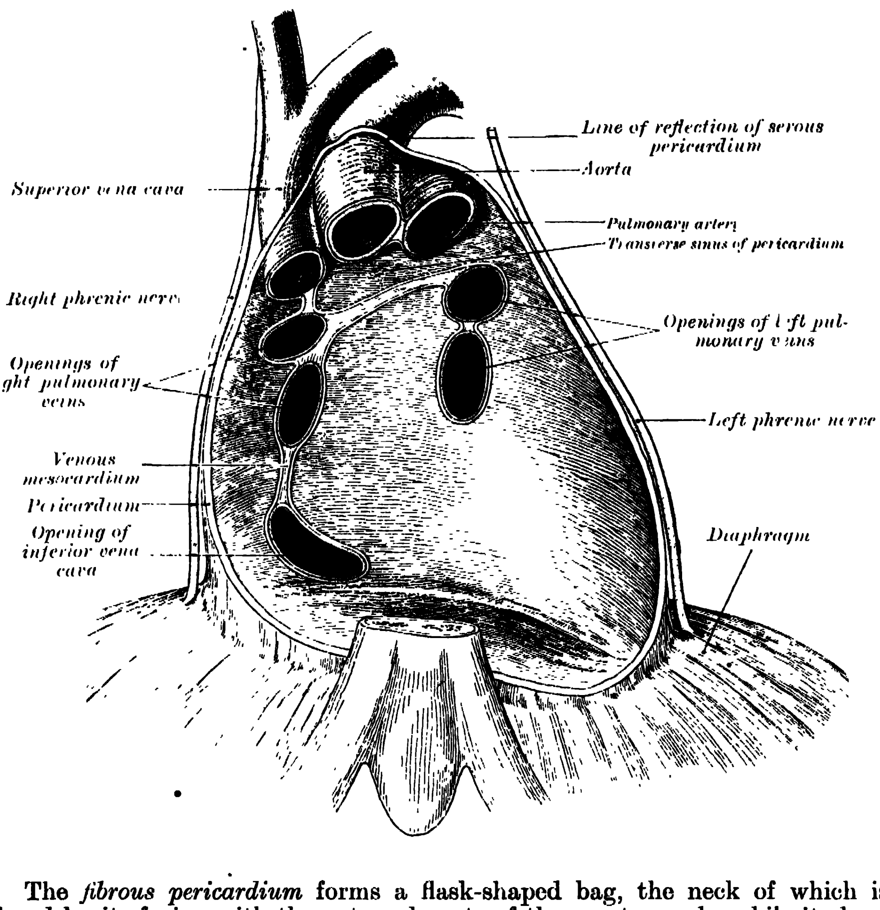
The **Pericardium** (fig. 560) is a conical fibro-serous sac, in which the heart and the roots of the great vessels are contained. It is placed behind the sternum and the cartilages of the third, fourth, fifth, sixth, and seventh ribs of the left side, in the interval between the pleuræ.

In *front*, it is separated from the anterior wall of the thorax, in the greater part of its extent, by the lungs and pleuræ; but a small area, somewhat variable in size, and usually corresponding with the left half of the lower portion of the gladiolus of the sternum and the inner extremities of the cartilages of the fourth and fifth ribs of the left side, comes into direct relationship with the chest-wall. The lower extremity of the thymus gland, in the child, is in contact with the front of the upper part of the pericardium. *Behind*, it rests upon the bronchi, the œsophagus, and the descending thoracic aorta. *Laterally*, it is covered by the pleuræ, and is in relation with the inner

surfaces of the lungs; the phrenic nerve, with its accompanying vessels, descends between the pericardium and pleura on either side.

Structure of the Pericardium.—Although the pericardium is usually described as a single sac, an examination of its structure shows that it consists essentially of two sacs intimately connected with one another, but totally different in structure. The outer sac, known as the *fibrous pericardium*, consists of fibrous tissue. The inner sac, or *serous pericardium*, is composed of a delicate membrane which lies within the fibrous sac and lines its walls; the heart invaginates the wall of the serous sac from above and behind, and practically obliterates its cavity, the space being a potential one, except in front, where a small interspace exists below the apex of the heart.

FIG. 560.—Posterior wall of the pericardial sac, showing the lines of reflection of the serous pericardium on the great vessels.



The *fibrous pericardium* forms a flask-shaped bag, the neck of which is closed by its fusion with the external coats of the great vessels, while its base is attached to the central tendon and to the muscular fibres of the left side of the Diaphragm. In some of the lower mammals the base is either completely separated from the Diaphragm or joined to it by some loose areolar tissue; in man much of its diaphragmatic attachment consists of loose fibrous tissue which can be readily broken down, but over a small area the central tendon of the Diaphragm and the pericardium are completely fused. Above, the fibrous pericardium not only blends with the external coats of the great vessels, but is continuous with the pretracheal layer of the deep cervical fascia. By means of these upper and lower connections it is securely anchored within the thoracic cavity. It is also attached to the posterior surface of the sternum by two fibrous bands, the *superior* and *inferior sterno-pericardiac ligaments* (ligg. sternopericardiaca); the upper passing to the manubrium, and the

lower to the ensiform cartilage. On either side of the ascending aorta it sends upwards a diverticulum: the one on the left side, somewhat conical in shape, passes upwards and outwards, between the arch of the aorta and the pulmonary artery, as far as the obliterated ductus arteriosus, where it terminates in a cæcal extremity which is attached by loose connective tissue to the obliterated duct. The one on the right side passes upwards and to the right, between the ascending aorta and vena cava superior, and also terminates in a blind extremity.

The vessels receiving fibrous prolongations from this membrane are, the aorta, the superior vena cava, the right and left pulmonary arteries, the four pulmonary veins, and the obliterated ductus arteriosus. The inferior vena cava enters the pericardium through the central tendon of the Diaphragm, and receives no covering from the fibrous layer.

The *serous pericardium* is, as already stated, a closed sac which lines the fibrous pericardium and is invaginated by the heart; it therefore consists of a *visceral* and a *parietal* portion. The visceral portion, or *epicardium*, covers the heart and the great vessels, and from the latter is continuous with the parietal layer which lines the fibrous pericardium. The portion which covers the vessels is arranged in the form of two tubes. The aorta and pulmonary artery are enclosed in one tube, the *arterial mesocardium*. The superior and inferior venæ cavæ and the four pulmonary veins are enclosed in a second tube, the *venous mesocardium*, the attachment of which to the parietal layer presents the shape of an inverted U. The *cul-de-sac* enclosed between the limbs of the ∩ is known as the *oblique sinus*, while the passage between the venous and arterial mesocardia—i.e. between the aorta and pulmonary artery in front and the auricles behind—is termed the *transverse sinus* (sinus transversus pericardii). The serous pericardium is smooth and glistening, and secretes a serous fluid, which serves to facilitate the movements of the heart.

The vestigial fold of the pericardium. — Between the left pulmonary artery and subjacent pulmonary vein is a triangular fold of the serous pericardium; it is known as the *vestigial fold of Marshall.* It is formed by the duplicature of the serous layer over the remnant of the lower part of the left superior vena cava (duct of Cuvier), which becomes obliterated after birth, and remains as a fibrous band stretching from the left superior intercostal vein to the left auricle, where it is continuous with a small vein, the oblique vein of Marshall, which opens into the coronary sinus.

The *arteries* of the pericardium are derived from the internal mammary and its musculo-phrenic branch, and from the descending thoracic aorta.

The *nerves* of the pericardium are derived from the pneumogastrics, the phrenics, and the sympathetic.

Applied Anatomy.—The effusion of fluid into the pericardial sac often occurs in acute rheumatism or pneumonia, or in patients with chronic vascular and renal disease, embarrassing the heart's action and giving rise to signs of cardiac distress, such as pallor, a rapid and feeble pulse, dyspnœa, and restlessness. On examination, the apical cardiac impulse is absent, or replaced by a more extensive indefinite and wavering pulsation; it may appear to be in the second, third, or fourth left space, and is then not an apex-impulse, as Potain has stated, but due to the impact of some portion of the heart-wall nearer its base. In children the præcordial intercostal spaces may bulge outwards. The most striking sign, however, is the great increase in all directions of the præcordial dulness on percussion. This becomes pear-shaped, the stalk of the pear reaching up to about the left sterno-clavicular articulation: the dulness also extends some distance to the right of the sternum, particularly in the fifth interspace (Rotch). The fluid collects mainly on either side of the heart, and below it, especially on the left side, where the Diaphragm can yield more readily to pressure than it can on the right. Ewart has drawn attention to the presence of a square patch of dulness over the base of the left lung behind, reaching up to the level of the ninth or tenth rib, and extending outwards as far as the lower angle of the scapula; the underlying lung-tissue gives the physical signs of compression or collapse.

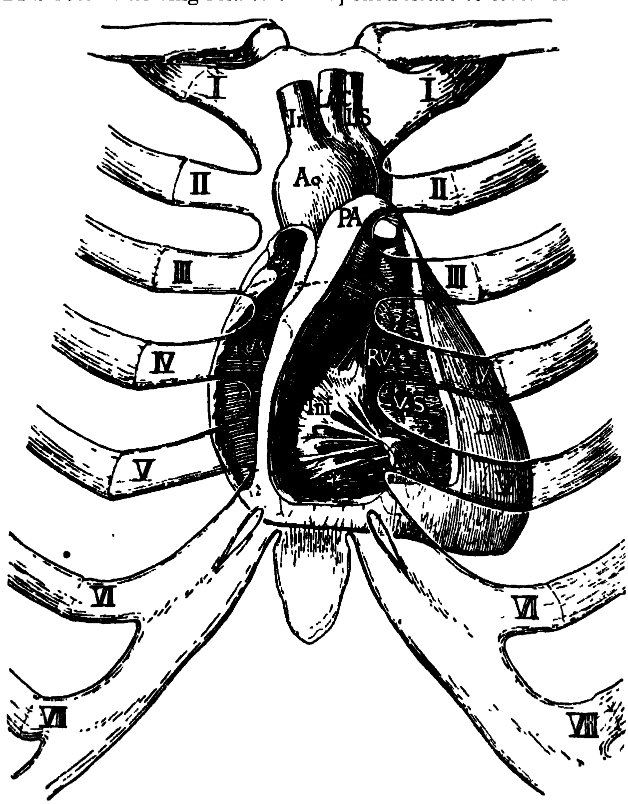
Paracentesis of the pericardium is often required to relieve the urgent cardiac or respiratory distress in these cases, and should be performed without hesitation and before the patient is *in extremis*. It may also be required when the pericardium is filled with blood or pus, and as it is advisable to perform this operation without transfixing the pleura, the puncture should be made either in the fifth or sixth intercostal space on the left side and close to the sternum, so as to avoid wounding the internal mammary artery, which descends about half an inch from the sternal margin; or the needle may be entered at the left costo-xiphoid angle and made to pass upwards and backwards behind the lower

end of the body of the sternum into the pericardial sac. Curschmann,* however, argues that the heart itself necessarily lies almost in contact with the anterior wall of the thorax even in cases of the largest pericardial effusion, so that there is risk of piercing it if the puncture is made in the fourth or fifth left intercostal space within even so much as two or three inches of the sternal margin. He therefore advises that in moderately large pericardial effusions the trochar should be inserted in the left mamillary line, and outside it if the effusion is very large, in the fifth or sixth interspace. In consequence of the uncertain and varying position of the anterior reflexion of the pleura, transfixion of the pleural sac cannot always be avoided. *Pericardiotomy* is required when the effusion is of a purulent nature. In this operation a portion of the fifth or sixth costal cartilage is excised. An incision is made along the left border of the sternum from the upper border of the fourth cartilage to the seventh. Transverse incisions an inch long are then made outwards from either extremity of this, and the rectangular flap thus formed reflected outwards. The fifth costal cartilage is now separated from the sternum by means of a gouge, great care being taken not to let the instrument slip and penetrate too deeply. The cartilage is then seized with lion forceps and raised, the tissues beneath it being peeled off, so as to avoid wounding the internal mammary artery or the pleura. The Triangularis sterni is now scratched through, with a director or the nail of the index finger, close to the sternum, and the pericardium felt for and opened, the finger guarding the pleura and left internal mammary artery.

The Heart

The **Heart** (cor) is a hollow muscular organ of a somewhat conical form; it lies between the lungs in the middle mediastinum and is enclosed in the pericardium.

Fig. 561.—Showing relations of opened heart to front of chest.



Ao. Aorta. AP. Anterior papillary muscle. In. Innominate artery. Inf. Infundibular segment of tricuspid valve. LCC. Left common carotid artery. LS. Left subclavian artery. LV. Left ventricle. PA. Pulmonary artery. RA. Right auricle. RV. Right ventricle. VS. Ventricular septum.

Position (fig. 561).—It is placed obliquely in the chest behind the gladiolus and adjoining parts of the rib cartilages, and projects farther into the left than into the right half of the thoracic cavity, so that about one-

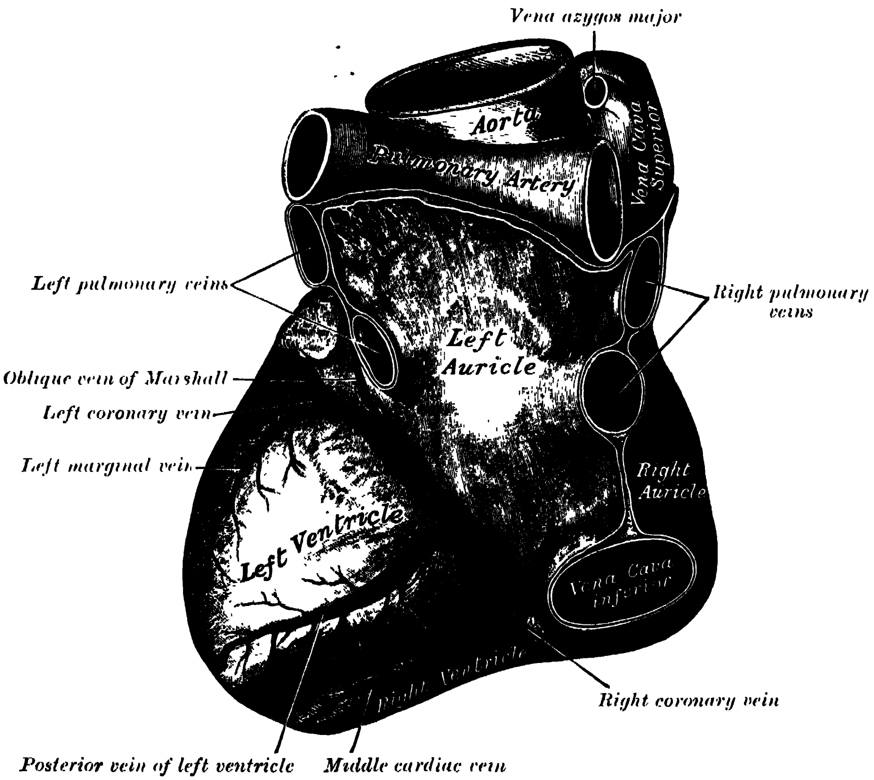
* *Therapie der Gegenwart*, 1905.

third of it is situated on the right and two-thirds on the left of the mesial plane.

Size.—The heart, in the adult, measures about five inches in length, three inches and a half in breadth at the broadest part, and two inches and a half in thickness. Its weight, in the male, varies from ten to twelve ounces; in the female, from eight to ten: the proportions to the body-weight being as 1 to 169 in males; 1 to 149 in females. The heart continues to increase in weight and size up to an advanced period of life: this increase is more marked in men than in women.

Component Parts.—As has already been stated (page 597), the heart is subdivided by a septum into right and left halves, and a transverse constriction subdivides each half of the organ into two cavities, the upper cavity being called the *auricle*, the lower the *ventricle*. The heart therefore consists of

FIG. 562.—Base and postero-inferior surface of heart.



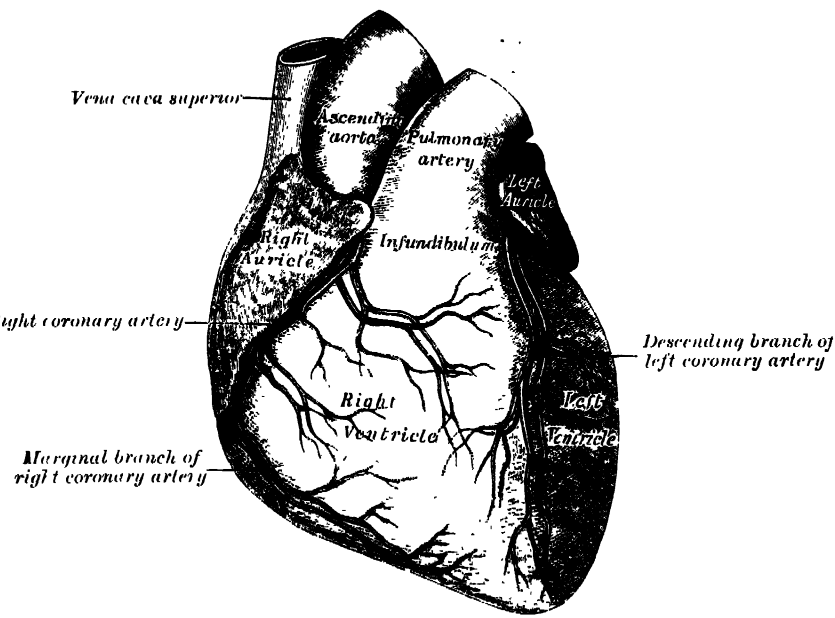
four chambers, viz. right and left auricles, and right and left ventricles. The course of the blood through the heart cavities and blood-vessels has already been described (page 597).

The division of the heart into four cavities is indicated on its surface by grooves. The auricles are separated from the ventricles by the *auriculo-ventricular groove* (sulcus coronarius). It contains the trunks of the nutrient vessels of the heart, and is deficient in front, where it is crossed by the root of the pulmonary artery. The *interauricular groove*, separating the two auricles, is scarcely marked on the posterior surface, while anteriorly it is hidden by the pulmonary artery and aorta. The ventricles are separated by two grooves, the *interventricular grooves*, one of which (sulcus longitudinalis anterior) is situated on the antero-superior surface close to the left margin of the heart, the other (sulcus longitudinalis posterior) on the postero-inferior surface near the right margin; these grooves extend from the base of the ventricular portion to a point a little to the right of the apex of the heart.

The *base* (basis cordis) (fig. 562), directed upwards, backwards, and to the right, is separated from the fifth, sixth, seventh, and eighth thoracic vertebræ by the œsophagus, aorta, and thoracic duct. It is formed mainly by the left auricle, and, to a small extent, by the back part of the right auricle. Somewhat quadrilateral in form, it is in relation above with the bifurcation of the pulmonary artery, and is bounded below by the posterior part of the auriculo-ventricular sulcus, containing the coronary sinus. On the right it is limited by the sulcus terminalis of the right auricle, and on the left by the vestigial fold and oblique vein of Marshall. The four pulmonary veins, two on either side, open into the left auricle, whilst the superior vena cava opens into the upper, and the inferior vena cava into the lower, part of the right auricle.

The *apex* (apex cordis) is directed downwards, forwards, and to the left, and is overlapped by the left lung and pleura: it lies behind the fifth left intercostal space, three and a half inches from the mid-sternal line, or about an inch and a half below and three-quarters of an inch to the inner side of the left nipple.

FIG. 563.—Antero-superior surface of heart.



The *antero-superior surface* (facies sternocostalis) (fig. 563) is directed forwards, upwards, and to the left. Its lower part is convex, formed chiefly by the right ventricle, and is traversed near its left margin by the anterior interventricular furrow. Its upper part is separated from the lower by the auriculo-ventricular groove; it is formed by the auricles, and presents a deep concavity (fig. 566), occupied by the ascending aorta and the pulmonary artery.

The *postero-inferior surface* (facies diaphragmatica) (fig. 562), which looks downwards and slightly backwards, is formed by the ventricles, and rests upon the central tendon and a small part of the left muscular portion of the Diaphragm. It is separated from the base by the posterior part of the auriculo-ventricular furrow, and is traversed obliquely by the posterior interventricular groove.

The *right margin* of the heart is long, and is formed by the right auricle above and the right ventricle below. The auricular portion is almost vertical, and is situated behind the third, fourth, and fifth right costal cartilages about half an inch from the margin of the sternum. The ventricular portion, thin and sharp, is named the *margo acutus*; it is nearly horizontal, and extends from the sternal end of the sixth right costal cartilage behind the lower end of the gladiolus to the apex of the heart.

The *left margin*, or *margo obtusus*, is short, thick, and rounded: it is formed mainly by the left ventricle, but to a slight extent, above, by the left auricle. It extends from a point in the second left intercostal space, about an inch from the sternal margin, obliquely downwards, with a convexity to the left, to the apex of the heart.

The **Right Auricle** (atrium dextrum) is the larger of the two auricles, although its walls are somewhat thinner than those of the left, measuring about 2 mm.; its cavity is capable of containing about two ounces. It consists of two parts: a principal cavity, or *sinus venosus* (sinus venarum), situated posteriorly, and an anterior, smaller portion, the *appendix auriculæ*.

The *sinus venosus* is the large quadrangular cavity placed between the two venæ cavæ. Its walls, which are extremely thin, are connected below with the right ventricle, and internally with the left auricle, but are free in the rest of their extent.

The *appendix auriculæ*, so called from its fancied resemblance to a dog's ear, is a small conical muscular pouch, the margins of which present a dentated edge. It projects from the sinus forwards and towards the left side, overlapping the root of the aorta.

The separation of the appendix from the sinus venosus is indicated externally by a groove, the *sulcus terminalis* (His), which extends from the front of the superior vena cava to the front of the inferior vena cava, and represents the line of union of the sinus venosus of the embryo with the primitive auricle. On the inner wall of the auricle the separation is marked by a vertical, smooth, muscular ridge, the *crista terminalis* (His). Behind the crista the internal surface of the auricle is smooth, while in front of it the muscular fibres of the wall are raised into parallel ridges resembling the teeth of a comb, and hence named the *musculi pectinati*.

Its interior (fig. 564) presents the following parts for examination:

Openings:
- rior vena cava.
- Inferior vena cava.
- Coronary sinus.
- Foramina ~~Thebesii~~.
- Auriculo-ventricular.

Valves:
- Eustachian.
- Thebesian.

- Fossa ovalis.
- ~~Annulus~~ ovalis.
- Tubercle of Lower.
- Musculi pectinati.
- Crista terminalis.

The *superior vena cava* returns the blood from the upper half of the body, and opens into the upper and back part of the auricle, the direction of its orifice being downwards and forwards. Its opening has no valve.

The *inferior vena cava*, larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the auricle, near the interauricular septum, its orifice being directed upwards and inwards, and guarded by a rudimentary valve, the *Eustachian valve*. The blood which enters the auricle through the superior vena cava is directed downwards and forwards, i.e. towards the auriculo-ventricular orifice, whilst that entering it through the inferior vena cava is directed upwards and backwards towards the interauricular septum. This is the normal direction of the two currents in fœtal life.

The *coronary sinus* opens into the auricle, between the inferior vena cava and the auriculo-ventricular opening. It returns blood from the substance of the heart, and is protected by a semicircular valve, the *coronary valve*, or *valve of Thebesius*.

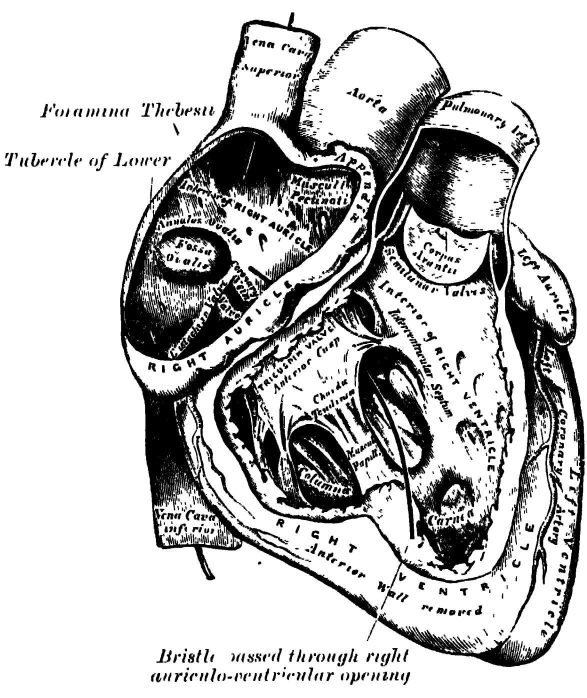
The *foramina Thebesii* (foramina venarum minimarum) are depressions in the walls of the auricle: the majority of these are culs-de-sac, but about one-third are the orifices of minute veins (*venæ minimæ cordis*), which return blood directly from the muscular substance of the heart.

The *auriculo-ventricular opening* is the large oval aperture of communication between the auricle and the ventricle; it will be described with the right ventricle.

The *Eustachian valve* (valvula venæ cavæ inferioris) is situated in front of the orifice of the inferior vena cava. It is semilunar in form, its convex margin being attached to the anterior margin of the caval orifice ; its concave margin, which is free, terminates in two cornua, of which the left is continuous with the anterior edge of the annulus ovalis while the right is lost on the wall of the auricle. The valve is formed by a duplicature of the lining membrane of the auricle, containing a few muscular fibres. *In the fœtus* this valve is of large size, and serves to direct the blood from the inferior vena cava, through the foramen ovale, into the left auricle. *In the adult* it occasionally persists, and may assist in preventing the reflux of blood into the inferior vena cava ; more commonly it is small, and may present a cribriform or filamentous appearance ; sometimes it is altogether wanting.

The *Thebesian valve* (valvula sinus coronarii) is a semicircular fold of the lining membrane of the auricle, at the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the auricle. This valve may be double.

Fig. 564.—The right auricle and ventricle laid open, the anterior walls of both having been removed.



The *fossa ovalis* is an oval depression on the posterior wall of the auricle, and corresponds to the situation of the foramen ovale in the fœtus. It is situated at the lower part of the auricular septum, above and to the left of the orifice of the inferior vena cava.

The *annulus ovalis* (limbus fossæ ovalis) is the prominent oval margin of the fossa ovalis. It is most distinct above and at the sides of the fossa ; below, it is deficient. A small slit-like valvular opening is occasionally found, at the upper margin of the fossa ovalis, leading upwards, beneath the annulus, into the left auricle ; it is the remains of the fœtal aperture between the two auricles.

The *tubercle of Lower* (tuberculum intervenosum) is a small projection on the posterior wall of the auricle, above the fossa ovalis. It is distinct in the hearts of quadrupeds, but in man is scarcely visible. It was supposed by Lower to direct the blood from the superior vena cava towards the auriculo-ventricular opening.

The **Right Ventricle** (ventriculus dexter) is triangular in form, and extends from the right auricle to near the apex of the heart. Its antero-superior surface is rounded and convex, and forms the larger part of the front of the heart. Its under surface is flattened, rests upon the Diaphragm, and forms a small part of the postero-inferior surface of the heart. Its posterior wall is formed by the septum between the two ventricles, the *septum ventriculorum*, which bulges into the right ventricle, so that a transverse section of the cavity presents a semilunar outline. Its upper and inner angle forms a conical pouch, the *infundibulum*, or *conus arteriosus*, from which the pulmonary artery arises. A tendinous band, which may be named the *tendon of the conus arteriosus*, extends upwards from the right auriculo-ventricular fibrous ring and connects the posterior surface of the conus arteriosus to the aorta. The wall of the right ventricle is thinner than that of the left, the proportion between them being as 1 to 3; it is thickest at the base, and gradually becomes thinner towards the apex. The cavity equals in size that of the left ventricle, and is capable of containing about three fluid ounces.

Its interior (fig. 564) presents the following parts for examination :

Openings	Right auriculo-ventricular. Pulmonary artery.	Valves	Tricuspid. Pulmonary.
	Columnæ carneæ.		Chordæ tendineæ.

The *right auriculo-ventricular orifice* is the large oval aperture of communication between the right auricle and ventricle. Situated at the base of the ventricle, it measures about an inch and a half in diameter, and is surrounded by a fibrous ring, covered by the lining membrane of the heart; it is considerably larger than the corresponding aperture on the left side, being sufficient to admit the ends of four fingers. It is guarded by the tricuspid valve.

The *opening of the pulmonary artery* is circular in form, and situated at the summit of the conus arteriosus, close to the septum ventriculorum. It is placed above and to the left of the auriculo-ventricular opening, and is guarded by the pulmonary valves.

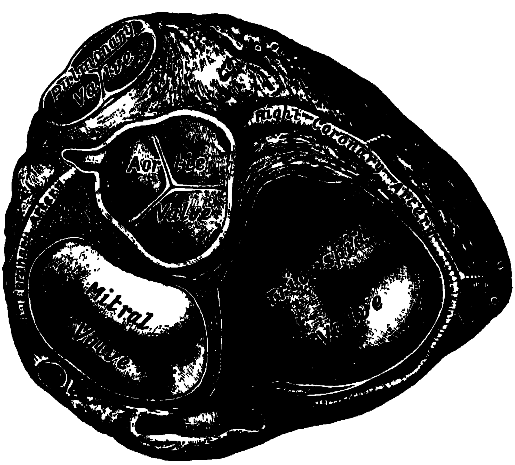


FIG. 565.—Base of ventricles exposed by removal of the auricles.

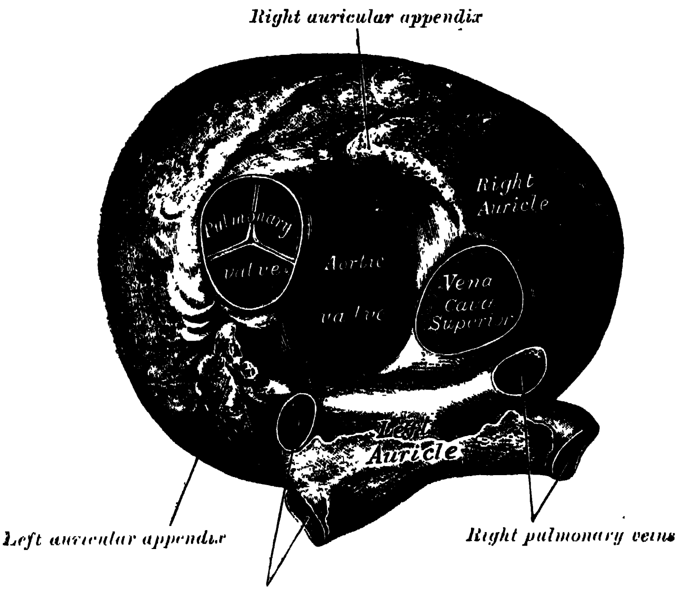
The *tricuspid valve* (valvula tricuspidalis) (figs. 564, 565) consists of three somewhat triangular cusps or segments. The largest cusp is interposed between the auriculo-ventricular orifice and the infundibulum, and is termed the *infundibular cusp*. A second, the *marginal cusp*, is in relation to the right margin of the ventricle, and a third, the *septal cusp*, to the interventricular septum. They are formed by duplicatures of the lining membrane of the heart, strengthened by intervening layers of fibrous tissue: their central parts are thick and strong, their marginal portions thin and translucent, and in the angles between the latter small intermediate segments are sometimes seen. Their bases are attached to a fibrous ring surrounding the auriculo-ventricular orifice and are also joined to each other so as to form a continuous annular membrane, while their apices project into the ventricular cavity. Their auricular surfaces, directed towards the blood current from the auricle, are smooth; their ventricular surfaces, directed towards the wall of the ventricle, are rough and irregular and, together with the apices and margins of the cusps, give attachment to a number of delicate tendinous cords, the *chordæ tendineæ*.

The *columnæ carneæ* (trabeculæ carneæ) are rounded or irregular muscular columns which project from the whole of the inner surface of the ventricle, with the exception of the conus arteriosus. They are of three kinds: some are attached along their entire length on one side and merely form prominent ridges, others are fixed at their extremities but free in the middle, while a third set (*musculi papillares*) are continuous by their bases with the wall of the ventricle, while their apices give origin to the chordæ tendineæ which pass to be attached to the segments of the tricuspid valve. There are two papillary muscles, anterior and posterior: of these, the anterior is the larger, and its chordæ tendineæ are connected with the marginal and infundibular cusps of the valve; the posterior sometimes consists of two or three muscular columns; its chordæ tendineæ are connected with the septal and marginal segments. In addition to these, some chordæ tendineæ spring directly from the ventricular septum, or from small papillary eminences on it, and pass to the septal and infundibular segments. A fleshy band, well marked in sheep and some other animals, frequently extends from the base of the anterior papillary muscle to the interventricular septum. From its attachments it may assist in

FIG. 566.—Heart seen from above.



preventing over-distension of the ventricle, and so has been named the *moderator band*.

The *pulmonary valve* (fig. 566) consists of three semilunar segments (valvulæ semilunares a. pulmonalis), two in front and one behind, formed by a duplicature of the lining membrane, strengthened by fibrous tissue. They are attached, by their outer convex margins, to the wall of the artery, at its junction with the ventricle, their inner borders being free and directed upwards into the lumen of the vessel. The free and attached margins of each are strengthened by tendinous fibres, and the former presents, at its middle, a small projecting thickened nodule, called the *corpus Arantii* (nodulus valvulæ semilunaris). From this nodule tendinous fibres radiate through the segment to its attached margin, but are absent from two narrow crescentic portions, the *lunulæ* (lunulæ valvularum semilunarum), placed one on either side of the nodule immediately adjoining the free margin.

Between the semilunar segments and the wall of the pulmonary artery are three pouches or dilatations, the *sinuses of Valsalva*. Similar but larger sinuses exist between the semilunar segments of the aortic valve and the wall of the aorta.

The **Left Auricle** (atrium sinistrum) is rather smaller than the right, but its walls are thicker, measuring about 3 mm.; it consists, like the right, of two parts, a *principal cavity* and an *appendix auriculæ*.

The *principal cavity* is cuboidal in form, and concealed, in front, by the pulmonary artery and aorta; in front and to the right, it is separated from the right auricle by the septum auricularum; behind, it receives on either side the two pulmonary veins.

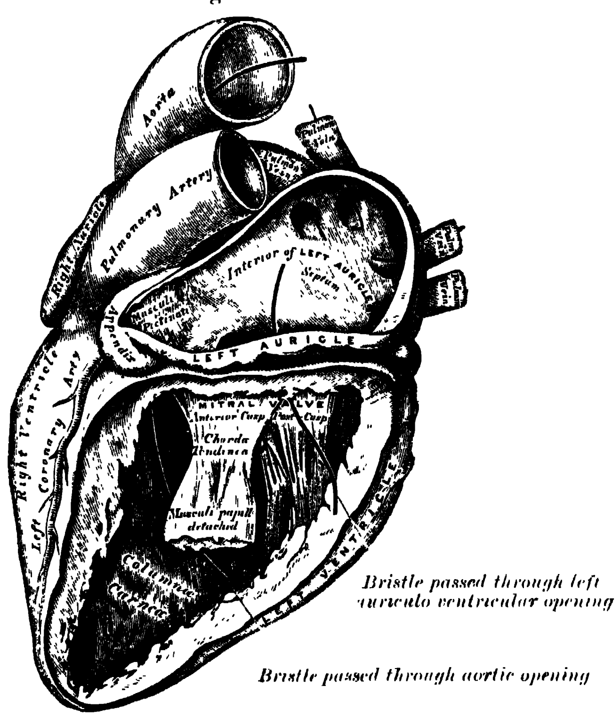
The *appendix auriculæ* is somewhat constricted at its junction with the principal cavity; it is longer, narrower, and more curved than that of the right side, and its margins are more deeply indented. It is directed forwards and towards the right and overlaps the root of the pulmonary artery.

The interior of the left auricle (fig. 567) presents the following parts for examination:

The openings of the four pulmonary veins.
Left auriculo-ventricular opening.
Musculi pectinati.

The *pulmonary veins*, four in number, open into the upper part of the posterior surface of the left auricle— two on either side of its middle line

FIG. 567.—The left auricle and ventricle laid open, the posterior walls of both having been removed.



they are not provided with valves. The two left veins frequently terminate by a common opening.

The *left auriculo-ventricular opening* is the aperture between the left auricle and ventricle, and is rather smaller than the corresponding opening on the right side.

The *musculi pectinati*, fewer and smaller than in the right auricle, are confined to the inner surface of the appendix.

On the septum auricularum may be seen a lunated impression, bounded below by a crescentic ridge, the concavity of which is turned upwards. The depression is just above the fossa ovalis of the right auricle.

The **Left Ventricle** (ventriculus sinister) is longer and more conical in shape than the right, and on transverse section its cavity presents an oval or

nearly circular outline. It forms a small part of the antero-superior surface and a considerable part of the postero-inferior surface of the heart. It also forms the apex of the heart. Its walls are about three times as thick as those of the right ventricle.

Its interior (fig. 567) presents the following parts for examination :

Openings	Left auriculo-ventricular. Aortic.	Valves	Bicuspid or Mitral. Aortic.
	Chordæ tendineæ.		Columnæ carneæ.

The *left auriculo-ventricular opening* is placed below and to the left of the aortic orifice. It is a little smaller than the corresponding aperture of the opposite side, admitting only two fingers. It is surrounded by a dense fibrous ring, covered by the lining membrane of the heart, and is guarded by the bicuspid or mitral valve.

The *aortic opening* is a circular aperture, in front and to the right side of the auriculo-ventricular, from which it is separated by the aortic cusp of the mitral valve. Its orifice is guarded by the *aortic valve*, which consists of three semilunar segments. The portion of the ventricle immediately below the aortic orifice is termed the *aortic vestibule*, and possesses fibrous instead of muscular walls.

The *bicuspid* or *mitral valve* (fig. 565) is attached to the circumference of the auriculo-ventricular orifice in the same way that the tricuspid valve is on the opposite side. It consists of two triangular cusps, formed by duplicatures of the lining membrane, strengthened by fibrous tissue, and containing a few muscular fibres. The cusps are of unequal size, and are larger, thicker, and stronger than those of the tricuspid valve. The larger cusp is placed in front and to the right between the auriculo-ventricular and aortic orifices, and is known as the *aortic cusp* ; the smaller is placed behind and to the left of the opening. Two smaller cusps are usually found at the angles of junction of the larger. The cusps of the mitral valve are furnished with chordæ tendineæ, which are attached in a manner similar to those on the right side ; they are, however, thicker, stronger, and less numerous.

The *aortic valve* (fig. 566) consists of three semilunar segments, which surround the orifice of the aorta ; two are posterior (right and left) and one anterior.* They are similar in structure, and in their mode of attachment, to those of the pulmonary valve, but larger, thicker, and stronger ; the lunulæ are more distinct, and the corpora Arantii thicker and more prominent. Opposite the segments the wall of the aorta presents slight dilatations (*sinuses of Valsalva*), which are larger than those at the origin of the pulmonary artery.

The *columnæ carneæ* are of three kinds, like those upon the right side, but they are more numerous, and present a dense interlacement, especially at the apex, and upon the posterior wall. The *musculi papillares* are two in number, one being connected to the anterior, the other to the posterior wall ; they are of large size, and terminate by free rounded extremities, from which the chordæ tendineæ arise. The chordæ tendineæ from each papillary muscle are connected to both cusps of the mitral valve.

The **interventricular septum** (septum ventriculorum) (fig. 568) is directed obliquely backwards and to the right, and is curved with the convexity towards the right ventricle : its margins correspond with the interventricular grooves. The greater portion of it is thick and muscular (septum musculare ventriculorum), but its upper and posterior part, which separates the aortic vestibule from the lower part of the right auricle and upper part of the right ventricle, is thin and fibrous, and is termed the *pars membranacea* (septum membranaceum ventriculorum). An abnormal communication may exist between the ventricles at this part owing to defective development of the septum.

Structure.—The heart consists of muscular fibres, and of fibrous rings which serve for their attachment. It is covered by the visceral layer of the serous pericardium (*epicardium*), and lined by the *endocardium*. Between these two membranes is the muscular wall or *myocardium*.

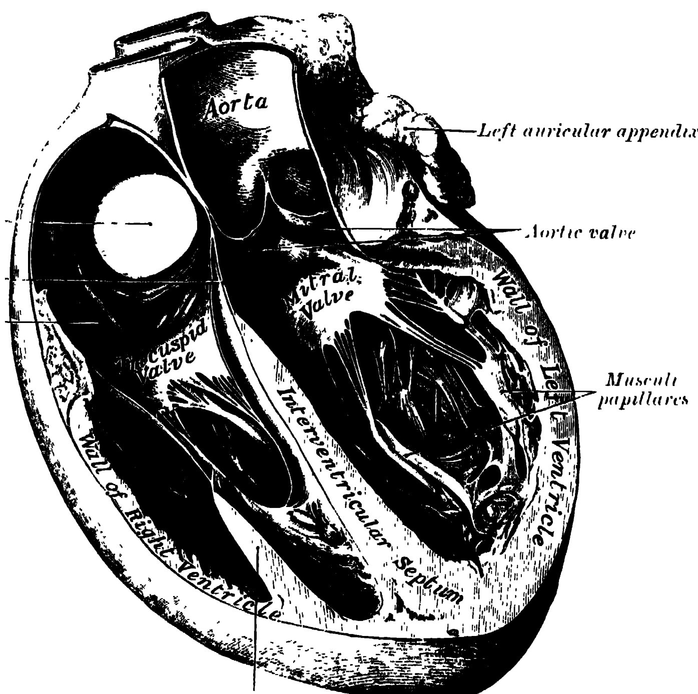
The *endocardium* is a thin, smooth membrane which lines and gives the glistening appearance to the inner surface of the heart ; it assists in forming the valves by its reduplications, and is continuous with the lining membrane of the large blood-vessels. It consists of connective tissue and elastic fibres, and is

attached to the muscular structure by loose elastic tissue which contains blood-vessels and nerves; its free surface is covered by endothelial cells.

The *fibrous rings* (annuli fibrosi) surround the auriculo-ventricular and arterial orifices, and are stronger upon the left than on the right side of the heart. The auriculo-ventricular rings serve for the attachment of the muscular fibres of the auricles and ventricles, and for the attachment of the mitral and tricuspid valves. The left auriculo-ventricular ring is closely connected, by its right margin, with the aortic arterial ring; between these and the right auriculo-ventricular ring is a triangular mass of fibrous tissue (trigonum fibrosum) which represents the *os cordis* seen in the heart of some of the larger animals, as the ox and elephant. Lastly, there is the tendinous band, already referred to (p. 606), on the posterior surface of the conus arteriosus.

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and semilunar valves. Each ring receives, by its ventricular margin, the attachment of some of the muscular fibres of the ventricles; its opposite margin presents three deep semicircular notches, to which the middle coat of the

FIG. 568.—Section of the heart showing the interventricular septum.



artery is firmly fixed. The attachment of the artery to its fibrous ring is strengthened by the thin cellular coat and serous membrane externally, and by the endocardium internally. From the margins of the semicircular notches, the fibrous structure of the ring is continued into the segments of the valve. The middle coat of the artery in this situation is thin, and the wall of the vessel is dilated to form the sinuses of Valsalva.

The *muscular structure of the heart* consists of bands of fibres, which present an exceedingly intricate interlacement. They consist of (*a*) the fibres of the auricles, (*b*) the fibres of the ventricles, and (*c*) the auriculo-ventricular bundle of His.

The *fibres of the auricles* are arranged in two layers,—a superficial common to both cavities, and a deep proper to each. The *superficial fibres* are more distinct on the front of the auricles, across the bases of which they run in a transverse direction, forming a thin and incomplete layer. Some of these fibres run into the septum auricularum. The *deep fibres* consist of looped and annular fibres. The

looped fibres pass upwards over each auricle, being attached by their two extremities to the corresponding auriculo-ventricular ring, in front and behind. The *annular fibres* surround the appendices auricularum, and form annular bands around the terminations of the veins and around the fossa ovalis.

The *fibres of the ventricles* are arranged in a complex manner, and various accounts have been given of their course and connections. The following description is based on the work of McCallum.* They consist of superficial and deep layers, all of which, with the exception of two, are inserted into the papillary muscles of the ventricles. The *superficial layers* consist of the following. (*a*) Fibres which spring from the tendon of the conus arteriosus and sweep downwards and towards the left across the anterior interventricular furrow and around the apex of the heart, where they pass upwards and inwards to terminate in the papillary muscles of the left ventricle. Those which spring from the upper half of the tendon of the conus arteriosus pass to the anterior papillary muscle, those from the lower half to the posterior papillary muscle and the papillary muscles of the septum. (*b*) Fibres which arise from the right auriculo-ventricular ring and run diagonally across the back of the right ventricle and round its right border on to its anterior surface, where they dip beneath the fibres just described, and, crossing the interventricular groove, wind around the apex of the heart and terminate in the posterior papillary muscle of the left ventricle. (*c*) Fibres which spring from the left auriculo-ventricular ring, and, crossing the posterior interventricular furrow, pass successively into the right ventricle and end in its papillary muscles. The *deep layers* are three in number: they arise in the papillary muscles of one ventricle and, curving in an S-shaped manner, turn in at the interventricular furrow and end in the papillary muscles of the other ventricle. The layer which is most superficial in the right ventricle lies next the lumen of the left, and *vice versa*. Those of the first layer almost encircle the right ventricle, and, crossing in the septum to the left, unite with the superficial fibres from the right auriculo-ventricular ring to form the posterior papillary muscle. Those of the second layer have a less extensive course in the wall of the right ventricle, and a correspondingly greater course in the left, where they join with the superficial fibres from the anterior half of the tendon of the conus arteriosus to form the papillary muscles of the septum. Those of the third layer pass almost entirely round the left ventricle and unite with the superficial fibres from the lower half of the tendon of the conus arteriosus to form the anterior papillary muscle. Besides the layers just described there are two bands which do not end in papillary muscles. One springs from the right auriculo-ventricular ring and crosses in the auriculo-ventricular septum: it then encircles the deep layers of the left ventricle and ends in the left auriculo-ventricular ring. The second band is apparently confined to the left ventricle; it is attached to the left auriculo-ventricular ring, and encircles the portion of the ventricle adjacent to the aortic orifice.

The *auriculo-ventricular bundle of His* is the only direct muscular connection known to exist between the auricles and the ventricles. It arises near the orifice of the coronary sinus in the annular and septal fibres of the right auricle, passes forwards in the lower part of the pars membranacea septi, and divides into right and left fasciculi. These run down in the right and left ventricles, one on either side of the interventricular septum, just covered by endocardium. In the lower parts of the ventricles they break up into numerous strands which end in the papillary muscles and in the ventricular muscle generally. The undivided portion of the auriculo-ventricular bundle consists of narrow, somewhat fusiform fibres, but its two divisions and their terminal strands are composed of Purkinje fibres.

Applied Anatomy.—Clinical and experimental evidence go to prove that this bundle conveys the impulse to systolic contraction from the auricular septum to the ventricles, and much attention has recently been paid to it, because it appears to become fibrosed and to lose much of its conducting power (heart-block) in many cases of Stokes-Adams' disease. This condition is characterised by a slow pulse, a tendency to syncopal or epileptiform seizures, and the fact that while the cardiac auricles beat at a normal rate, the ventricles contract much less frequently.

Vessels and Nerves.—The *arteries* supplying the heart are the right and left coronary from the aorta.

* Johns Hopkins' *Hospital Reports*, vol. ix.

The *veins* terminate in the right auricle, and will be described with the general venous system.

The *lymphatics* end in the thoracic and right lymphatic ducts.

The *nerves* are derived from the cardiac plexuses, which are formed partly from the pneumogastrics, and partly from the sympathetic. They are freely distributed both on the surface and in the substance of the heart, the separate filaments being furnished with small ganglia.

The cardiac cycle and the actions of the valves.—By the contractions of the heart the blood is pumped through the arteries to all parts of the body. These contractions occur regularly and at the rate of about seventy per minute. Each wave of contraction or *period of activity* is followed by a *period of rest*, the two periods constituting what is known as a *cardiac cycle*.

Each cardiac cycle consists of three phases, which succeed each other as follows: (1) a short simultaneous contraction of both auricles, termed the *auricular systole*, followed, after a slight pause, by (2) a simultaneous, but more prolonged, contraction of both ventricles, named the *ventricular systole*, and (3) a *period of rest*, during which the whole heart is relaxed, i.e. in a state of *diastole*. The auricular contraction commences around the venous openings and sweeping over the auricles forces their contents through the auriculo-ventricular openings into the ventricles, regurgitation into the veins being prevented by the contraction of their muscular coats. When the ventricles contract the auriculo-ventricular valves are closed, and prevent the passage of the blood back into the auricles; the musculi papillares at the same time are shortened, and, pulling on the chordæ tendineæ, prevent the inversion of the valves into the auricles. As soon as the pressure in the ventricles exceeds that in the pulmonary artery and aorta, the valves guarding the orifices of these vessels are opened and the blood is driven from the right ventricle into the pulmonary artery and from the left into the aorta. The moment the systole of the ventricles ceases, the pressure of the blood in the pulmonary artery and aorta closes the pulmonary and aortic valves to prevent regurgitation of blood into the ventricles, the valves remaining shut until reopened by the next ventricular systole. During the period of rest the tension of the auriculo-ventricular valves is relaxed, and blood is flowing from the veins into the auricles and slightly also from the auricles into the ventricles, being aspirated by negative *intrathoracic* pressure. The average duration of a cardiac cycle is about $\frac{8}{10}$ of a second, made up as follows:

Auricular systole, $\frac{1}{10}$.	Auricular diastole, $\frac{7}{10}$.
Ventricular systole, $\frac{3}{10}$.	Ventricular diastole, $\frac{5}{10}$.
Total systole, $\frac{4}{10}$.	Complete diastole, $\frac{4}{10}$.

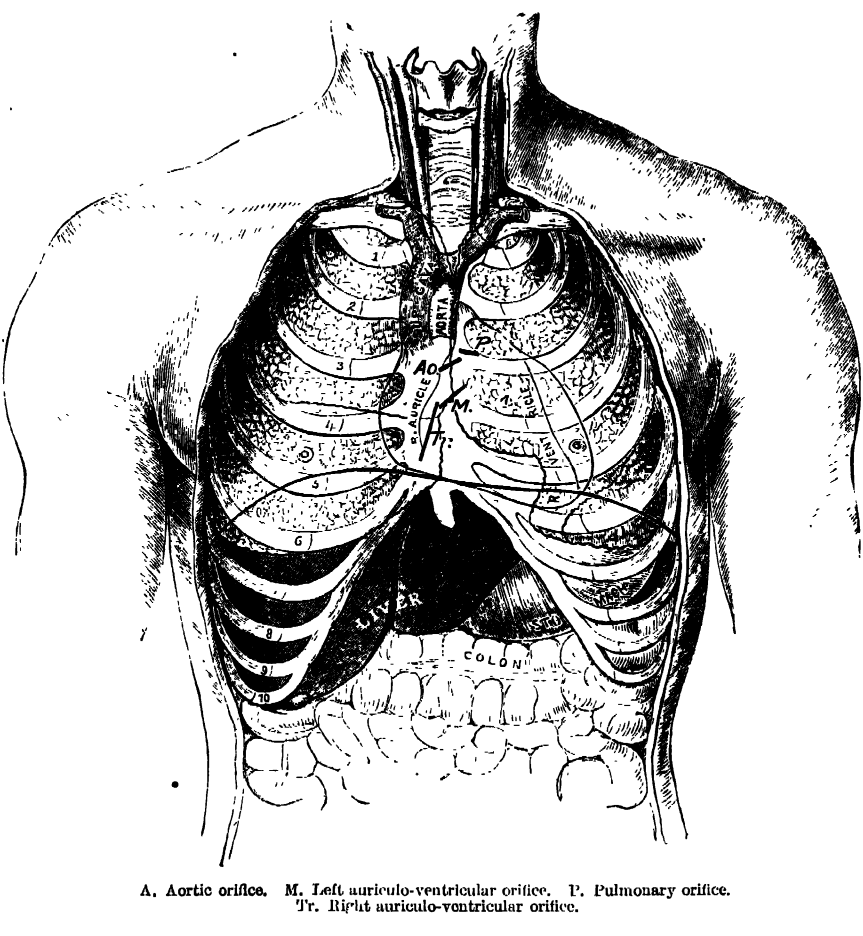
The rhythmical action of the heart is *muscular* in origin, that is to say, the heart muscle itself possesses the inherent property of contraction apart from any nervous stimulation. The more embryonic the muscle the better is it able to initiate and propagate the contraction wave; this explains why the normal systole of the heart starts at the entrance of the veins, for there the muscle is most embryonic in nature. At the auriculo-ventricular junction there is a slight pause in the wave of muscular contraction due to the tissue there being less irritable (i.e. less embryonic). To obviate this as far as possible a peculiar band of marked embryonic type passes across the junction and so carries on the contraction wave to the ventricles. This band, composed of special fibres, the fibres of Purkinje (p. 42), is the auriculo-ventricular bundle of His (p. 611). The nerves, although not concerned in originating the contractions of the heart muscle, play an important rôle in regulating their force and frequency in order to subserve the physiological needs of the organism.

Surface Marking.—To show the extent of the heart in relation to the front of the chest (fig. 569), draw a line from the lower border of the second left costal cartilage, one inch from the sternum, to the upper border of the third right costal cartilage, half an inch from the sternum. This represents the base line, or upper limit of the organ. Take a point an inch and a half below, and three-quarters of an inch internal to the left nipple—that is, about three and a half inches to the left of the median line of the body. This represents the apex of the heart. Draw a line from this apex point, with a slight convexity downwards, to the junction of the seventh right costal cartilage with the sternum. This represents the lower limit of the heart. Join the right extremity of the first line—that is, the base line—with the right extremity of this line—that is, to the seventh right chondrosternal joint—with a slight curve outwards, so that it projects about an inch and a half from the middle line of the sternum. Lastly, join the left extremity of the base line and the apex point by a line curved slightly to the left.

The position of the various orifices is as follows: the pulmonary orifice is situated in the upper angle formed by the articulation of the third left costal cartilage with the sternum; the aortic orifice is a little below and internal to this, behind the left border of the sternum, close to the third left chondrosternal articulation. The left auriculo-ventricular opening is behind the sternum, rather to the left of the median line and opposite the fourth costal cartilages. The right auriculo-ventricular opening is a little lower, opposite the fourth interspace and in the middle line of the body (fig. 569).

A portion of the area of the heart thus mapped out is uncovered by lung, and therefore gives a dull note on percussion; the remainder, being overlapped by the lung, gives a more or less resonant note. The former is known as the area of superficial cardiac dulness; the latter, as the area of deep cardiac dulness. The area of superficial cardiac dulness is included between a line drawn from the centre of the sternum, on a level with the fourth

Fig. 569.—Front view of thorax, showing relation of the heart, lungs, &c., to the ribs and sternum.



A. Aortic orifice. M. Left auriculo-ventricular orifice. P. Pulmonary orifice. Tr. Right auriculo-ventricular orifice.

costal cartilages, to the junction of the body of the sternum with the ensiform cartilage: from the two extremities of this line, two others are to be drawn to the position of the apex of the heart in the fifth intercostal space. Below, this area merges into the dulness which corresponds to the liver. Latham lays down the following rule as a sufficient practical guide for the definition of the portion of the heart which is uncovered by lung or pleura: 'Make a circle of two inches in diameter round a point midway between the nipple and the end of the sternum.'

Applied Anatomy.—Wounds of the heart are often immediately fatal, but not necessarily so. They may be non-penetrating, when death may occur from hæmorrhage if one of the coronary vessels has been wounded, or subsequently from pericarditis. Even a penetrating wound is not necessarily fatal, as a considerable number of cases have now been recorded in which the wound has been sutured.

Peculiarities in the Vascular System of the Fœtus

The development of the heart and vascular system is described on pp. 135 to 150.

The chief peculiarities of the fœtal heart are the direct communication between the auricles through the foramen ovale, and the large size of the Eustachian valve. Amongst other peculiarities the following may be noted. (1) In early fœtal life it lies immediately below the mandibular arch, and as development proceeds is gradually drawn back within the thorax. (2) For a time the auricular portion exceeds the ventricular in size, and the walls of the ventricles are of equal thickness: towards the end of fœtal life the ventricular portion becomes the larger and the wall of the left ventricle exceeds that of the right in thickness. (3) Its size is large as compared with that of the rest of the body, the proportion at the second month being 1 to 50, and at birth 1 to 120, while in the adult the average is about 1 to 160.

The *foramen ovale* is situated at the lower and back part of the auricular septum, forming a communication between the auricles. It remains as a free oval opening until the middle period of fœtal life. The septum (*septum secundum*) which grows down from the upper wall of the auricle to the right of the foramen ovale advances over the opening, so as to form a sort of valve, which allows the blood to pass only from the right to the left auricle, and not in the opposite direction.

The *Eustachian valve* is directed upwards on the left side of the opening of the inferior vena cava, and serves to direct the blood from this vessel through the foramen ovale into the left auricle.

The peculiarities in the arterial system of the fœtus are the communication between the pulmonary artery and the descending aorta by means of the ductus arteriosus, and the continuation of the internal iliac arteries as the umbilical or hypogastric arteries to the placenta.

The *ductus arteriosus* is a short tube, about half an inch in length at birth, and of the diameter of a goose-quill. In the early condition it forms the continuation of the pulmonary artery, and opens into the descending aorta, just below the origin of the left subclavian artery; and so conducts the chief part of the blood from the right ventricle into the aorta. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery; and the fibrous cord, which is all that remains of the ductus arteriosus in later life, is attached to the root of that vessel.

The *umbilical* or *hypogastric arteries* are continued from the internal iliacs, along the sides of the bladder to its apex; they pass out of the abdomen at the umbilicus and are carried in the umbilical cord to the placenta. They convey the blood which has circulated through the fœtus to the placenta.

The peculiarities in the venous system of the fœtus are the communications established between the placenta and the liver and portal vein, through the umbilical vein; and between the umbilical vein and the inferior vena cava through the ductus venosus.

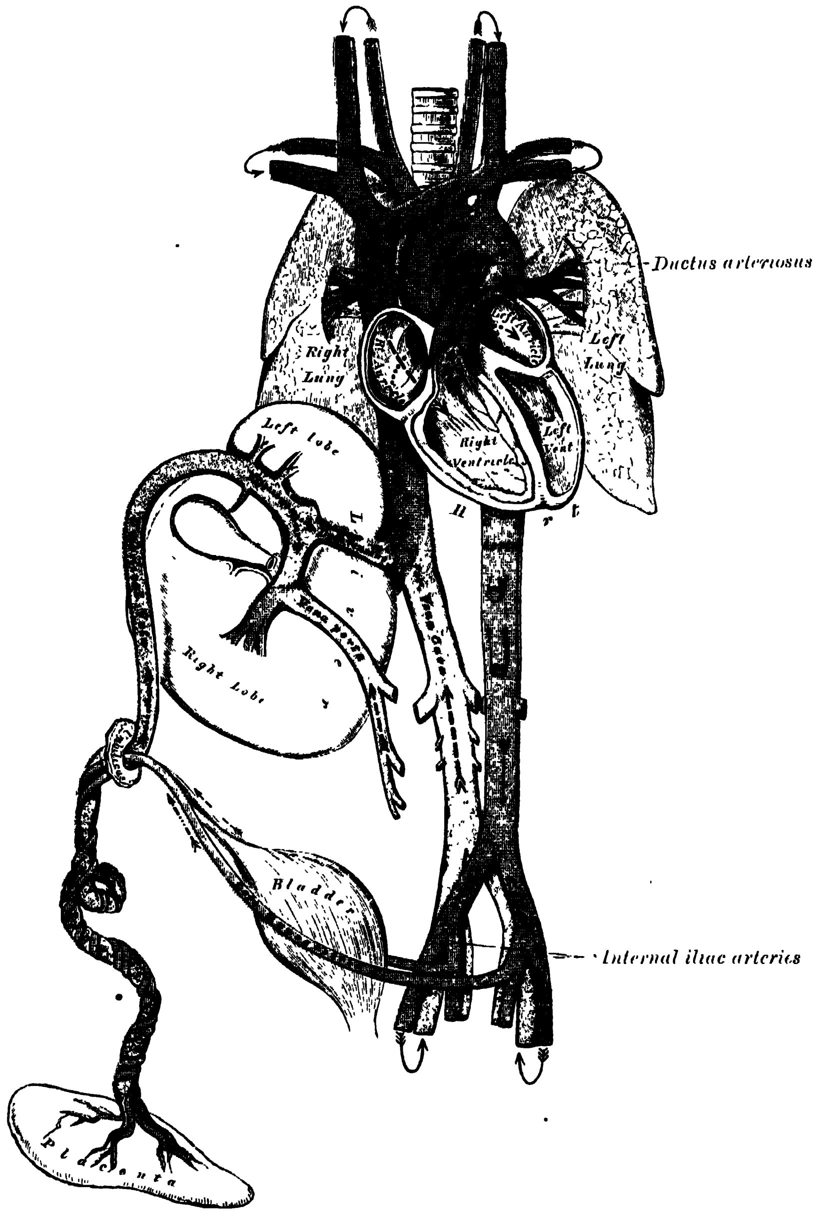
Fœtal Circulation (fig. 570)

The blood destined for the nutrition of the fœtus is returned from the placenta to the fœtus by the umbilical vein. This vein enters the abdomen at the umbilicus, and passes upwards along the free margin of the falciform ligament of the liver to the under surface of that organ, where it gives off two or three branches, one of which is of large size, to the left lobe, and others to the lobus quadratus and lobus Spigelii. At the transverse fissure it divides into two branches: of these, the larger is joined by the portal vein, and enters the right lobe; the smaller is continued upwards, under the name of the ductus venosus, and joins the left hepatic vein at the point of junction of that vessel with the inferior vena cava. The blood, therefore, which traverses the umbilical vein, passes to the inferior vena cava in three different ways. The greater quantity circulates through the liver with the portal venous blood, before entering the vena cava by the hepatic veins; some enters the liver directly, and is also returned to the inferior cava by the hepatic veins:

the smaller quantity passes directly into the vena cava, by the junction of the ductus venosus with the left hepatic vein.

In the inferior cava, the blood carried by the ductus venosus and hepatic veins becomes mixed with that returning from the lower extremities and

FIG. 570.—Plan of the fœtal circulation.



In this plan the figured arrows represent the kind of blood, as well as the direction which it takes in the vessels. Thus—arterial blood is figured ⋙··········⋙; venous blood, ⋙——⋙; mixed (arterial and venous) blood, ⋙···——···⋙.

abdominal wall. It enters the right auricle, and, guided by the Eustachian valve, passes through the foramen ovale into the left auricle, where it mixes with a small quantity of blood returned from the lungs by the pulmonary veins. From the left auricle it passes into the left ventricle; and from the left ventricle into the aorta, by means of which it is distributed almost

entirely to the head and upper extremities, a small quantity being probably carried into the descending aorta. From the head and upper extremities the blood is returned by the superior vena cava to the right auricle, where it becomes mixed with a small portion of the blood from the inferior cava. From the right auricle it descends over the Eustachian valve into the right ventricle; and from the right ventricle passes into the pulmonary artery. The lungs of the fœtus being inactive, only a small quantity of the blood of the pulmonary artery is distributed to them by the right and left pulmonary arteries, and returned by the pulmonary veins to the left auricle: the greater part passes through the ductus arteriosus into the commencement of the descending aorta, where it becomes mixed with a small quantity of the blood transmitted by the left ventricle into the aorta. Through this vessel it descends to supply the lower extremities and the viscera of the abdomen and pelvis, the chief portion being, however, conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the fœtus, it will be seen:

1. That the placenta serves the purposes of nutrition and excretion, receiving the impure blood from the fœtus, and returning it purified and charged with additional nutritive material.

2. That nearly the whole of the blood of the umbilical vein traverses the liver before entering the inferior cava; hence the large size of this organ, especially at an early period of fœtal life.

3. That the right auricle is the point of meeting of a double current, the blood in the inferior cava being guided by the Eustachian valve into the left auricle, while that in the superior cava descends into the right ventricle. At an early period of fœtal life it is highly probable that the two streams are quite distinct; for the inferior cava opens almost directly into the left auricle, and the Eustachian valve would exclude the current along the vein from entering the right ventricle. At a later period, as the separation between the two auricles becomes more distinct, it seems probable that some mixture of the two streams must take place.

4. The pure blood carried from the placenta to the fœtus by the umbilical vein, mixed with the blood from the portal vein and inferior cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities.

5. The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and limbs, together with a small quantity from the left ventricle, is distributed to the abdomen and lower extremities.

Changes in the Vascular System at Birth

At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, and the placental circulation is cut off. The foramen ovale is closed by about the tenth day after birth: the valvular fold above mentioned adheres to the margin of the foramen for the greater part of its circumference, but a slit-like opening is left between the two auricles above, and this sometimes persists.

The *ductus arteriosus* begins to contract immediately after respiration is established, becomes completely closed from the fourth to the tenth day, and ultimately degenerates into an impervious cord, which connects the left pulmonary artery to the arch of the aorta.

Of the *umbilical* or *hypogastric arteries*, the portion of each continued on to the bladder from the trunk of the corresponding internal iliac remains pervious, as the superior vesical artery; the part extending from the side of the bladder to the umbilicus becomes obliterated between the second and fifth days after birth, and projects as a fibrous cord towards the abdominal cavity, carrying on it a fold of peritoneum.

The *umbilical vein* and *ductus venosus* are completely obliterated between the second and fifth days after birth, and ultimately dwindle to fibrous cords; the former becoming the ligamentum teres, the latter the ligamentum venosum of the liver.

THE ARTERIES

Arteries are cylindrical tubular vessels, which convey blood from the ventricles of the heart to the different parts of the body. These vessels were named arteries from the belief entertained by the ancients that they contained air. Galen was the first to show that during life they contain blood.

The distribution of the systemic arteries is like a highly ramified tree, the common trunk of which, formed by the aorta, commences at the left ventricle, while the smallest ramifications extend to the peripheral parts of the body and the contained organs. Arteries are found in all parts of the body, except in the hairs, nails, epidermis, cartilages, and cornea; the larger trunks usually occupy the most protected situations, running, in the limbs, along the flexor side, where they are less exposed to injury.

There is considerable variation in the mode of division of the arteries: occasionally a short trunk subdivides into several branches at the same point, as may be observed in the cœliac and thyroid axes; the vessel may give off several branches in succession, and still continue as the main trunk, as is seen in the arteries of the limbs; or the division may be dichotomous, as, for instance, when the aorta divides into the two common iliacs, or the common carotid into the external and internal carotids.

A branch of an artery is smaller than the trunk from which it arises; but if an artery divides into two branches, the combined sectional area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk; and the combined sectional area of all the arterial branches greatly exceeds that of the aorta; so that the arteries collectively may be regarded as a cone, the apex of which corresponds to the aorta, and the base to the capillary system.

The arteries, in their distribution, communicate with one another, forming what are called *anastomoses*, and these communications are very free between the large as well as between the smaller branches. The anastomosis between trunks of equal size is found where great activity of the circulation is requisite, as in the brain; here the two vertebral arteries unite to form the basilar, and the two anterior cerebral arteries are connected by a short communicating trunk; it is also found in the abdomen, the intestinal arteries having very ample anastomoses between their larger branches. In the limbs, the anastomoses are most numerous and of largest size around the joints; the branches of an artery above uniting with branches from the vessels below. These anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a *collateral circulation* is established after the application of a ligature to an artery. The smaller branches of arteries anastomose more frequently than the larger; and between the smallest twigs these anastomoses become so numerous as to constitute a close network that pervades nearly every tissue of the body.

Throughout the body generally the larger arterial branches pursue a fairly straight course, but in certain situations they are tortuous. Thus the facial artery in its course over the face, and the arteries of the lips, are extremely tortuous to accommodate themselves to the movements of the parts. The uterine arteries are also tortuous, to accommodate themselves to the increase of size which the uterus undergoes during pregnancy.

The arteries are dense in structure, of considerable strength, highly elastic, and, when divided, they preserve, although empty, their cylindrical form. Their structure has been described on page 55.

Applied Anatomy.—All the arteries, and most of all the aorta, are liable to a degenerative process known as atheroma, arteriosclerosis, or, more recently, atherosclerosis (Marchand), that is of the greatest clinical importance. It is essentially a senile change, although it may begin at any age and is predisposed to by renal disease, gout, diabetes mellitus, lead poisoning, and a number of other morbid states, and results in the replacement of the arterial elastic tissue by fibrous tissue. Its chief ill effects are two. In the first place, it is associated with a permanent and often considerable rise in the arterial blood-pressure, entailing a corresponding hypertrophy of the heart; in the second, it weakens the vessel walls, rendering them more liable to rupture, while at the same time it is apt to lessen the calibre of the affected vessels.

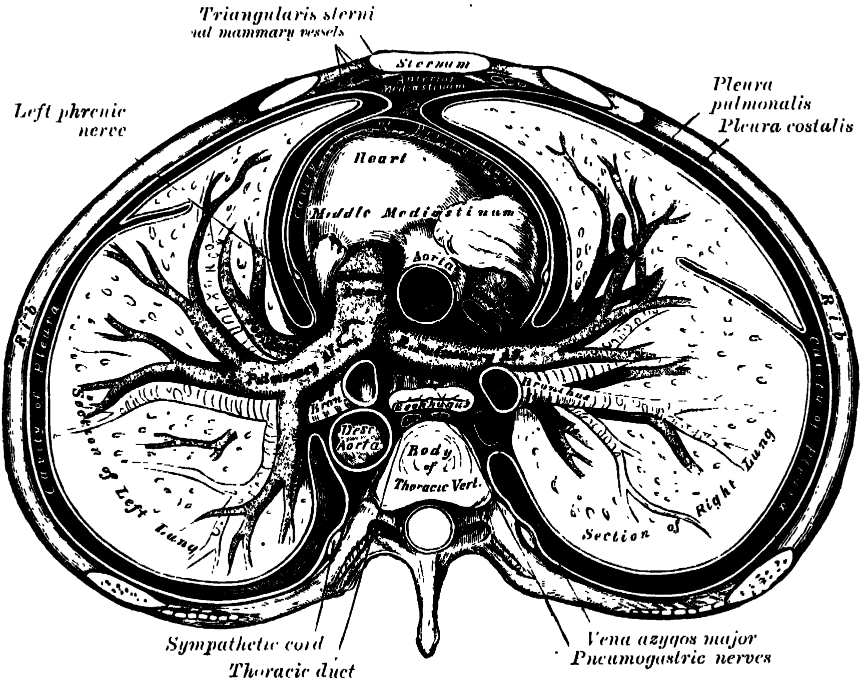
The arteries are also frequently attacked by syphilis, which gives rise to inflammation and degeneration of their middle coats. Recent researches * go to prove that arterial aneurysms, other than those due to direct injury, occur almost solely in syphilitic patients.

PULMONARY ARTERY (fig. 571)

The **pulmonary artery** (a. pulmonalis) conveys the venous blood from the right side of the heart to the lungs. It is a short, wide vessel, about 5 cm. in length and 30 mm. in diameter, arising from the left side of the base (conus arteriosus) of the right ventricle. It extends obliquely upwards and backwards, passing at first in front and then to the left of the ascending aorta, as far as the under surface of the arch, but on a plane posterior to it, where it divides, about the level of the intervertebral disc between the fifth and sixth thoracic vertebræ, into right and left branches of nearly equal size.

Relations.—The whole of this vessel is contained within the pericardium. It is enclosed with the ascending aorta in a single tube of the visceral layer of the

FIG. 571.—Transverse section of thorax, showing relations of pulmonary artery.



serous pericardium, which is continued upwards upon them from the base of the heart. The fibrous layer of the pericardium becomes gradually lost upon the external coats of its two branches. In front, the pulmonary artery is separated from the anterior extremity of the second left intercostal space by the pleura and left lung, in addition to the pericardium ; it rests at first upon the ascending aorta, and higher up lies in front of the left auricle on a plane posterior to the ascending aorta. On either side of its origin is the appendix of the corresponding auricle and a coronary artery, the left coronary artery passing, in the first part of its course, behind the vessel. The superficial cardiac plexus lies above its bifurcation, between it and the arch of the aorta.

The **right branch of the pulmonary artery** (ramus dexter), longer and larger than the left, runs horizontally outwards, behind the ascending aorta and superior vena cava and in front of the right bronchus, to the root of the right lung, where it divides into two branches. The lower and larger of these goes to the middle and lower lobes of the lung ; the upper and smaller is distributed to the upper lobe.

* C. U. Aitchison, *Arch. of the Pathological Institute of the London Hosp.*, 1908, ii. p. 1.

The **left branch of the pulmonary artery** (ramus sinister), shorter and somewhat smaller than the right, passes horizontally in front of the descending aorta and left bronchus to the root of the left lung, where it divides into two branches for the two lobes of the lung.

The root of the left branch of the pulmonary artery is connected to the under surface of the arch of the aorta by a short fibrous cord, the *ligamentum arteriosum*; this is the remains of a fœtal vessel, the *ductus arteriosus*.

The terminal branches of the pulmonary artery will be described with the anatomy of the lung.

Applied Anatomy.—Stenosis of the pulmonary artery, either with, or, more rarely, without defective formation of the interventricular septum, is one of the commonest congenital defects of the heart. It may be due either to fœtal endocarditis, or to maldevelopment of the bulbus cordis (p. 140).* As in most forms of congenital heart-disease, the child is cyanosed (morbus cœruleus), especially when excited or on exertion, and rarely lives to grow up, commonly dying of heart-failure in infancy, or of pulmonary tuberculosis or intercurrent disease in childhood. The chief signs of the condition are the loud, harsh systolic cardiac murmur best heard over the second left costal cartilage, cyanosis, clubbing of the finger-tips, and the presence of an excess of red corpuscles in the blood.

Embolism of the pulmonary artery by a clot of blood coming from the right side of the heart in patients with heart-disease, or from a thrombosed vein in cases, for example, of influenza, enteric fever, puerperal sepsis, or fractured limbs, is a common cause of sudden or rapid death. The patient may cry out with sudden excruciating pain in the præcordia when the detached embolus lodges, and after a brief period of intense dyspnœa, pallor, and anguish, die.

The Aorta

The **aorta** is the main trunk of a series of vessels which convey the oxygenated blood to the tissues of the body for their nutrition. It commences at the upper part of the left ventricle, where it is about 30 mm. in diameter, and after ascending for a short distance, arches backwards, and to the left side, over the root of the left lung; it then descends within the thorax on the left side of the vertebral column, passes into the abdominal cavity through the aortic opening in the Diaphragm, and terminates, considerably diminished in size (about 17·5 mm. in diameter), opposite the lower border of the fourth lumbar vertebra, by dividing into the right and left common iliac arteries. Hence it is described in several portions, viz. the *ascending aorta*, the *arch* of the aorta, and the *descending aorta*, which last is again divided into the *thoracic* and *abdominal aortæ*.

Ascending Aorta

The **ascending aorta** (aorta ascendens) (fig. 572) is about two inches in length. It commences at the upper part of the base of the left ventricle, on a level with the lower border of the third costal cartilage behind the left half of the sternum; it passes obliquely upwards, forwards, and to the right, in the direction of the heart's axis, as high as the upper border of the second right costal cartilage, describing a slight curve in its course, and being situated, when distended, about a quarter of an inch behind the posterior surface of the sternum. At its origin it presents, opposite the segments of the aortic valve, three small dilatations called the sinuses of Valsalva. At the union of the ascending with the transverse part of the aorta the calibre of the vessel is increased, owing to a bulging outwards of its right wall. This dilatation is termed the *great sinus of the aorta* (bulbus aortæ), and on transverse section presents a somewhat oval figure. The ascending aorta is contained within the pericardium, and is enclosed in a tube of the serous pericardium, common to it and the pulmonary artery.

Relations.—The ascending aorta is covered at its commencement by the trunk of the pulmonary artery and the right auricular appendix, and, higher up, is separated from the sternum by the pericardium, the right pleura, and the anterior margin of the right lung, some loose areolar tissue, and the remains of the thymus gland; *behind*, it rests upon the right pulmonary artery and left auricle. On the

* Keith (*Studies in Pathology*, Aberdeen University, 1906) believes that the great majority of cases which are classified as congenital stenosis of the pulmonary or of the aortic orifices are, in reality, due to an arrest of development or malformation of the bulbus cordis.

right side, it is in relation with the superior vena cava and right auricle, the former lying partly behind it; on the *left side*, with the pulmonary artery.

Branches.—The only branches of the ascending aorta are the coronary arteries which supply the heart. They are two in number, right and left, and arise near the commencement of the aorta immediately above the attached margins of the semilunar valves.

The **right coronary artery** (a. coronaria [cordis] dextra), about the size of a crow's quill, arises from the anterior sinus of Valsalva. It passes forwards between the pulmonary artery and the right auricular appendix, then runs obliquely to the right side, in the groove between the right auricle and ventricle, and, curving around the right border of the heart, runs along the posterior surface as far as the posterior interventricular groove, where it divides into two branches. One of these (*transverse*) continues onwards in the groove between the left auricle and ventricle, and anastomoses with the left coronary; the other (*descending*) courses along the posterior interventricular furrow, supplies branches to both ventricles and to the septum, and anastomoses at the apex of the heart with the descending branches of the left coronary.

This vessel sends a large branch (*marginal*) along the thin margin of the right ventricle to the apex, and from this numerous small branches are given to the anterior and posterior surfaces of the ventricle. It also gives a branch close to its origin (*right auricular*), which passes upwards between the right auricle and the aorta, and distributes twigs to the right auricle, the auricular septum, the aorta, and the pulmonary artery.

The **left coronary artery** (a. coronaria [cordis] sinistra), larger than the former, arises from the left posterior sinus of Valsalva; it passes forwards between the pulmonary artery and the left auricular appendix, and divides into two branches. Of these, one (*transverse*) runs transversely outwards in the left auriculo-ventricular groove, and winds around the left border of the heart to the posterior surface, where it anastomoses with the transverse branch of the right coronary; the other (*descending*) passes along the anterior interventricular groove to the apex of the heart, where it anastomoses with the descending branch of the right coronary. The left coronary supplies the left auricle and its appendix, gives branches to both ventricles, and numerous twigs to the pulmonary artery and commencement of the aorta.

In addition to the already mentioned anastomosis in the auriculo-ventricular and interventricular grooves there is a free anastomosis between the minute branches of the two coronary arteries in the substance of the heart.

Peculiarities.—These vessels occasionally arise by a common trunk, or their number may be increased to three, the additional branch being of small size. More rarely, there are two additional branches.

Applied Anatomy.—The sudden blocking of a coronary artery by an embolus, or its more gradual obstruction by arterial disease or thrombosis, is a common cause of sudden death in persons past middle age. If the obstruction to the passage of blood is incomplete, true *angina pectoris* may occur. In this condition the patient is suddenly seized with a spasm of agonising pain in the præcordial region and down the left arm, together with an indescribable sense of anguish. He may die in such an attack, or succumb a few hours or days later from heart failure, or survive a number of attacks.

Arch of the Aorta

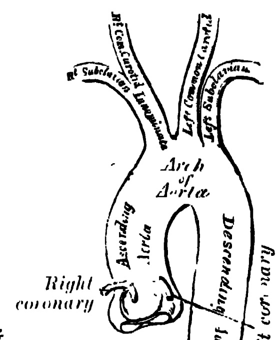
The **arch of the aorta** (arcus aortæ) (fig. 572) begins at the upper border of the second chondro-sternal articulation of the right side, and runs at first upwards, backwards, and to the left in front of the trachea; it is then directed backwards on the left side of the trachea, and finally passes downwards on the left side of the body of the fourth thoracic vertebra, at the lower border of which it becomes continuous with the descending aorta. It thus forms two curvatures: one with its convexity upwards, the other with its convexity forwards and to the left. Its upper border is usually about an inch below the upper margin of the sternum.

Relations.—The arch of the aorta is covered *in front* by the pleuræ and anterior margins of the lungs, and by the remains of the thymus gland. As the vessel runs backwards its *left* side is in contact with the left lung and pleura. Passing downwards on the left side of this part of the arch are four nerves—in order from before

backwards these are: the left phrenic, the inferior cervical cardiac branch of the left pneumogastric, the superior cardiac branch of the left sympathetic, and the trunk of the left pneumogastric. As the last nerve crosses the arch it gives off its recurrent laryngeal branch, which hooks round below the vessel and then passes upwards on its right side. The left superior intercostal vein runs obliquely upwards and forwards, on the left side of the arch between the phrenic and pneumogastric nerves. On the *right* are the deep cardiac plexus, the left recurrent laryngeal nerve, the œsophagus, and the thoracic duct; the trachea lies behind and to the right of the vessel. *Above* are the innominate, left common carotid, and left subclavian arteries,

FIG. 572.—The arch of the aorta, and its branches.

FIG. 573.
Plan of the branches.



which arise from the convexity of the arch and are crossed close to their origins by the left innominate vein. *Below* are the bifurcation of the pulmonary artery, the left bronchus, the ligamentum arteriosum, the superficial cardiac plexus, and the left recurrent laryngeal nerve. As already stated, the ligamentum arteriosum connects the commencement of the left pulmonary artery to the aortic arch.

Between the origin of the left subclavian artery and the attachment of the ductus arteriosus the lumen of the fœtal aorta is considerably narrowed, forming what is termed the *isthmus aortæ*, while immediately beyond the ductus arteriosus the vessel presents a fusiform dilatation which His has named the *aortic spindle* —the point of junction of the two parts being marked in the concavity of the

arch by an indentation or angle. These conditions persist, to some extent, in the adult, where His found that the average diameter of the spindle exceeded that of the isthmus by 3 mm. (about one-eighth of an inch).

Distinct from this diffuse and moderate stenosis at the isthmus is the condition known as *coarctation of the aorta*, or marked stenosis often amounting to complete obliteration of its lumen, seen in adults and occurring at or near, oftenest a little below, the insertion of the ductus arteriosus into the aorta. According to Bonnet * this coarctation is never found in the fœtus or at birth, and is due to an abnormal extension of the peculiar tissue of the ductus into the aortic wall, which gives rise to a simultaneous stenosis of both vessels as it contracts after birth—the ductus is usually obliterated in these cases. An extensive collateral circulation is set up, by the superior intercostals, internal mammaries, and the posterior scapular branches of the transversalis colli above the stenosis, and below it by the first four aortic intercostals, the phrenics, and the superficial and deep epigastrics.

Peculiarities.—The height to which the aorta rises in the chest is usually about an inch below the upper border of the sternum; but it may ascend nearly to the top of the bone. Occasionally it is found an inch and a half, more rarely two or even three inches below this point. Sometimes the aorta arches over the root of the right instead of over that of the left lung, and passes down on the right side of the vertebral column, a condition which is found in birds. In such cases all the thoracic and abdominal viscera are transposed. Less frequently the aorta, after arching over the root of the right lung, is directed to its usual position on the left side of the vertebral column, this peculiarity not being accompanied by any transposition of the viscera. The aorta occasionally divides, as in some quadrupeds, into an ascending and a descending trunk, the former of which is directed vertically upwards, and subdivides into three branches, to supply the head and upper extremities. Sometimes the aorta subdivides soon after its origin into two branches, which soon reunite. In one of these cases the œsophagus and trachea were found to pass through the interval left by their division; this is the normal condition of the vessel in the reptilia.

Applied Anatomy.—Of all the vessels of the arterial system, the aorta, and more especially its arch, is most frequently the seat of disease; hence it is important to consider some of the consequences that may ensue from aneurysm of this part.

Aneurysm of the ascending aorta, in the situation of the sinuses of Valsalva, in the great majority of cases, affects the anterior sinus; this is mainly owing to the fact that the regurgitation of blood upon the sinuses takes place chiefly on the anterior aspect of the vessel. As the aneurysmal sac enlarges, it may compress any or all of the structures in immediate proximity with it, but chiefly projects towards the right anterior side; and, consequently, interferes mainly with those structures that have a corresponding relation with the vessel. If it project forwards, it may absorb the sternum and the cartilages of the ribs, usually on the right side, and appear as a pulsating tumour on the front of the chest, just below the manubrium; or it may burst into the pericardium, or may compress, or open into the right lung, the trachea, bronchi, or œsophagus. In the majority of cases it bursts into the cavity of the pericardium, the patient suddenly drops down dead, and, upon a post-mortem examination, the pericardial sac is found full of blood; or it may compress the right auricle, or the pulmonary artery, and adjoining part of the right ventricle, and open into one or the other of these parts. It may press upon the superior vena cava or the innominate veins, causing great venous engorgement. The face becomes livid and swollen, the right arm and anterior thoracic wall œdematous, and the congestion of the brain gives rise to headache and vertigo. An aneurysm has occasionally perforated into the superior vena cava, setting up an arterio-venous aneurysm. When this happens the patient suddenly becomes very short of breath, intensely congested and œdematous in the face and upper part of the body, and develops a palpable thrill and a continuous humming murmur, loudest during systole, over the sternum. Death follows a few days or weeks after such a perforation; and somewhat similar symptoms are occasioned when an aortic aneurysm erodes and bursts into the pulmonary artery.

Regarding the arch of the aorta, the student is reminded that the vessel lies against the trachea, œsophagus, and thoracic duct; that the recurrent laryngeal nerve winds around it; and that from its upper part are given off three large trunks, which supply the head, neck, and upper extremities. Now, an aneurysmal tumour taking origin from the posterior part of the vessel, its most usual site, may press upon the trachea and give rise to the sign known as "tracheal tugging," impede the breathing, or produce cough, dyspnœa, bronchiectasis, hæmoptysis, or stridulous breathing, or it may ultimately burst into that tube, producing fatal hæmorrhage. Again, its pressure on the left recurrent laryngeal nerve may give rise to symptoms of laryngeal paralysis; or it may press upon the thoracic duct and destroy life by inanition; or it may involve the œsophagus, producing dysphagia, and has not infrequently been mistaken for œsophageal stricture; or it may burst into the œsophagus, when fatal hæmorrhage will occur. Compression or stretching of the sympathetic filaments may, in the former case, produce dilatation of the pupil; in the latter,

* *Rev. de Méd.*, Paris, 1903.

contraction, if the conducting power is abolished, on the affected side. This has proved to be an important diagnostic sign in this disease. Again, the innominate artery, or the subclavian, or left carotid, may be so obstructed by clots as to produce a weakness, or even a disappearance, of the pulse in one or the other wrist, or in the left temporal artery; or the tumour may present itself at or above the manubrium, generally either in the median line, or to the right of the sternum, and may simulate an aneurysm of one of the arteries of the neck.

It is important to remember that many of the physical signs of an aortic aneurysm may be simulated with extraordinary fidelity by the preternatural pulsation or throbbing of a distended and elastic aorta, when no true aneurysmal dilatation exists. This condition may be met with in young persons with aortic reflux and greatly hypertrophied hearts, in patients who are of a neurotic or hysterical temperament, and in cases of Graves's disease or of marked anæmia. The condition is known as dynamic dilatation of the aorta, and in no way threatens life.

Branches (figs. 572, 573).—The branches given off from the arch of the aorta are three in number: the innominate, the left common carotid, and the left subclavian.

Peculiarities.—Position of the branches.—The branches, instead of arising from the highest part of the arch, may spring from the commencement of the arch or upper part of the ascending aorta; or the distance between them at their origins may be increased or diminished, the most frequent change in this respect being the approximation of the left carotid towards the innominate artery.

The *number* of the primary branches may be reduced to one, or more commonly two: the left carotid arising from the innominate artery; or (more rarely) the carotid and subclavian arteries of the left side arising from a left innominate artery. But the number may be increased to four, from the right carotid and subclavian arteries arising directly from the aorta, the innominate being absent. In most of these latter cases the right subclavian has been found to arise from the left end of the arch; in other cases it is the second or third branch given off, instead of the first. Another common form in which there are four primary branches is that in which the left vertebral artery arises from the arch of the aorta between the left carotid and subclavian arteries. Lastly, the number of trunks from the arch may be increased to five or six; in these instances, the external and internal carotids arise separately from the arch, the common carotid being absent on one or both sides. In some few cases six branches have been found, and this condition is associated with the origin of both vertebral arteries from the arch.

Number usual, arrangement different.—When the aorta arches over to the right side, the three branches have an arrangement the reverse of what is usual, the innominate artery is a left one, and the right carotid and subclavian arise separately. In other cases, where the aorta takes its usual course, the two carotids may be joined in a common trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch.

In some instances other arteries spring from the arch of the aorta. Of these the most common are the bronchial, one or both, and the thyreoidea ima; but the internal mammary and the inferior thyroid have been seen to arise from this vessel.

Innominate Artery

The **innominate** or **brachio-cephalic artery** (a. anonyma) (fig. 572) is the largest branch given off from the arch of the aorta. It arises, on a level with the upper border of the second right costal cartilage, from the commencement of the arch of the aorta, on a plane anterior to the origin of the left carotid, and, ascending obliquely upwards, backwards, and outwards to the level of the upper border of the right sterno-clavicular articulation, divides into the right common carotid and right subclavian arteries. This vessel varies from an inch and a half to two inches in length.

Relations.—*In front*, it is separated from the first piece of the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the remains of the thymus gland, the left innominate and right inferior thyroid veins which cross its root, and sometimes the inferior cervical cardiac branch of the right pneumogastric. *Behind*, it lies upon the trachea, which it crosses obliquely. On the *right side* are the right innominate vein, the superior vena cava, the right phrenic nerve, and the pleura; and on the *left side*, the remains of the thymus gland, the origin of the left carotid artery, the left inferior thyroid vein, and the trachea.

Branches.—The innominate usually gives off no branches; but occasionally a small branch, the *thyreoidea ima*, arises from this vessel. It also sometimes gives off a *thymic* or *bronchial branch*.

The **thyreoidea ima** ascends in front of the trachea to the lower part of the thyroid body, which it supplies. It varies greatly in size, and appears to compensate for deficiency or absence of one of the other thyroid vessels. It occasionally arises from the aorta, the right common carotid, the subclavian or the internal mammary.

Peculiarities in point of division.—When the bifurcation of the innominate artery varies from the point above mentioned, the vessel sometimes ascends a considerable distance above the sternal end of the clavicle; less frequently it divides below it. In cases of the former class, its length may exceed two inches; and, in the latter, be reduced to an inch or less.

Position.—When the aorta arches over to the right side, the innominate is directed to the left side of the neck instead of the right.

Collateral Circulation.—Allan Burns demonstrated, on the dead subject, the possibility of the establishment of the collateral circulation after ligature of the innominate artery, by tying and dividing that artery. He then found that 'Even coarse injection, impelled into the aorta, passed freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely.'* The branches by which this circulation would be carried on are very numerous; thus, all the communications across the middle line between the branches of the carotid arteries of opposite sides would be available for the supply of blood to the right side of the head and neck; while the anastomosis between the superior intercostal of the subclavian and the first aortic intercostal (see *infra* on the collateral circulation after obliteration of the thoracic aorta) would bring the blood, by a free and direct course, into the right subclavian. The numerous connections, also, between the intercostal arteries and the branches of the axillary and internal mammary arteries would, doubtless, assist in the supply of blood to the right arm, while the deep epigastric from the external iliac would, by means of its anastomosis with the internal mammary, compensate for any deficiency in the vascularity of the wall of the chest.

Applied Anatomy.—Aneurysm of the innominate artery not infrequently occurs as an accompaniment to aneurysm of the arch of the aorta. It causes bulging of the right sterno-clavicular articulation, pushing forwards the Sterno-mastoid muscle and filling up the suprasternal notch. It produces serious pressure symptoms: from pressure on the innominate veins it may cause œdema of the upper extremities, and of the head and neck; from pressure on the trachea it produces dyspnœa; and from pressure on the right recurrent laryngeal nerve, hoarseness and laryngeal cough.

Although the operation of tying the innominate artery has been performed by several surgeons, not many successes have been recorded. The chief danger of the operation appears to be the frequency of secondary hæmorrhage; but in the present day, with the practice of aseptic surgery and our greater knowledge of the use of the ligature, more favourable results may be anticipated. The main obstacles to the operation are, the deep situation of the artery behind and beneath the sternum, and the number of important structures which surround it in every part.

In order to apply a ligature to this vessel, the patient is to be placed upon his back with the thorax slightly raised, the head bent a little backwards, and the right shoulder strongly depressed, so as to draw out the artery from behind the sternum into the neck. An incision three or more inches long is then made along the anterior border of the Sterno-mastoid muscle, terminating at the sternal end of the clavicle. From this point, a second incision is carried about the same length along the upper border of the clavicle. The skin is then dissected back, and the Platysma divided on a director: the sternal end of the Sterno-mastoid is now brought into view, and a director being passed beneath it, and close to its under surface, so as to avoid any small vessels, it is to be divided; in like manner the clavicular origin is to be divided throughout the whole or greater part of its attachment. By pressing aside any loose cellular tissue or vessels that may now appear, the Sterno-hyoid and Sterno-thyroid muscles will be exposed, and must be divided, a director being previously passed beneath them. The inferior thyroid veins may come into view, and must be carefully drawn either upwards or downwards, by means of a blunt hook, or tied with double ligatures and divided. After tearing through a strong fibro-cellular lamina, the right carotid is brought into view, and being traced downwards, the arteria innominata is arrived at. The left innominate vein should now be depressed; the right innominate vein, the internal jugular vein, and the pneumogastric nerve drawn to the right side; and a curved aneurysm needle may then be passed around the vessel, close to its surface, and in a direction from below upwards and inwards; care being taken to avoid the right pleural sac, the trachea, and cardiac nerves. The ligature should be applied to the artery as high as possible, in order to allow room between it and the aorta for the formation of the coagulum. The importance of avoiding the thyroid plexus of veins during the primary steps of the operation, and the pleural sac while including the vessel in the ligature, should be most carefully borne in mind.

* *Surgical Anatomy of the Head and Neck*, p. 62.

ARTERIES OF THE HEAD AND NECK

The principal arteries of supply to the head and neck are the two common carotids; they ascend in the neck and each divides into two branches, viz. (1) the external carotid, supplying the superficial parts of the head and face, and the greater part of the neck; (2) the internal carotid, supplying to a great extent the parts within the cranial cavity.

Common Carotid Arteries

The **common carotid arteries** differ in length and in their mode of origin. The *right* (a. carotis communis dextra) begins at the bifurcation of the innominate artery behind the sterno-clavicular joint and is confined to the neck. The *left* (a. carotis communis sinistra) springs from the highest part of the arch of the aorta to the left of and on a plane posterior to the innominate artery, and therefore consists of a thoracic and a cervical portion.

The **thoracic portion of the left common carotid artery** ascends from the arch of the aorta through the superior mediastinum to the level of the left sterno-clavicular joint, where it is continuous with the cervical portion.

Relations.—*In front*, it is separated from the first piece of the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the anterior portions of the left pleura and lung, the left innominate vein, and the remains of the thymus gland; *behind*, it lies on the trachea, œsophagus, left recurrent laryngeal nerve, and thoracic duct. To its *right side* below is the innominate artery, and above, the trachea, the inferior thyroid veins, and the remains of the thymus gland; to its *left side* are the left pneumogastric and phrenic nerves, left pleura, and lung. The left subclavian artery is posterior and slightly external to it.

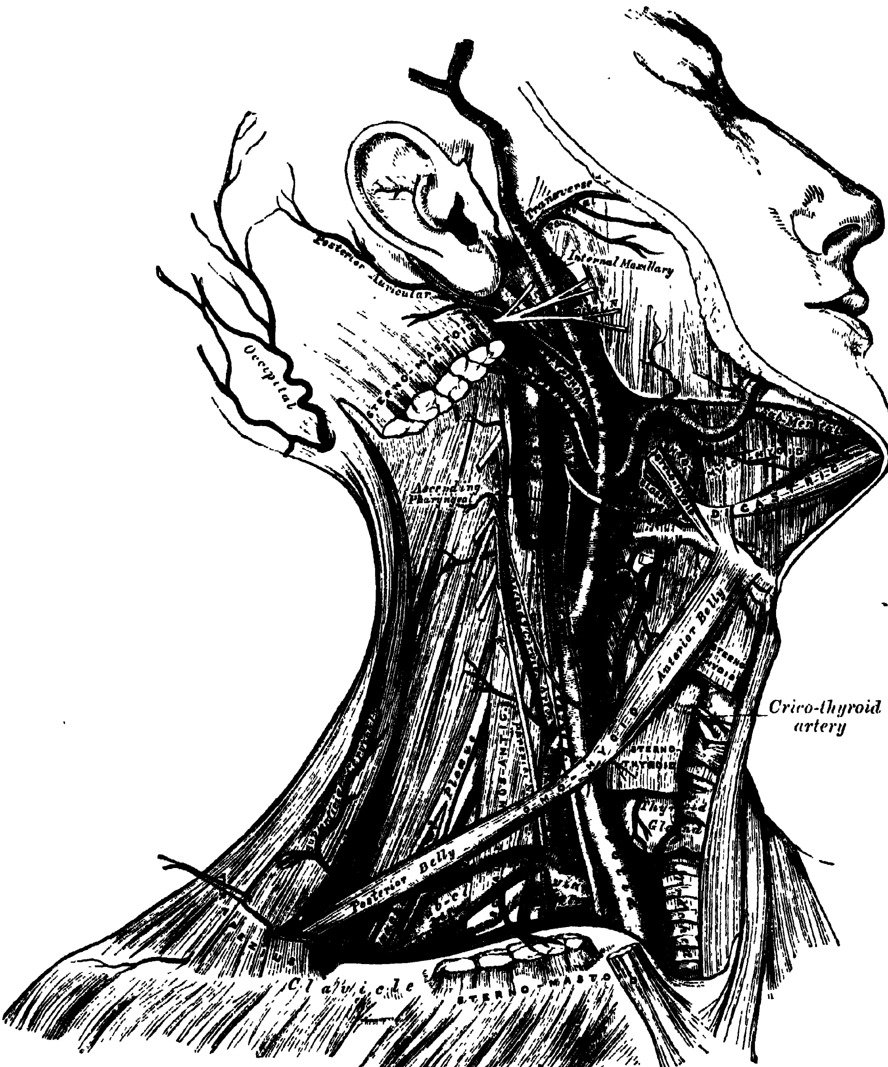
The **cervical portions** of the two common carotids resemble each other so closely, that one description will apply to both (fig. 574). Each vessel passes obliquely upwards, from behind the sterno-clavicular articulation, to the level of the upper border of the thyroid cartilage, opposite the lower border of the third cervical vertebra, where it divides into the external and internal carotid arteries.

At the lower part of the neck the two common carotid arteries are separated from each other by a very small interval, which contains the trachea; but at the upper part, the thyroid body, the larynx and pharynx project forwards between the two vessels, and give them the appearance of being placed farther back in this situation. The common carotid artery is contained in a sheath, which is derived from the deep cervical fascia and encloses also the internal jugular vein and pneumogastric nerve, the vein lying on the outer side of the artery, and the nerve between the artery and vein, on a plane posterior to both. On opening the sheath, these three structures are seen to be separated from one another, each being enclosed in a separate fibrous investment.

Relations.—At the lower part of the neck the common carotid artery is very deeply seated, being *covered by* the integument, superficial fascia, Platysma, and deep cervical fascia, the Sterno-mastoid, Sterno-hyoid, Sterno-thyroid and Omo-hyoid muscles; in the upper part of its course it is more superficial, being covered merely by the integument, the superficial fascia, Platysma, deep cervical fascia, and inner margin of the Sterno-mastoid. When the latter muscle is drawn backwards, the artery is seen to be contained in a triangular space, the *carotid triangle*, bounded behind by the Sterno-mastoid, above by the Stylo-hyoid and posterior belly of the Digastric, and below by the anterior belly of the Omo-hyoid. This part of the artery is crossed obliquely, from within outwards, by the sterno-mastoid artery; it is also crossed by the superior and middle thyroid veins which terminate in the internal jugular; descending on its sheath in front is the descendens hypoglossi nerve, this filament being joined by one or two branches from the cervical nerves, which cross the vessel from without inwards. Sometimes the descendens hypoglossi is contained within the sheath. The superior thyroid vein crosses the artery near its termination, and the middle thyroid vein a little below the level of the cricoid cartilage; the anterior jugular vein crosses the artery just above the clavicle, but is separated from it by the Sterno-hyoid and Sterno-thyroid muscles. *Behind*, the artery is separated from

the transverse processes of the cervical vertebræ by the Longus colli and Rectus capitis anticus major, the sympathetic cord being interposed between it and the muscles. The recurrent laryngeal nerve and inferior thyroid artery cross behind the vessel at its lower part. *Internally*, it is in relation with the œsophagus, trachea, and thyroid gland (which overlaps it), the inferior thyroid artery and recurrent laryngeal nerve being interposed; higher up, with the larynx and pharynx. On its *outer side* are placed the internal jugular vein and pneumogastric nerve.

FIG. 574.—Superficial dissection of the right side of the neck, showing the carotid and subclavian arteries.



At the lower part of the neck, the internal jugular vein on the right side diverges from the artery, but on the left side it approaches it, and often overlaps its lower part.

On the posterior aspect of the angle of bifurcation of the common carotid artery is a reddish-brown oval body, known as the *carotid body*. It is similar in structure to the coccygeal body, which is situated on the middle sacral artery.

Peculiarities as to origin.—The *right common carotid* may arise above the upper border of the sterno-clavicular articulation; this variation occurs in about 12 per cent. of

cases. In other cases the artery arises as a separate branch from the arch of the aorta, or it may arise in conjunction with the left carotid. The *left common carotid* varies in its origin more than the right. In the majority of abnormal cases it arises with the innominate artery, or, if the innominate artery is absent, the two carotids arise usually by a single trunk. It is rarely joined with the left subclavian, except in cases of transposition of the arch.

Peculiarities as to point of division.—In the majority of abnormal cases, this occurs higher than usual, the artery dividing into two branches opposite the hyoid bone, or even higher; more rarely, it occur sbelow, opposite the middle of the larynx, or the lower border of the cricoid cartilage; and one case is related by Morgagni, where the common carotid, only an inch and a half in length, divided at the root of the neck. Very rarely, the common carotid ascends in the neck without any subdivision, either the external or the internal carotid being wanting; and in a few cases the common carotid has been found to be absent, the external and internal carotids arising directly from the arch of the aorta. This peculiarity existed on both sides in some instances, on one side in others.

Occasional branches—The common carotid usually gives off no branch previous to its bifurcation; but it occasionally gives origin to the superior thyroid or its laryngeal branch, the ascending pharyngeal, the inferior thyroid, or, more rarely, the vertebral artery.

Surface Marking.—The course of the artery is indicated by a line drawn from the upper part of the sternal end of the clavicle below, to a point midway between the angle of the jaw and the mastoid process above. The portion of this line below the level of the upper border of the thyroid cartilage represents the course of the vessel.

Applied Anatomy.—Aneurysms are not commonly met with on the common carotid; when they do occur they are usually situated low down at the root of the neck, or just below the point of bifurcation of the vessel. They do not frequently assume a large size, and are more commonly found on the right side. As they increase in size they displace the trachea and larynx, and therefore dyspnœa becomes a prominent symptom. Dysphagia also may be present from pressure on the œsophagus, especially if the aneurysm is on the left side; and pressure on the recurrent laryngeal nerve may produce hoarseness and laryngeal cough. Pressure on the sympathetic will cause pupillary changes—dilatation of the pupil when the sympathetic is irritated, contraction when it has become paralysed—and may also give rise to unilateral sweating. Pressure on the superficial branches of the cervical plexus may give rise to pain in the head, face, and neck; pressure on the vagus to irregular action of the heart and to asthmatic attacks. It is important to bear in mind that an enlarged gland in the superior carotid triangle, receiving a transmitted pulsation from the carotid artery, may simulate aneurysm of that vessel, but may be distinguished from it by the character of the pulsation, which is not distensile.

Embolism of the left common carotid has been known to produce aphasia by interference with the blood supply of the brain.

Digital compression of the common carotid is sometimes required, and is best effected by compressing the vessel with the thumb against the anterior tubercle of the transverse process of the sixth cervical vertebra (see page 185). *Ligature* of the common carotid artery may be necessary in a case of wound of that vessel or its branches, in aneurysm, or in a case of pulsating tumour of the orbit or skull. If the wound involves the trunk of the common carotid, it will be necessary to tie the artery above and below the wounded part. In cases of aneurysm, the whole of the artery is accessible, and any part may be tied, except close to either end. When the case is such as to allow of a choice being made, the lower part of the carotid should never be selected as the spot upon which to place a ligature, for not only is the artery in this situation placed very deeply in the neck, but it is covered by three layers of muscles, and, on the left side, the internal jugular vein, in the great majority of cases, passes obliquely in front of it. Neither should the upper end be selected, for here the superior thyroid vein and its tributaries would give rise to very considerable difficulty in the application of a ligature. The part of the vessel which is most favourable for the operation is that opposite the level of the cricoid cartilage. It occasionally happens that the carotid artery bifurcates below its usual position: if the artery be exposed at its point of bifurcation, both divisions of the vessel should be tied near their origin, in preference to tying the trunk of the artery near its termination; and if, in consequence of the entire absence of the common carotid, or from its early division, two arteries, the external and internal carotids, are met with, the ligature should be placed on that vessel which is found on compression to be connected with the diseased area.

In this operation, the direction of the vessel and the inner margin of the Sterno-mastoid are the chief guides to its performance. The patient should be placed on his back with the head extended and turned slightly to the opposite side: an incision is to be made, three inches long, in the direction of the anterior border of the Sterno-mastoid, so that the centre corresponds to the level of the cricoid cartilage. After dividing the integument, superficial fascia, and Platysma, the deep fascia must be cut through on a director, so as to avoid wounding numerous small veins that are usually found beneath. The head may now be brought forwards so as to relax the parts somewhat, and the margins of the wound held asunder by retractors. The descendens hypoglossi nerve may now be exposed, and

must be avoided, and the sheath of the vessel having been raised by forceps, is to be opened to a small extent over the artery at its inner side. The internal jugular vein may present itself alternately distended and relaxed; this should be compressed both above and below, and drawn outwards, in order to facilitate the operation. The aneurysm needle is passed from the outside, care being taken to keep the needle in close contact with the artery, and thus avoid the risk of injuring the internal jugular vein, or including the vagus nerve. Before the ligature is tied, it should be ascertained that nothing but the artery is included in it.

Ligature of the common carotid at the lower part of the neck.—This operation is sometimes required in cases of aneurysm of the upper part of the carotid, especially if the sac is of large size. It is best performed by dividing the sternal origin of the Sterno-mastoid muscle, but may be done in some cases, if the aneurysm is not of very large size, by an incision along the anterior border of the Sterno-mastoid, extending down to the sterno-clavicular articulation, and by then retracting the muscle. The easiest and best plan, however, is to make an incision two or three inches long down the lower part of the anterior border of the Sterno-mastoid muscle to the sterno-clavicular joint, and a second incision, starting from the termination of the first, along the upper border of the clavicle for about two inches. This incision is made through the superficial and deep fasciæ and the sternal origin of the muscle is exposed. This is to be divided on a director and turned up, with the superficial structures, as a triangular flap. Some loose connective tissue is to be divided or torn through, and the outer border of the Sterno-hyoid muscle exposed. In doing this, care must be taken not to wound the anterior jugular vein, which crosses the muscle to reach the external jugular or subclavian vein. The Sterno-hyoid and Sterno-thyroid are to be drawn inwards by means of a retractor, and the sheath of the vessel exposed. This must be opened with great care on its inner or tracheal side, so as to avoid the internal jugular vein. This is especially necessary on the left side, where the artery is commonly overlapped by the vein. On the right side there is usually an interval between the artery and the vein, and the risk of wounding the vein is less.

The common carotid artery, being a long vessel without any branches, is particularly suitable for the performance of Brasdor's operation for the cure of an aneurysm of the lower part of the vessel. Brasdor's procedure consists in ligaturing the artery on the distal side of the aneurysm, and in the case of the common carotid there are no branches given off from the vessel between the aneurysm and the site of the ligature; hence the flow of blood through the sac of the aneurysm is diminished, and cure takes place in the usual way by the deposit of laminated fibrin.

Collateral Circulation.—After ligature of the common carotid, the collateral circulation can be perfectly established, by the free communication which exists between the carotid arteries of opposite sides, both without and within the cranium, and by enlargement of the branches of the subclavian artery on the side corresponding to that on which the vessel has been tied. The chief communications outside the skull take place between the superior and inferior thyroid arteries, and the profunda cervicis and arteria princeps cervicis of the occipital; the vertebral takes the place of the internal carotid within the cranium.

External Carotid Artery

The **external carotid artery** (a. carotis externa) (fig. 574) commences opposite the upper border of the thyroid cartilage, and, taking a slightly curved course, passes upwards and forwards, and then inclines backwards to the space behind the neck of the mandible, where it divides into the superficial temporal and internal maxillary arteries. It rapidly diminishes in size in its course up the neck, owing to the number and large size of the branches given off from it. In the child, it is somewhat smaller than the internal carotid; but in the adult, the two vessels are of nearly equal size. At its origin, this artery is more superficial, and placed nearer the middle line than the internal carotid, and is contained within the carotid triangle.

Relations.—The external carotid artery is *covered by* the skin, superficial fascia, Platysma, deep fascia, and anterior margin of the Sterno-mastoid; it is crossed by the hypoglossal nerve, by the lingual, ranine, facial, and superior thyroid veins; and by the Digastric and Stylo-hyoid muscles; higher up it passes deeply into the substance of the parotid gland, where it lies beneath the facial nerve and the junction of the temporal and internal maxillary veins. *Internally* are the hyoid bone, the wall of the pharynx, the superior laryngeal nerve, and a portion of the parotid gland. *Externally*, in the lower part of its course, is the internal carotid artery. *Behind* it, near its origin, is the superior laryngeal nerve; and higher up, it is separated from the internal carotid by the Stylo-glossus and Stylo-pharyngeus muscles, the glosso-pharyngeal nerve, the pharyngeal branch of the vagus, and part of the parotid gland.

Surface Marking.—The position of the external carotid artery may be marked out with sufficient accuracy by a line drawn from the side of the cricoid cartilage to the front of the meatus of the external ear, arching the line slightly forwards.

Applied Anatomy.—The application of a ligature to the external carotid may be required in cases of wound of this vessel, or of its branches when these cannot be tied, and in some cases of pulsating tumours of the scalp or face. It is also done as a preliminary measure to excision of the maxilla. The operation is to be preferred to ligature of the common carotid, as it does not interfere with the cerebral circulation. The seat of election for ligature is between the origins of the superior thyroid and lingual branches, about a finger's breadth below the tip of the great cornu of the hyoid bone. To tie the vessel, an incision is to be made from the angle of the mandible to the upper border of the thyroid cartilage, and the superficial tissues and the deep fascia divided. The anterior border of the Sterno-mastoid must be retracted and the lower border of the parotid gland raised, so as to expose the tendon of the Digastric and the hypoglossal nerve, which cross the artery. The great difficulty in doing this is due to the plexus of veins derived from the superior thyroid and lingual veins, which overlie the artery. If necessary, these must be ligatured and divided. Care must be taken not to mistake the lingual and facial, when they arise by a common trunk, as they sometimes do, for the external carotid. When the vessel is exposed, the needle is to be passed from without inwards, carefully avoiding the superior laryngeal nerve, which lies in close proximity to the artery. The circulation is at once re-established by the free communication between most of the large branches of the artery (facial, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side, and by the anastomosis of its branches with those of the internal carotid, and of the occipital with branches of the subclavian, &c.

Branches of the External Carotid Artery

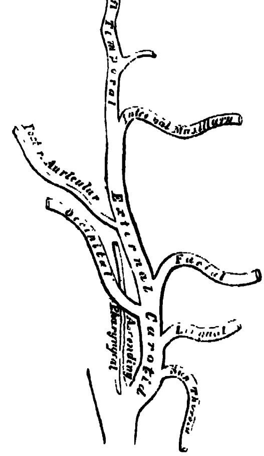
The external carotid artery gives off eight branches, which, for convenience of description, may be divided into four sets. (See fig. 575.)

Anterior.	*Posterior.*	*Ascending.*	*Terminal.*
Superior thyroid.	Occipital.	Ascending	Superficial temporal.
Lingual.	Posterior auricular.	pharyngeal.	Internal maxillary.
Facial.			

1. The **superior thyroid artery** (a. thyreoidea superior) (fig. 574) arises from the external carotid artery just below the level of the great cornu of the hyoid bone and terminates in the thyroid gland.

Relations.—From its origin under the anterior border of the Sterno-mastoid it runs upwards and forwards for a short distance in the carotid triangle, where it is covered by the skin, Platysma, and fascia; it then arches downwards beneath the Omo-hyoid, Sterno-hyoid, and Sterno-thyroid. To its inner side are the Inferior constrictor of the pharynx and the external laryngeal nerve.

Fig. 575.—Plan of the branches of the external carotid



Branches. — It distributes twigs to the adjacent muscles, and numerous branches to the thyroid gland, anastomosing with its fellow of the opposite side, and with the inferior thyroid arteries. The branches to the gland are generally two in number: one, the larger, supplies principally the anterior surface of the gland; it courses along the inner border of the lateral lobe to the isthmus, in which it anastomoses with the corresponding artery of the opposite side: a second branch descends on the posterior surface of the lateral lobe and anastomoses with the inferior thyroid artery.

Besides the arteries distributed to the muscles and to the thyroid gland, the branches of the superior thyroid are:

Infrahyoid.	Superior laryngeal.
Sterno-mastoid.	Crico-thyroid.

The **infrahyoid branch** (ramus hyoideus) is small and runs along the lower border of the hyoid bone beneath the Thyro-hyoid muscle; after supplying the muscles connected to the hyoid bone, it forms an arch, by anastomosing with the vessel of the opposite side.

The **sterno-mastoid branch** (ramus sternocleidomastoideus) runs downwards and outwards across the sheath of the common carotid artery, and supplies the Sterno-mastoid and neighbouring muscles and integument. There is frequently a separate branch from the external carotid distributed to the Sterno-mastoid.

The **superior laryngeal** (a. laryngea superior), larger than either of the preceding, accompanies the internal laryngeal nerve, beneath the Thyro-hyoid muscle; it pierces the thyro-hyoid membrane, and supplies the muscles, mucous membrane, and glands of the larynx, anastomosing with the branch from the opposite side.

The **crico-thyroid branch** (ramus cricothyreoideus) is small and runs transversely across the crico-thyroid membrane, communicating with the artery of the opposite side.

Applied Anatomy.—The superior thyroid, or one of its branches, is often divided in cases of cut throat, giving rise to considerable hæmorrhage. In such cases, the artery should be secured, the wound being enlarged for that purpose, if necessary. The operation may be easily performed, the artery being very superficial, and the only structures of importance covering it being a few small veins. The operation of tying the superior thyroid artery in bronchocele has been performed, but the collateral circulation between this vessel and the artery of the opposite side, and the inferior thyroid, is so free that the operation has been given up, especially as better results are obtained by other means.

The position of the sterno-mastoid branch is of importance in connection with the operation of ligature of the common carotid artery. It crosses and lies on the sheath of this vessel and may chance to be wounded in opening the sheath. The position of the crico-thyroid branch should be remembered, as it may prove the source of troublesome hæmorrhage during the operation of laryngotomy.

2. The **lingual artery** (a. lingualis) (fig. 580) arises from the external carotid between the superior thyroid and facial; it first runs obliquely upwards and inwards to the great cornu of the hyoid bone; it then curves downwards and forwards, forming a loop which is crossed by the hypoglossal nerve, and passing beneath the Digastric and Stylo-hyoid muscles it runs horizontally forwards, beneath the Hyo-glossus, and finally, ascending almost perpendicularly to the tongue, turns forwards on its lower surface as far as the tip, under the name of the *ranine artery.*

Relations.—Its first, or oblique, portion is superficial, being contained within the carotid triangle; it rests upon the Middle constrictor of the pharynx, and is covered by the Platysma and the fascia of the neck. Its second, or curved, portion also lies upon the Middle constrictor, being covered at first by the tendon of the Digastric and by the Stylo-hyoid muscle, and afterwards by the Hyo-glossus. Its third, or horizontal, portion lies between the Hyo-glossus and Genio-hyo-glossus muscles. The fourth, or terminal, part, under the name of the *ranine*, runs along the under surface of the tongue to its tip: here it is very superficial, being covered only by the mucous membrane; above it is the Lingualis inferior, and on the inner side the Genio-hyo-glossus. The hypoglossal nerve crosses the first part of the lingual artery, but is separated from the second part by the Hyo-glossus.

The branches of the lingual artery are:

Suprahyoid.	Sublingual.
Dorsales linguæ.	Ranine.

The **suprahyoid** (ramus hyoideus) runs along the upper border of the hyoid bone, supplying the muscles attached to it and anastomosing with its fellow of the opposite side.

The **dorsales linguæ** consist usually of two or three small branches which arise beneath the Hyo-glossus muscle; they ascend to the back part of the dorsum of the tongue, and supply the mucous membrane in this situation, the tonsil, soft palate, and epiglottis; anastomosing with the vessels of the opposite side.

The **sublingual** (a. sublingualis) arises at the anterior margin of the Hyo-glossus muscle, and runs forward between the Genio-hyo-glossus and Mylo-hyoid to the sublingual gland. It supplies the substance of the gland, giving branches to the Mylo-hyoid and neighbouring muscles, and to the mucous membrane of the mouth and gums. One branch runs behind the alveolar process of the mandible in the substance of the gum to anastomose with a similar artery from the other side.

The **ranine** (a. profunda linguæ) is the terminal portion of the lingual artery; it pursues a tortuous course and runs along the under surface of the tongue, below the Inferior lingualis, and above the mucous membrane; it lies on the outer side of the Genio-hyo-glossus, accompanied by the lingual nerve. On arriving at the tip of the tongue, it has been said to anastomose with the artery of the opposite side; but this is denied by Hyrtl. In the mouth, these vessels are placed one on either side of the frænulum.

Applied Anatomy.—The lingual artery may be divided near its origin in cases of cut throat, a complication that not infrequently happens in wounds of this class; or severe hæmorrhage, which cannot be restrained by ordinary means, may ensue from a wound, or deep ulcer, of the tongue. In the former case, the primary wound may be enlarged if necessary, and the bleeding vessel secured. In the latter case, it has been suggested that the lingual artery should be tied near its origin. Ligature of the lingual artery has been also occasionally practised, as a palliative measure, in cases of cancer of the tongue, in order to check the progress of the disease by starving the growth, and it is sometimes tied as a preliminary measure to removal of the tongue. The operation is a difficult one on account of the depth of the artery, the number of important parts by which it is surrounded, the loose and yielding nature of the parts upon which it is supported, and its occasional irregularity of origin. An incision is to be made in a curved direction from a finger's breadth external to the symphysis of the jaw downwards to the cornu of the hyoid bone, and then upwards to near the angle of the jaw. Care must be taken not to carry this incision too far backwards, for fear of endangering the facial vein. In the first incision the skin, superficial fascia, and Platysma will be divided, and the deep fascia exposed. This is then to be incised and the submaxillary gland exposed and pulled upwards by retractors. A triangular space is now seen, bounded internally by the posterior border of the Mylo-hyoid muscle; below and externally, by the tendon of the Digastric; and above, by the hypoglossal nerve. The floor of the space is formed by the Hyo-glossus muscle, beneath which the artery lies. The parts are to be drawn forwards by a blunt hook inserted beneath the tendon of the Digastric muscle, and the fibres of the Hyo-glossus cut through horizontally just above the Digastric. The vessel will then be exposed; and in passing the aneurysm needle, care must be taken not to open the pharynx. The hypoglossal nerve must also be avoided.

Troublesome hæmorrhage may occur in the division of the frænulum linguæ in children, if the ranine arteries, which lie one on either side of it, be wounded. The operation should always be performed with a pair of blunt-pointed scissors, and only the mucous membrane divided by a very superficial cut, which cannot endanger any vessel. Any further liberation of the tongue which may be necessary can be effected by tearing.

3. The **facial or external maxillary artery** (a. maxillaris externa) (fig. 576) arises a little above the lingual, and passes obliquely upwards, beneath the Digastric and Stylo-hyoid muscles, and frequently beneath the hypoglossal nerve, and runs forwards under cover of the body of the mandible, lodged in a groove on the posterior surface of the submaxillary gland; this may be called the cervical part of the artery. It then curves upwards over the body of the mandible at the antero-inferior angle of the Masseter muscle; passes forwards and upwards across the cheek to the angle of the mouth, then upwards along the side of the nose, and terminates at the inner canthus of the eye, under the name of the *angular artery.* This vessel, both in the neck and on the face, is remarkably tortuous: in the former situation, to accommodate itself to the movements of the pharynx in deglutition; and in the latter, to the movements of the mandible, lips, and cheeks.

Relations.—*In the neck*, its origin is superficial, being covered by the integument, Platysma, and fascia; it then passes beneath the Digastric and Stylo-hyoid muscles, and part of the submaxillary gland. It lies upon the Middle constrictor of the pharynx, and is separated from the Stylo-glossus and Hyo-glossus by a portion of the submaxillary gland. *On the face*, where it passes over the body of the mandible, it is comparatively superficial, lying immediately beneath the Platysma. In this situation its pulsation may be distinctly felt, and compression of the vessel against the bone can be effectually made. In its course over the face, it is covered by the integument, the fat of the cheek, and, near the angle of the mouth, by the Platysma, Risorius, and Zygomatici muscles. It rests on the Buccinator, the Levator anguli oris, and the Levator labii superioris (sometimes piercing or passing under this last muscle). The facial vein lies to the outer side of the artery, and takes a more direct course across the face, where it is separated from the artery by a considerable interval. In the neck it lies superficial to the

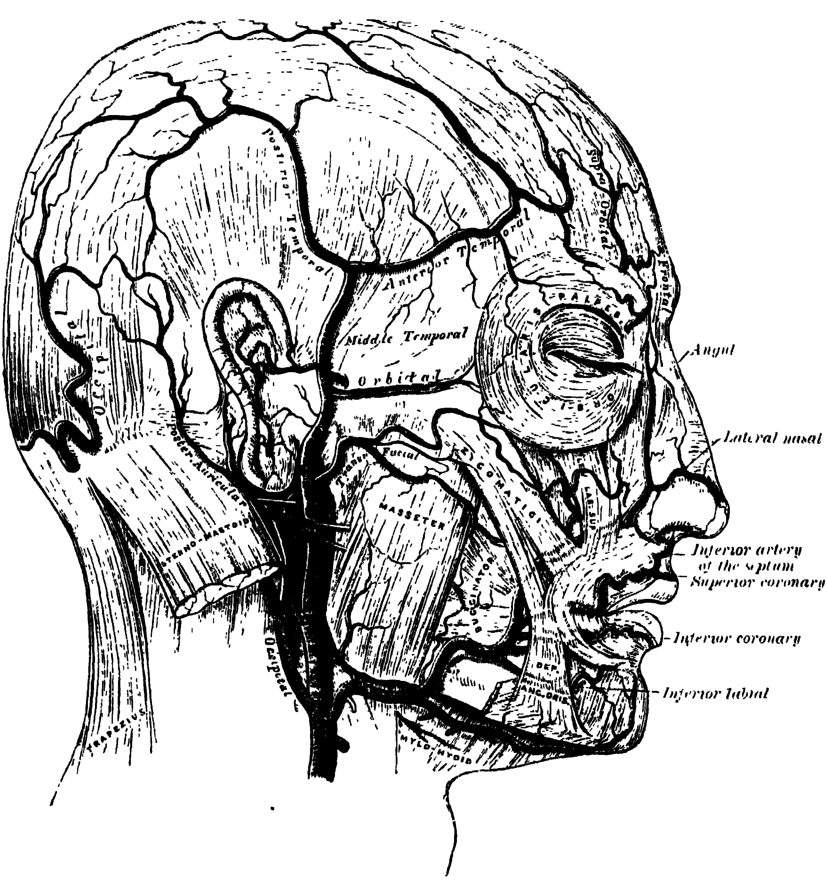
artery. The branches of the facial nerve cross the artery, and the **infra-orbital** nerve lies beneath it.

The branches of the facial artery may be divided into two sets: those given off below the mandible (cervical), and those on the face (facial).

Cervical Branches.	*Facial Branches.*
Ascending palatine.	Inferior labial.
Tonsillar.	Inferior coronary.
Submaxillary.	Superior coronary.
Submental.	Lateral nasal.
Muscular.	Angular.
	Muscular.

The **ascending palatine** (a. palatina ascendens) (fig. 580) passes up between the Stylo-glossus and Stylo-pharyngeus to the outer side of the pharynx, along

FIG. 576.—The arteries of the face and scalp.*



which it is continued between the Superior constrictor and the Internal pterygoid to near the base of the skull. It divides, near the Levator palati, into two branches: one follows the course of the Levator palati, and, winding over the upper border of the Superior constrictor, supplies the soft palate and the palatine glands, anastomosing with its fellow of the opposite side and with the posterior palatine branch of the internal maxillary artery; the other pierces the Superior constrictor and supplies the tonsil and Eustachian tube, anastomosing with the tonsillar and ascending pharyngeal arteries.

* The muscular tissue of the lips must be supposed to have been cut away, in order to show the course of the coronary arteries.

The **tonsillar branch** (ramus tonsillaris) (fig. 580) ascends between the Internal pterygoid and Stylo-glossus, and then along the side of the pharynx, perforating the Superior constrictor, to ramify in the substance of the tonsil and root of the tongue.

The **submaxillary** or **glandular branches** (rami glandulares) consist of three or four large vessels, which supply the submaxillary gland, some being prolonged to the neighbouring muscles, lymphatic glands, and integument.

The **submental** (a. submentalis), the largest of the cervical branches, is given off from the facial artery just as that vessel quits the submaxillary gland: it runs forwards upon the Mylo-hyoid muscle, just below the body of the mandible, and beneath the Digastric. After supplying the surrounding muscles, and anastomosing with the sublingual artery by branches which perforate the Mylo-hyoid muscle, it arrives at the symphysis menti, where it turns over the border of the mandible and divides into a superficial and a deep branch. The superficial branch passes between the integument and Depressor labii inferioris, supplies both, and anastomoses with the inferior labial artery; the deep branch runs between the muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

The **inferior labial** passes beneath the Depressor anguli oris, to supply the muscles and integument of the lower lip, anastomosing with the inferior coronary and submental branches of the facial, and with the mental branch of the inferior dental artery.

The **inferior coronary** (a. labialis inferior) arises near the angle of the mouth; it passes upwards and inwards beneath the Depressor anguli oris, and, penetrating the Orbicularis oris muscle, runs in a tortuous course along the edge of the lower lip between this muscle and the mucous membrane, anastomosing with the artery of the opposite side. It supplies the labial glands, the mucous membrane, and the muscles of the lower lip; and anastomoses with the inferior labial, and the mental branch of the inferior dental artery.

The **superior coronary** (a. labialis superior) is larger and more tortuous than the preceding. It follows a similar course along the edge of the upper lip, lying between the mucous membrane and the Orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the textures of the upper lip, and gives off in its course two or three vessels which ascend to the nose. One, named the *inferior artery of the septum*, ramifies on the nasal septum as far as the point of the nose; another, the *artery of the ala*, supplies the ala of the nose.

The **lateral nasal** is derived from the facial, as that vessel ascends along the side of the nose; it supplies the ala and dorsum of the nose, anastomosing with its fellow, and with the nasal branch of the ophthalmic, the inferior artery of the septum, the artery of the ala, and the infra-orbital.

The **angular** (a. angularis) is the termination of the trunk of the facial: it ascends to the inner angle of the orbit, imbedded in the fibres of the Levator labii superioris alæque nasi, and accompanied by a large vein, the *angular*. It distributes branches on the cheek which anastomose with the infra-orbital, and, after supplying the lachrymal sac and Orbicularis palpebrarum muscle, terminates by anastomosing with the nasal branch of the ophthalmic artery.

The **muscular branches** (rami musculares) in the neck are distributed to the Internal pterygoid and Stylo-hyoid, and on the face to the Masseter and Buccinator.

The anastomoses of the facial artery are very numerous, not only with the vessel of the opposite side, but, *in the neck*, with the sublingual branch of the lingual; with the ascending pharyngeal; with the posterior palatine branch of the internal maxillary, by its inferior or ascending palatine and tonsillar branches; *on the face*, with the mental branch of the inferior dental as it emerges from the mental foramen; with the transverse facial branch of the superficial temporal; with the infra-orbital branch of the internal maxillary; and with the nasal branch of the ophthalmic.

Peculiarities.—The facial artery not infrequently arises by a trunk common to it and the lingual. It varies in its size and in the extent to which it supplies the face. It occasionally terminates as the submental, and not infrequently extends only as high as the angle of the mouth or nose. The deficiency is then compensated for by enlargement of one of the neighbouring arteries.

Applied Anatomy.—The passage of the facial artery over the body of the mandible would appear to afford a favourable position for the application of pressure in cases of

hæmorrhage from the lips, the result either of an accidental wound or during an operation; but its application is useless, except for a very short time, on account of the free communication of this vessel with its fellow, and with numerous branches from different sources. In a wound involving the lip, it is better to seize the part between the fingers, and evert it, when the bleeding vessel may be at once secured with pressure-forceps. In order to prevent hæmorrhage in cases of removal of growths from the part, the lip should be compressed on either side between the fingers and thumb, or by a pair of specially devised clamp-forceps, while the surgeon excises the diseased part. In order to stop hæmorrhage when the lip has been divided in an operation, it is necessary, in uniting the edges of the wound, to pass the sutures through the cut edges, almost as deep as its mucous surface; by these means, not only are the cut surfaces more neatly and securely adapted to each other, but the possibility of hæmorrhage is prevented by including in the suture the divided artery. If, on the contrary, the suture be passed through merely the cutaneous portion of the wound, hæmorrhage occurs into the cavity of the mouth. The student should, lastly, observe the relation of the angular artery to the lachrymal sac; as the vessel passes up along the inner margin of the orbit, it ascends on the nasal side of the sac. In operating for fistula lacrimalis, the sac should always be opened on its outer side, in order that this vessel may be avoided.

4. The **occipital artery** (a. occipitalis) (fig. 576) arises from the posterior part of the external carotid, opposite the facial, near the lower margin of the posterior belly of the Digastric, and terminates in the posterior part of the scalp.

Relations.—At its origin, it is covered by the posterior belly of the Digastric and Stylo-hyoid, and the hypoglossal nerve winds around it from behind forwards; higher up, it crosses the internal carotid artery, the internal jugular vein, and the pneumogastric and spinal accessory nerves. It next ascends to the interval between the transverse process of the atlas and the mastoid process of the temporal bone, and passes horizontally backwards, grooving the surface of the latter bone, being covered by the Sterno-mastoid, Splenius, Trachelo-mastoid, and Digastric muscles, and resting upon the Rectus lateralis, the Superior oblique, and Complexus muscles. It then changes its course and runs vertically upwards, pierces the fascia connecting the cranial attachment of the Trapezius with the Sterno-mastoid, and ascends in a tortuous course in the superficial fascia of the scalp, where it divides into numerous branches, which reach as high as the vertex of the skull and anastomose with the posterior auricular and superficial temporal arteries. Its terminal portion is accompanied by the great occipital nerve.

The branches of the occipital artery are:

Muscular.	Sterno-mastoid.	Auricular.
Meningeal.	Arteria princeps cervicis.	

The **muscular branches** (rami musculares) supply the Digastric, Stylo-hyoid, Splenius, and Trachelo-mastoid.

The **sterno-mastoid branch** (a. sternocleidomastoidea) is large and constant, generally arising from the artery close to its commencement, but sometimes springing directly from the external carotid. It passes downwards and backwards over the hypoglossal nerve, and enters the substance of the muscle, in company with the spinal accessory nerve.

The **auricular branch** (ramus auricularis) supplies the back of the concha and frequently gives off a branch, which enters the skull through the mastoid foramen and supplies the dura mater, the diploë, and the mastoid cells. This branch sometimes arises from the occipital artery, and is then known as the *mastoid* branch.

The **meningeal branches** (rami meningei) ascend with the internal jugular vein, and enter the skull through the jugular and posterior condyloid foramina, to supply the dura mater in the posterior fossa.

The **arteria princeps cervicis** (ramus descendens) (fig. 580), the largest branch of the occipital, descends on the back of the neck, and divides into a superficial and deep portion. The superficial portion runs beneath the Splenius, giving off branches which pierce that muscle to supply the Trapezius and anastomose with the superficial cervical branch of the transversalis colli: the deep portion passes beneath the Complexus, between it and the Semispinalis colli, and anastomoses with branches from the vertebral and with the deep cervical artery, a branch of the superior intercostal. The anastomosis between these vessels assists in establishing the collateral circulation after ligature of the common carotid or subclavian artery.

The cranial branches of the occipital artery are distributed upon the occiput: they are very tortuous, and lie between the integument and Occipito-frontalis, anastomosing with the artery of the opposite side and with the posterior auricular and temporal arteries. They supply the back part of the Occipito-frontalis muscle, the integument, and pericranium.

5. The **posterior auricular artery** (a. auricularis posterior) (fig. 576) is small and arises from the external carotid, above the Digastric and Stylo-hyoid muscles, opposite the apex of the styloid process. It ascends, under cover of the parotid gland, on the styloid process of the temporal bone, to the groove between the cartilage of the ear and the mastoid process, immediately above which it divides into its auricular and mastoid branches.

Besides several small branches to the Digastric, Stylo-hyoid, and Sterno-mastoid muscles, and to the parotid gland, this vessel gives off three branches:

Stylo-mastoid.	Auricular.	Mastoid.

The **stylo-mastoid branch** (a. stylomastoidea) enters the stylo-mastoid foramen and supplies the tympanum, mastoid cells, and semicircular canals. In the young subject a branch from this vessel forms, with the tympanic branch from the internal maxillary, a vascular circle, which surrounds the membrana tympani, and from which delicate vessels ramify on that membrane. It anastomoses with the petrosal branch of the middle meningeal artery by a twig which enters the hiatus Fallopii.

The **auricular branch** (ramus auricularis) ascends behind the ear, beneath the Retrahens aurieulam muscle, and is distributed to the back part of the cartilage of the ear, upon which it ramifies minutely, some branches curving round the margin of the fibro-cartilage, others perforating it, to supply the anterior surface. It anastomoses with the posterior branch and also with the anterior auricular branches of the superficial temporal.

The **mastoid branch** (ramus occipitalis) passes backwards, over the Sterno-mastoid muscle, to the scalp above and behind the ear. It supplies the posterior belly of the Occipito-frontalis muscle and the scalp in this situation. It anastomoses with the occipital artery.

6. The **ascending pharyngeal artery** (a. pharyngea ascendens) (fig. 580), the smallest branch of the external carotid, is a long, slender vessel, deeply seated in the neck, beneath the other branches of the external carotid and under the Stylo-pharyngeus muscle. It arises from the back part of the external carotid, near the commencement of that vessel, and ascends vertically between the internal carotid and the side of the pharynx, to the under surface of the base of the skull, lying on the Rectus capitis anticus major. It ends by dividing into branches which supply the pharynx and soft palate.

Its branches may be divided into five sets:

Pharyngeal.		Prevertebral.
Palatine.		Tympanic.
	Meningeal.	

The **pharyngeal branches** (rami pharyngei) are three or four in number. Two of these descend to supply the Middle and Inferior constrictors and the Stylo-pharyngeus, ramifying in their substance and in the mucous membrane lining them.

The **palatine branch** varies in size, and may take the place of the ascending palatine branch of the facial artery, when that vessel is small. It passes inwards upon the Superior constrictor, sends ramifications to the soft palate and tonsil, and supplies a branch to the Eustachian tube.

The **prevertebral branches** are numerous small vessels, which supply the Recti capitis antici and Longi colli, the sympathetic, hypoglossal, and pneumo-gastric nerves, and the lymphatic glands; they anastomose with the ascending cervical artery.

The **tympanic branch** (a. tympanica inferior) is a small artery which passes through a minute foramen in the petrous portion of the temporal bone, in company with the tympanic branch of the glosso-pharyngeal nerve, to supply the inner wall of the tympanum and anastomose with the other tympanic arteries.

The **meningeal branches** consist of several small vessels, which supply the dura mater. One, the *posterior meningeal* (a. meningea posterior), enters the cranium through the jugular foramen; a second passes through the foramen lacerum medium; and occasionally a third through the anterior condyloid foramen.

Applied Anatomy.—The ascending pharyngeal artery has been wounded from the throat; as in the case in which the stem of a tobacco-pipe was driven into the vessel, causing fatal hæmorrhage.

7. The **superficial temporal artery** (a. temporalis superficialis) (fig. 576), the smaller of the two terminal branches of the external carotid, appears, from its direction, to be the continuation of that vessel. It commences in the substance of the parotid gland, behind the neck of the mandible, and crosses over the posterior root of the zygoma. It then passes beneath the Attrahens auriculam muscle, lying on the temporal fascia, and divides, about two inches above the zygomatic arch, into two branches, an anterior and a posterior temporal.

Relations.—As it crosses the zygoma, it is covered by the Attrahens auriculam muscle, and by a dense fascia: it is crossed by the temporo-facial division of the facial nerve and one or two veins, and is accompanied by the auriculo-temporal nerve, which lies behind it.

Besides some twigs to the parotid gland, to the temporo-mandibular joint, and to the Masseter muscle, its branches are:

Transverse facial.	Anterior auricular.
Middle temporal.	Anterior temporal.
Posterior temporal.	

The **transverse facial** (a. transversa faciei) is given off from the superficial temporal before that vessel quits the parotid gland; running forwards through the substance of the gland, it passes transversely across the side of the face, between Stenson's duct and the lower border of the zygoma, and divides into numerous branches, which supply the parotid gland, the Masseter muscle, and the integument, and anastomose with the facial, masseteric, and infra-orbital arteries. This vessel rests on the Masseter, and is accompanied by one or two branches of the facial nerve. It is sometimes a branch of the external carotid.

The **middle temporal** (a. temporalis media) arises immediately above the zygomatic arch, and, perforating the temporal fascia, gives branches to the Temporal muscle, anastomosing with the deep temporal branches of the internal maxillary. It occasionally gives off an *orbital* branch, which runs along the upper border of the zygoma, between the two layers of the temporal fascia, to the outer angle of the orbit. This branch, which may arise directly from the superficial temporal artery, supplies the Orbicularis palpebrarum, and anastomoses with the lachrymal and palpebral branches of the ophthalmic artery.

The **anterior auricular branches** (rami auriculares anteriores) are distributed to the anterior portion of the pinna, the lobule, and part of the external meatus, anastomosing with branches of the posterior auricular.

The **anterior temporal** (ramus frontalis) runs tortuously upwards and forwards to the forehead, supplying the muscles, integument, and pericranium in this region, and anastomoses with the supra-orbital and frontal arteries.

The **posterior temporal** (ramus parietalis), larger than the anterior, curves upwards and backwards along the side of the head, lying superficial to the temporal fascia, and anastomoses with its fellow of the opposite side, and with the posterior auricular and occipital arteries.

Applied Anatomy.—The temporal artery, as it crosses the zygoma, lies immediately beneath the skin, and its pulsations may be readily felt during the administration of an anæsthetic, or under circumstances where the radial pulse is not available; or it may be easily compressed against the bone in order to check bleeding from the temporal region of the scalp. When a flap is raised from this part of the head, as in the operation of trephining, the incision should be shaped like a horse-shoe, with its convexity upwards, so that the flap shall contain the temporal artery, which ensures a sufficient supply of blood. The same principle is applied, as far as possible, in making incisions to raise flaps in other parts of the scalp. Formerly the operation of arteriotomy was performed upon this vessel in cases of inflammation of the eye or brain, but this operation is now obsolete.

8. The **internal maxillary artery** (a. maxillaris interna) (fig. 577), the larger of the two terminal branches of the external carotid, arises behind the neck of the mandible, and is at first imbedded in the substance of the parotid gland; it passes inwards between the ramus of the mandible and the internal lateral ligament, and then upon the outer surface of the External pterygoid muscle to the spheno-maxillary fossa to supply the deep structures of the face. For convenience of description, it is divided into maxillary, pterygoid, and spheno-maxillary portions.

The *first* or *maxillary portion* passes horizontally forwards and inwards, between the ramus of the mandible and the internal lateral ligament, where

FIG. 577.—The internal maxillary artery, and its branches.

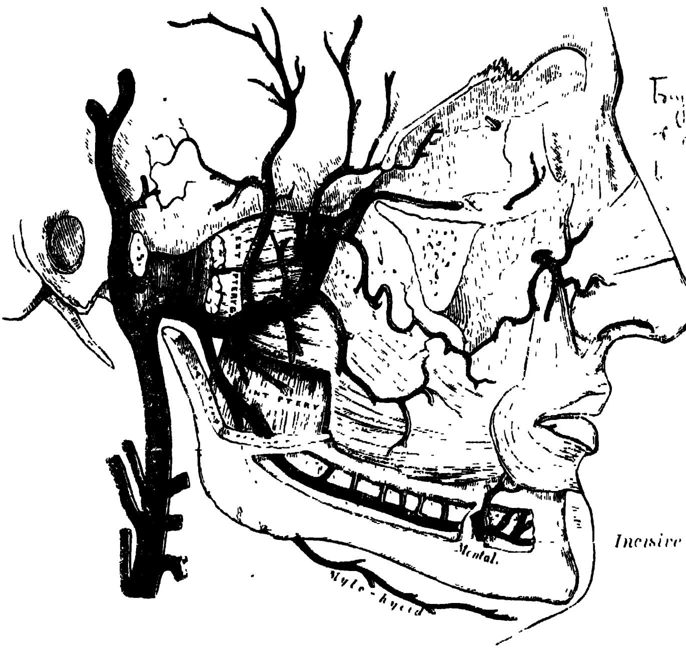


FIG. 578.—Plan of the branches.

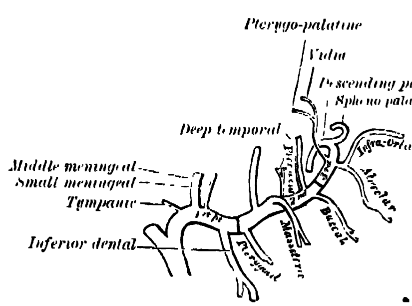


it lies parallel to and a little below the auriculo-temporal nerve; it crosses the inferior dental nerve, and runs along the lower border of the External pterygoid.

The *second* or *pterygoid portion* runs obliquely forwards and upwards under cover of the ramus of the mandible, on the outer (very frequently on the inner) surface of the External pterygoid; it then passes between the two heads of origin of this muscle and enters the spheno-maxillary fossa.

The *third* or *spheno-maxillary portion* lies in the spheno-maxillary fossa in relation with Meckel's ganglion.

The branches of this vessel may be divided into three groups (fig. 578), corresponding with its three divisions.

BRANCHES OF THE FIRST OR MAXILLARY PORTION

Tympanic (anterior).	Middle meningeal.
Deep auricular.	Small meningeal.
Inferior dental.	

The **tympanic** (a. tympanica anterior) passes upwards behind the temporo-mandibular articulation, enters the tympanum through the Glaserian fissure, and ramifies upon the membrana tympani, forming a vascular circle around the membrane with the stylo-mastoid branch of the posterior auricular, and anastomosing with the Vidian and with the tympanic branch from the internal carotid.

The **deep auricular** (a. auricularis profunda) often arises in common with the preceding. It ascends in the substance of the parotid gland, behind the temporo-mandibular articulation, pierces the cartilaginous or bony wall of the external auditory meatus, and supplies its cuticular lining and the outer surface of the membrana tympani. It gives a branch to the temporo-mandibular joint.

The **middle meningeal** (a. meningea media) is the largest of the branches which supply the dura mater. It ascends between the internal lateral ligament and the External pterygoid muscle, and between the two roots of the auriculo-temporal nerve to the foramen spinosum of the sphenoid bone, through which it enters the cranium ; it then runs upwards and forwards in a groove on the greater wing of the sphenoid bone, and divides into two branches, anterior and posterior. The *anterior branch*, the larger, crosses the greater wing of the sphenoid, reaches the groove, or canal, in the antero-inferior angle of the parietal bone, and then divides into branches which spread out between the dura mater and internal surface of the cranium, some passing upwards as far as the vertex, and others backwards to the occipital region. The *posterior branch* crosses the squamous portion of the temporal, and on the inner surface of the parietal bone divides into branches which supply the posterior part of the dura mater and cranium. The branches of this vessel are distributed partly to the dura mater, but chiefly to the bones ; they anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal.

The middle meningeal on entering the cranium gives off the following branches: 1. Numerous small vessels which supply the Gasserian ganglion and the dura mater in this situation. 2. A *petrosal* branch (ramus petrosus superficialis), which enters the hiatus Fallopii, supplies the facial nerve, and anastomoses with the stylo-mastoid branch of the posterior auricular artery. 3. A minute *tympanic* branch (a. tympanica superior), which runs in the canal for the Tensor tympani muscle, and supplies this muscle and the lining membrane of the canal. 4. *Orbital* branches, which pass through the sphenoidal fissure or through separate canals in the greater wing of the sphenoid, to anastomose with the lachrymal or other branches of the ophthalmic artery. 5. *Temporal* or *anastomotic* branches, which pass through foramina in the greater wing of the sphenoid, and anastomose in the temporal fossa with the deep temporal arteries.

Applied Anatomy.—The middle meningeal is an artery of considerable surgical importance, as it may be torn in fractures of the temporal region of the skull, or, indeed, by injuries causing separation of the dura mater from the bone, without fracture. The injury may be followed by considerable hæmorrhage between the bone and dura mater, which may produce compression of the brain, and require trephining for its relief. As the compression implicates the motor region of the cortex, paralysis on the opposite side of the body forms the prominent symptom of the lesion. The anterior branch of this artery crosses the antero-inferior angle of the parietal bone at a point 1½ inch behind the external angular process of the frontal bone, and 1¾ inch above the zygoma (fig. 753). From this point it passes upwards and slightly backwards to the sagittal suture, lying about ½ inch to ¾ inch behind the coronal suture. The posterior branch runs backwards over the squamous portion of the temporal bone. In order to expose the anterior branch of the artery, a point is taken 1½ inch above the zygoma and the same distance behind the external angular process of the frontal bone. Here the pin of the trephine is to be applied. A horseshoe-shaped flap, measuring three inches in length and transversely, and consisting of all the structures of the scalp down to the pericranium, is now to be made, with its base just above the zygoma. This flap is reflected, the pericranium is turned back, and an inch trephine applied. After the crown of bone has been removed, the blood-clot is exposed, and gently got rid of, and if possible the bleeding point must be found and controlled.

The **small meningeal** (ramus meningeus accessorius) is sometimes derived from the preceding. It enters the skull through the foramen ovale, and supplies the Gasserian ganglion and dura mater.

The **inferior dental** (a. alveolaris inferior) descends with the inferior dental nerve to the foramen on the inner side of the ramus of the mandible. It runs along the dental canal in the substance of the bone, accompanied by the nerve, and opposite the first bicuspid tooth divides into two branches, incisor and mental. The incisor branch is continued forwards beneath the incisor teeth as far as the symphysis menti, where it anastomoses with the artery of the opposite side; the *mental* branch (a. mentalis) escapes with the nerve at the mental foramen, supplies the chin, and anastomoses with the submental, inferior labial, and inferior coronary arteries. Near its origin the inferior dental artery gives off a *lingual* branch, which descends with the lingual nerve and supplies the mucous membrane of the mouth. As the inferior dental artery enters the foramen, it gives off a *mylo-hyoid* branch (ramus mylohyoideus) which runs in the mylo-hyoid groove, and ramifies on the under surface of the Mylo-hyoid. The inferior dental artery and its incisor branch during their course through the substance of the bone give off a few twigs which are lost in the cancellous tissue, and a series of branches which correspond in number to the roots of the teeth: these enter the minute apertures at the extremities of the fangs, and supply the pulp of the teeth.

Branches of the Second or Pterygoid Portion

Deep temporal.	Masseteric.
Pterygoid.	Buccal.

The **deep temporal branches,** two in number, anterior (a. temporalis profunda anterior) and posterior (a. temporalis profunda posterior), ascend between the Temporal muscle and the pericranium; they supply the muscle, and anastomose with the middle temporal artery; the anterior communicates with the lachrymal by means of small branches which perforate the malar bone and greater wing of the sphenoid.

The **pterygoid branches** (rami pterygoidei), irregular in their number and origin, supply the Pterygoid muscles.

The **masseteric** (a. masseterica) is a small branch which passes outwards, above the sigmoid notch of the mandible, to the deep surface of the Masseter. It supplies the muscle, and anastomoses with the masseteric branches of the facial and with the transverse facial artery.

The **buccal** (a. buccinatoria) is a small branch which runs obliquely forwards, between the Internal pterygoid and the ramus of the jaw, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the facial artery.

Branches of the Third or Spheno-maxillary Portion

Alveolar.	Vidian.
Infra-orbital.	Pterygo-palatine.
Descending palatine.	Naso- or Spheno-palatine.

The **alveolar** or **posterior dental** (a. alveolaris superior posterior) is given off from the internal maxillary, frequently in conjunction with the infra-orbital just as the trunk of the vessel is passing into the spheno-maxillary fossa. Descending upon the tuberosity of the maxilla, it divides into numerous branches, some of which enter the posterior dental canals, to supply the molar and bicuspid teeth and the lining of the antrum, while others are continued forwards on the alveolar process to supply the gums.

The **infra-orbital** (a. infraorbitalis) appears, from its direction, to be the continuation of the trunk of the internal maxillary, but often arises from that vessel in conjunction with the preceding branch. It runs along the infra-orbital canal with the superior maxillary nerve, and emerges on the face through the infra-orbital foramen, beneath the Levator labii superioris. While in the canal, it gives off (*a*) branches which ascend into the orbit, and assist in supplying the

Inferior rectus and Inferior oblique muscles and the lachrymal gland, and (*b*) *anterior dental* branches (aa. alveol. superiores anteriores) which descend through the anterior dental canals in the bone to supply the mucous membrane of the antrum and the front teeth of the maxilla. On the face, some branches pass upwards to the inner angle of the orbit and the lachrymal sac, anastomosing with the angular branch of the facial artery; others run inwards towards the nose, anastomosing with the nasal branch of the ophthalmic; and others descend beneath the Levator labii superioris and anastomose with the transverse facial and buccal arteries.

The four remaining branches arise from that portion of the internal maxillary which is contained in the spheno-maxillary fossa.

The **descending palatine** (a. palatina descendens) descends through the posterior palatine canal with the anterior palatine branch of Meckel's ganglion, and, emerging from the posterior palatine foramen, runs forwards in a groove on the inner side of the alveolar border of the hard palate to the anterior palatine canal. The terminal branch of the artery passes upwards through the foramen of Stenson to anastomose with the naso-palatine artery. Branches are distributed to the gums, the mucous membrane of the hard palate, and the palatine glands. In the palatine canal it gives off branches which descend in the accessory palatine canals to supply the soft palate and tonsil, anastomosing with the ascending palatine artery.

Applied Anatomy.—The position of the descending palatine artery on the hard palate should be borne in mind in performing an operation for the closure of a cleft in the hard palate, as it is in danger of being wounded, and may give rise to formidable hæmorrhage; it has even been found necessary to plug the posterior palatine canal in order to arrest the bleeding.

The **Vidian** (a. canalis pterygoidei) passes backwards along the Vidian canal with the Vidian nerve. It is distributed to the upper part of the pharynx and to the Eustachian tube, sending into the tympanum a small branch which anastomoses with the other tympanic arteries.

The **pterygo-palatine**, a very small branch, runs backwards through the pterygo-palatine canal with the pharyngeal nerve, and is distributed to the upper part of the pharynx and to the Eustachian tube.

The **spheno-palatine** (a. sphenopalatina) passes through the spheno-palatine foramen into the cavity of the nose, at the back part of the superior meatus, and divides into several branches. One, the *naso-palatine*, courses obliquely downwards and forwards along the septum nasi, supplies the mucous membrane, and anastomoses in front with the terminal branch of the descending palatine; the other branches, two or three in number, are distributed to the lateral wall of the nose, the antrum, and the ethmoidal and sphenoidal cells.

The Triangles of the Neck (fig. 579)

The student having considered the relative anatomy of the large arteries of the neck and their branches, and the relations they bear to the veins and nerves, should now examine these structures collectively, as they present themselves in certain regions of the neck, in each of which important operations are constantly being performed.

The side of the neck presents a somewhat quadrilateral outline, limited, above, by the lower border of the body of the mandible, and an imaginary line extending from the angle of the mandible to the mastoid process; below, by the prominent upper border of the clavicle; in front, by the middle line of the neck; behind, by the anterior margin of the Trapezius muscle. This space is subdivided into two large triangles by the Sterno-mastoid muscle, which passes obliquely across the neck, from the sternum and clavicle below, to the mastoid process and occipital bone above. The triangular space in front of this muscle is called the *anterior triangle*; and that behind it, the *posterior triangle*.

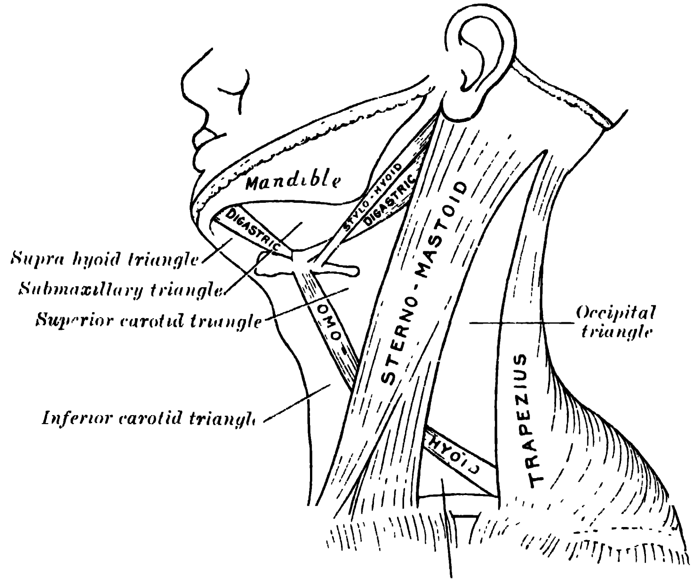
Anterior Triangle of the Neck

The anterior triangle is bounded, in front, by a line extending from the symphysis menti to the sternum; behind, by the anterior margin of the

Sterno-mastoid; its base, directed upwards, is formed by the lower border of the body of the mandible, and a line extending from the angle of the mandible to the mastoid process; its apex is below, at the sternum. This space is subdivided into four smaller triangles by the Digastric muscle above, and the anterior belly of the Omo-hyoid below. These smaller triangles are named the inferior carotid, the superior carotid, the submaxillary, and the supra-hyoid triangles.

The **inferior carotid,** or muscular triangle, is bounded, in front, by the median line of the neck from the hyoid bone to the sternum; behind, by the anterior margin of the Sterno-mastoid; above, by the anterior belly of the Omo-hyoid. It is covered by the integument, superficial fascia, Platysma, and deep fascia; ramifying in which are some of the descending branches of the superficial cervical plexus. Beneath these superficial structures are the Sterno-hyoid and Sterno-thyroid muscles, which, together with the anterior margin of the Sterno-mastoid, conceal the lower part of the common carotid artery.* This vessel is enclosed within its sheath, together with the internal jugular vein and pneumogastric nerve; the vein lies on the outer side of the artery on the right side of the neck, but overlaps it below

FIG. 579.—The triangles of the neck.



on the left side; the nerve lies between the artery and vein, on a plane posterior to both. In front of the sheath are a few filaments descending from the loop of communication between the descendens and communicantes hypoglossi; behind the sheath are the inferior thyroid artery, the recurrent laryngeal nerve, and the sympathetic cord; and on its inner side, the œsophagus, the trachea, the thyroid gland—much more prominent in the female than in the male—and the lower part of the larynx. By cutting into the upper part of this space, and slightly displacing the Sterno-mastoid muscle, the common carotid artery may be tied below the Omo-hyoid muscle.

The **superior carotid,** or carotid triangle, is bounded, behind, by the Sterno-mastoid; below, by the anterior belly of the Omo-hyoid; and above,

* Therefore the common carotid artery and internal jugular vein are not, strictly speaking, contained in this triangle, since they are covered by the Sterno-mastoid muscle; that is to say, they lie under that muscle, which forms the posterior border of the triangle. But as they lie very close to the structures which are really contained in the triangle, and whose position it is essential to remember in operating on this part of the artery, it is expedient to study the relations of all these parts together.

by the Stylo-hyoid muscle and the posterior belly of the Digastric. It is covered by the integument, superficial fascia, Platysma, and deep fascia; ramifying in which are branches of the facial and superficial cervical nerves. Its floor is formed by parts of the Thyro-hyoid, Hyo-glossus, and the Inferior and Middle constrictor muscles of the pharynx. This space when dissected is seen to contain the upper part of the common carotid artery, which bifurcates opposite the upper border of the thyroid cartilage into the external and internal carotid. These vessels are somewhat concealed from view by the anterior margin of the Sterno-mastoid muscle, which overlaps them. The external and internal carotids lie side by side, the external being the more anterior of the two. The following branches of the external carotid are also met with in this space: the superior thyroid, running forwards and downwards; the lingual, directly forwards; the facial, forwards and upwards; the occipital, backwards; and the ascending pharyngeal, directly upwards on the inner side of the internal carotid. The veins met with are: the internal jugular, which lies on the outer side of the common and internal carotid arteries; and veins corresponding to the above-mentioned branches of the external carotid—viz. the superior thyroid, the lingual, facial, ascending pharyngeal, and sometimes the occipital—all of which accompany their corresponding arteries, and terminate in the internal jugular. The nerves in this space are the following. In front of the sheath of the common carotid is the descendens hypoglossi. The hypoglossal nerve crosses both the internal and external carotids above, curving round the origin of the occipital artery. Within the sheath, between the artery and vein, and behind both, is the pneumogastric nerve; behind the sheath, the sympathetic. On the outer side of the vessels, the spinal accessory nerve runs for a short distance before it pierces the Sterno-mastoid muscle; and on the inner side of the external carotid, just below the hyoid bone, may be seen the internal laryngeal nerve; and, still more inferiorly, the external laryngeal nerve. The upper portion of the larynx and lower portion of the pharynx are also found in the front part of this space.

The **submaxillary** or **~~digastric triangle~~** corresponds to the region of the neck immediately beneath the body of the mandible. It is bounded, above, by the lower border of the body of the mandible, and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastric and Stylo-hyoid muscles; in front, by the anterior belly of the Digastric. It is covered by the integument, superficial fascia, Platysma, and deep fascia; ramifying in which are branches of the facial nerve and ascending filaments of the superficial cervical nerve. Its floor is formed by the Mylo-hyoid, Hyo-glossus, and Superior constrictor of the pharynx. It is divided into an anterior and a posterior part by the stylo-mandibular ligament. The anterior part contains the submaxillary gland, superficial to which is the facial vein, while imbedded in the gland is the facial artery and its glandular branches; beneath the gland, on the surface of the Mylo-hyoid muscle, are the submental artery and the mylo-hyoid artery and nerve. The posterior part of this triangle contains the external carotid artery, ascending deeply in the substance of the parotid gland; this vessel lies here in front of, and superficial to, the internal carotid, being crossed by the facial nerve, and gives off in its course the posterior auricular, temporal, and internal maxillary branches: more deeply are the internal carotid, the internal jugular vein, and the pneumogastric nerve, separated from the external carotid by the Stylo-glossus and Stylo-pharyngeus muscles, and the glosso-pharyngeal nerve.*

The **supra-hyoid triangle** is limited behind by the anterior belly of the Digastric, in front by the middle line of the neck between the symphysis menti and the hyoid bone, below by the body of the hyoid bone; its floor is formed by the Mylo-hyoid. It contains one or two lymphatic glands and some small veins; the latter unite to form the anterior jugular vein.

* The remark made about the carotid triangle applies also to this one. The structures enumerated as contained in its posterior part lie, strictly speaking, beneath the muscles which form the posterior boundary of the triangle; but as it is very important to bear in mind their close relation to the parotid gland, all these parts are spoken of together.

Posterior Triangle of the Neck

The **posterior triangle** is bounded, in front, by the Sterno-mastoid muscle; behind by the anterior margin of the Trapezius; its base corresponds to the middle third of the clavicle; its apex, to the occiput. The space is crossed, about an inch above the clavicle, by the posterior belly of the Omo-hyoid, which divides it into two triangles, an upper or occipital, and a lower or subclavian.

The **occipital triangle,** the larger division of the posterior triangle, is bounded, in front, by the Sterno-mastoid; behind, by the Trapezius; below, by the Omo-hyoid. Its floor is formed from above downwards by the Splenius capitis, Levator anguli scapulæ, and the Middle and Posterior scaleni. It is covered by the integument, the superficial and deep fasciæ, and by the Platysma below. The spinal accessory nerve is directed obliquely across the space from the Sterno-mastoid, which it pierces, to the under surface of the Trapezius; below, the descending branches of the cervical plexus and the transversalis colli vessels and the upper part of the brachial plexus cross the space. A chain of lymphatic glands is also found running along the posterior border of the Sterno-mastoid, from the mastoid process to the root of the neck. These glands are frequently enlarged and often require removal; when this is the case particular care must be taken not to divide the spinal accessory nerve.

The **subclavian triangle,** the smaller division of the posterior triangle, is bounded, above, by the posterior belly of the Omo-hyoid; below, by the clavicle; its base is formed by the posterior border of the Sterno-mastoid. Its floor is formed by the first rib with the first digitation of the Serratus magnus. The size of the subclavian triangle varies with the extent of attachment of the clavicular portions of the Sterno-mastoid and Trapezius, and also with the height at which the Omo-hyoid crosses the neck. Its height also varies according to the position of the arm, being diminished by raising the limb, on account of the ascent of the clavicle, and increased by drawing the arm downwards, when that bone is depressed. This space is covered by the integument, the superficial and deep fasciæ and the Platysma, and crossed by the descending branches of the cervical plexus. Just above the level of the clavicle, the third portion of the subclavian artery curves outwards and downwards from the outer margin of the Scalenus anticus, across the first rib, to the axilla, and this is the situation most commonly chosen for ligaturing the vessel. Sometimes this vessel rises as high as an inch and a half above the clavicle; occasionally, it passes in front of the Scalenus anticus, or pierces the fibres of that muscle. The subclavian vein lies behind the clavicle, and is not usually seen in this space; but in some cases it rises as high as the artery, and has even been seen to pass with that vessel behind the Scalenus anticus. The brachial plexus of nerves lies above the artery, and in close contact with it. Passing transversely behind the clavicle are the suprascapular vessels; and traversing its upper angle in the same direction, the transversalis colli artery and vein. The external jugular vein runs vertically downwards behind the posterior border of the Sterno-mastoid, to terminate in the subclavian vein; it receives the transversalis colli and suprascapular veins, which form a plexus in front of the artery, and occasionally a small vein which crosses the clavicle from the cephalic. The small nerve to the Subclavius muscle also crosses this triangle about its middle, and some lymphatic glands are usually found in the space.

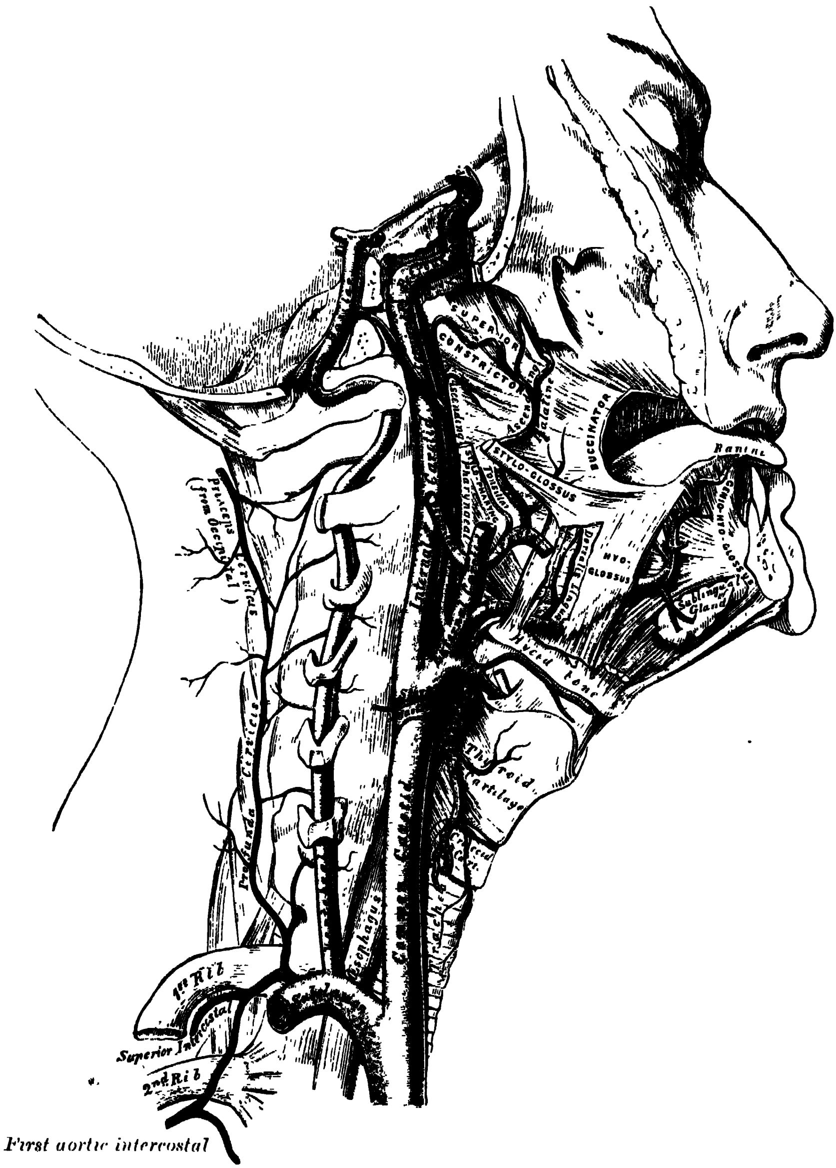
Internal Carotid Artery

The **internal carotid artery** (a. carotis interna) (fig. 580) supplies the anterior part of the brain, the eye and its appendages, and sends branches to the forehead and nose. Its size, in the adult, is equal to that of the external carotid, though, in the child, it is larger than that vessel. It is remarkable for the number of curvatures that it presents in different parts of its course. It occasionally has one or two flexures near the base of the skull, while in its passage through the carotid canal and along the side of the body of the sphenoid bone it describes a double curvature and resembles the italic letter *S*.

Relations.—In considering the course and relations of this vessel it may be divided into four portions: cervical, petrous, cavernous, and cerebral.

Cervical Portion.—This portion of the internal carotid commences at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage, and runs perpendicularly upwards, in front of the transverse processes of the upper three cervical vertebræ, to the carotid canal in the petrous portion

FIG. 580.—The internal carotid and vertebral arteries. Right side.



of the temporal bone. It is comparatively superficial at its commencement, where it is contained in the carotid triangle, and lies behind and to the outer side of the external carotid, overlapped by the Sterno-mastoid, and covered by the deep fascia, Platysma, and integument: it then passes beneath the parotid gland, being crossed by the hypoglossal nerve, the Digastric and Stylo-hyoid muscles, and the occipital and posterior auricular arteries. Higher up, it is separated from the external carotid by the Stylo-glossus and Stylo-pharyngeus muscles,

the tip of the styloid process and the stylo-hyoid ligament, the glosso-pharyngeal nerve and the pharyngeal branch of the pneumogastric. It is in relation, *behind*, with the Rectus capitis anticus major, the superior cervical ganglion of the sympathetic, and the superior laryngeal nerve; *externally*, with the internal jugular vein and pneumogastric nerve, the nerve lying on a plane posterior to the artery; *internally*, with the pharynx, tonsil, the superior laryngeal nerve, and ascending pharyngeal artery. At the base of the skull the glosso-pharyngeal, vagus, spinal accessory, and hypoglossal nerves lie between the artery and the internal jugular vein.

Petrous Portion.—When the internal carotid artery enters the canal in the petrous portion of the temporal bone, it first ascends a short distance, then curves forwards and inwards, and again ascends as it leaves the canal to enter the cavity of the skull between the lingula and petrosal process of the sphenoid. The artery lies at first in front of the cochlea and tympanic cavity; from the latter cavity it is separated by a thin, bony lamella, which is cribriform in the young subject, and often partly absorbed in old age. Farther forwards it is separated from the Gasserian ganglion by a thin plate of bone, which forms the floor of the fossa for the ganglion and the roof of the horizontal portion of the canal. Frequently this bony plate is more or less deficient, and then the ganglion is separated from the artery by fibrous membrane. The artery is separated from the bony wall of the carotid canal by a prolongation of dura mater, and is surrounded by a number of small veins and by filaments of the carotid plexus, derived from the ascending branch of the superior cervical ganglion of the sympathetic.

Cavernous Portion.—The internal carotid artery, in this part of its course, is situated between the layers of the dura mater forming the cavernous sinus, but covered by the lining membrane of the sinus. It at first ascends towards the posterior clinoid process, then passes forwards by the side of the body of the sphenoid bone, and again curves upwards on the inner side of the anterior clinoid process, and perforates the dura mater forming the roof of the sinus. In this part of its course it is surrounded by filaments of the sympathetic nerve, and on its outer side is the sixth nerve.

Cerebral Portion.—Having perforated the dura mater on the inner side of the anterior clinoid process, the internal carotid passes between the second and third cranial nerves to the anterior perforated space at the inner extremity of the fissure of Sylvius, where it gives off its terminal or cerebral branches. This portion of the artery has the optic nerve on its inner side, and the third nerve on its outer.

Peculiarities.—The length of the internal carotid varies according to the length of the neck, and also according to the point of bifurcation of the common carotid. It arises sometimes from the arch of the aorta; in such rare instances, this vessel has been found to be placed nearer the middle line of the neck than the external carotid, as far upwards as the larynx, when the latter vessel crossed the internal carotid. The course of the artery, instead of being straight, may be very tortuous. A few instances are recorded in which this vessel was altogether absent; in one of these the common carotid passed up the neck, and gave off the usual branches of the external carotid; the cranial portion of the internal carotid was replaced by two branches of the internal maxillary, which entered the skull through the foramen rotundum and foramen ovale, and joined to form a single vessel.

Applied Anatomy.—The cervical part of the internal carotid is very rarely wounded. It is, however, sometimes injured by a stab or gunshot wound in the neck, or even occasionally by a stab from within the mouth, as when a person receives a thrust from the end of a parasol, or falls down with a tobacco-pipe in his mouth. Although the internal carotid lies about three-quarters of an inch behind and external to the tonsil, instances have occurred in which the artery has been wounded during the operation of scarifying the tonsil, and fatal hæmorrhage has supervened. The incision for ligature of the cervical portion of the internal carotid should be made along the anterior border of the Sterno-mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The superficial structures being divided, and the Sterno-mastoid defined and drawn outwards, the cellular tissue must be carefully separated and the posterior belly of the Digastric and hypoglossal nerve sought for as guides to the vessel. When the artery is found, the external carotid should be drawn inwards and the Digastric muscle upwards, and the aneurysm needle passed from without inwards.

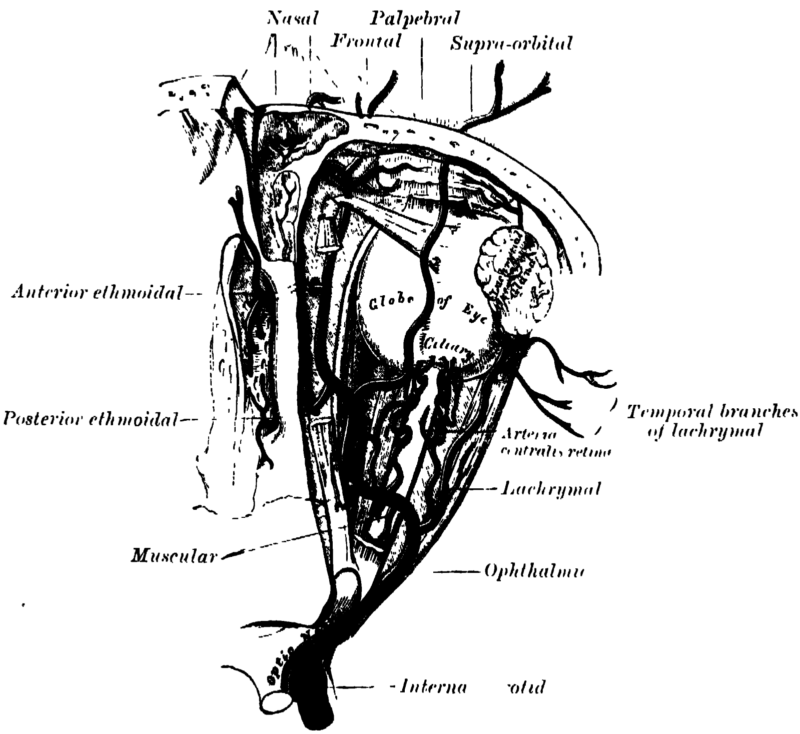
Obstruction of the internal carotid by embolism or thrombosis may give rise to symptoms of cerebral anæmia and softening if the collateral circulation is ill-developed. The patient suffers from giddiness, with failure of the mental powers, and convulsions, coma, or hemiplegia on the opposite side of the body, may be observed.

Branches.—The cervical portion of the internal carotid gives off no branches. Those from the other portions are :

From the Petrous portion	Tympanic (internal or deep). Vidian.
From the Cavernous portion	Arteriæ receptaculi. Pituitary. Gasserian. Anterior meningeal. Ophthalmic.
From the Cerebral portion	Anterior cerebral. Middle cerebral. Posterior communicating. Anterior choroidal.

1. The **tympanic** (ramus caroticotympanicus) is a small branch which enters the cavity of the tympanum, through a minute foramen in the carotid canal, and

FIG. 581.—The ophthalmic artery and its branches.



anastomoses with the tympanic branch of the internal maxillary, and with the stylo-mastoid artery.

2. The **Vidian** is a small, inconstant branch which passes through the Vidian canal and anastomoses with the Vidian branch of the internal maxillary artery.

3. The **arteriæ receptaculi** are numerous small vessels which supply the pituitary body, the Gasserian ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of them anastomose with branches of the middle meningeal.

4. The **pituitary** branches are one or two minute vessels supplying the pituitary body.

5. The **Gasserian** branches are small vessels to the Gasserian ganglion.

6. The **anterior meningeal** is a small branch which passes over the lesser wing of the sphenoid to supply the dura mater of the anterior cranial fossa ; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

7. The **ophthalmic artery** (a. ophthalmica) (fig. 581) arises from the internal carotid, just as that vessel is emerging from the cavernous sinus, on the inner side of the anterior clinoid process, and enters the orbital cavity through the optic foramen, below and on the outer side of the optic nerve. It then passes over the nerve to the inner wall of the orbit, and thence horizontally forwards, beneath the lower border of the Superior oblique muscle, to a point behind the internal angular process of the frontal bone, where it divides into two terminal branches, the *frontal* and *nasal*. As the artery crosses the optic nerve it is accompanied by the nasal nerve, and is separated from the frontal nerve by the Rectus superior and Levator palpebræ superioris muscles.

The branches of the ophthalmic artery may be divided into an *orbital group*, distributed to the orbit and surrounding parts; and an *ocular group*, to the muscles and globe of the eye.

Orbital Group.	*Ocular Group.*
Lachrymal.	Central artery of the retina.
Supra-orbital.	Short ciliary.
Posterior ethmoidal.	Long ciliary.
Anterior ethmoidal.	Anterior ciliary.
Internal palpebral.	Muscular.
Frontal.	
Nasal.	

The *lachrymal* (a. lacrimalis) arises close to the optic foramen, and is one of the largest branches derived from the ophthalmic: not infrequently it is given off before the artery enters the orbit. It accompanies the lachrymal nerve along the upper border of the External rectus muscle, and is distributed to the lachrymal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva: of those supplying the eyelids, two are of considerable size and are named the *external palpebral* (aa. palpebrales laterales); they run inwards in the upper and lower lids respectively and anastomose with the internal palpebral arteries, forming an arterial circle in this situation. The lachrymal artery gives off one or two *malar branches*, one of which passes through a foramen in the malar bone, to reach the temporal fossa, and anastomoses with the deep temporal arteries; another appears on the cheek through the malar foramen, and anastomoses with the transverse facial. A recurrent branch passes backwards through the sphenoidal fissure to the dura mater, and anastomoses with a branch of the middle meningeal artery. The lachrymal artery is sometimes derived from one of the anterior branches of the middle meningeal artery.

The *supra-orbital* (a. supraorbitalis) springs from the ophthalmic as that vessel is crossing over the optic nerve. Ascending so as to rise above all the muscles of the orbit, it runs forwards, with the supra-orbital nerve, between the periosteum and Levator palpebræ; and, passing through the supra-orbital foramen, divides into a superficial and a deep branch, which supply the integument, the muscles, and the pericranium of the forehead, anastomosing with the frontal, the anterior branch of the temporal, and the artery of the opposite side. This artery in the orbit supplies the Superior rectus and the Levator palpebræ, and sends a branch inwards, across the pulley of the Superior oblique muscle, to supply the parts at the inner canthus. At the supra-orbital foramen it frequently transmits a branch to the diploë.

The *ethmoidal branches* are two in number: posterior and anterior. The posterior (a. ethmoidalis posterior), which is the smaller, passes through the posterior ethmoidal canal, supplies the posterior ethmoidal cells, and, entering the cranium, gives off a meningeal branch to the adjacent dura mater, and nasal branches which descend into the nose through apertures in the cribriform plate, anastomosing with branches of the spheno-palatine. The anterior ethmoidal artery (a. ethmoidalis anterior) accompanies the nasal nerve through the anterior ethmoidal canal, supplies the anterior and middle ethmoidal cells and frontal sinuses, and, entering the cranium, gives off a meningeal branch to the adjacent dura mater, and nasal branches. These latter descend into the nose through the slit by the side of the crista galli, and, running along the groove on the under surface of the nasal bone, supply the skin of the nose.

The *palpebral arteries* (aa. palpebrales mediales), two in number, superior and inferior, arise from the ophthalmic, opposite the pulley of the Superior oblique muscle; they leave the orbit to encircle the eyelids near their free margins, forming a superior and an inferior arch, which lie between the Orbicularis muscle and tarsal plates. The superior palpebral anastomoses, at the outer angle of the orbit, with the orbital branch of the temporal artery, and with the upper of the two external palpebral branches from the lachrymal artery; the inferior palpebral anastomoses, at the outer angle of the orbit, with the lower of the two external palpebral branches from the lachrymal and with the transverse facial artery, and, at the inner side of the lid, with a branch from the angular artery.

From this last anastomosis a branch passes to the nasal duct, ramifying in its mucous membrane, as far as the inferior meatus.

The *frontal artery* (a. frontalis), one of the terminal branches of the ophthalmic, leaves the orbit at its inner angle with the supra-trochlear nerve, and, ascending on the forehead, supplies the integument, muscles, and pericranium, anastomosing with the supra-orbital artery, and with the artery of the opposite side.

The *nasal artery* (a. dorsalis nasi), the other terminal branch of the ophthalmic, emerges from the orbit above the tendo oculi, and, after giving a branch to the upper part of the lachrymal sac, divides into two branches, one of which crosses the root of the nose, and anastomoses with the angular artery; the other runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the artery of the opposite side, and with the lateral nasal branch of the facial.

The *central artery of the retina* (a. centralis retinæ) is the first and one of the smallest branches of the ophthalmic artery. It runs for a short distance within the dural sheath of the nerve, but about half an inch behind the eyeball it pierces the optic nerve obliquely, and runs forward in the centre of its substance, and enters the globe of the eye through the porus opticus. Its mode of distribution will be described in the account of the anatomy of the eye.

The *ciliary arteries* are divisible into three groups, the long and short posterior, and the anterior. The *short posterior ciliary arteries* (aa. ciliares posteriores breves), from six to twelve in number, arise from the ophthalmic, or some of its branches; they pass forwards around the optic nerve to the posterior part of the eyeball, pierce the sclera around the entrance of the nerve, and supply the choroid coat and ciliary processes. The *long posterior ciliary arteries* (aa. ciliares posteriores longæ), two in number, pierce the posterior part of the sclera at some little distance from the optic nerve, and run forwards, along each side of the eyeball, between the sclera and choroid, to the ciliary muscle, where they divide into two branches; these form an arterial circle, the *circulus iridis major*, around the circumference of the iris, from which numerous converging branches run inwards, in the substance of the iris, to its free margin, where they form a second arterial circle, the *circulus iridis minor*. The *anterior ciliary arteries* (aa. ciliares anteriores) are derived from the muscular branches; they run to the front of the eyeball in company with the tendons of the Recti, form a vascular zone beneath the conjunctiva, and then pierce the sclera a short distance from the cornea and terminate in the circulus major iridis.

The *muscular branches* (rami musculares), two in number, superior and inferior, frequently spring from a common trunk. The superior, the smaller, often wanting, supplies the Levator palpebræ, Superior rectus, and Superior oblique. The inferior, more constantly present, passes forwards between the optic nerve and Inferior rectus, and is distributed to the External, Internal, and Inferior recti, and the Inferior oblique. This vessel gives off most of the anterior ciliary arteries. Additional muscular branches are given off from the lachrymal and supra-orbital branches, or from the trunk of the ophthalmic.

8. The **anterior cerebral artery** (a. cerebri anterior) (fig. 582) arises from the internal carotid, at the inner extremity of the fissure of Sylvius. It passes forwards and inwards across the anterior perforated space, above the optic nerve, to the commencement of the great longitudinal fissure. Here it comes into close relationship with the artery of the opposite side, and the two vessels are connected by a short trunk, the *anterior communicating artery* (a. communicans anterior). From this point, the two vessels run side by side in the longitudinal fissure, curve round the genu, and turning backwards continue along the upper surface of the corpus callosum to its posterior part, where they terminate by anastomosing with the posterior cerebral arteries.

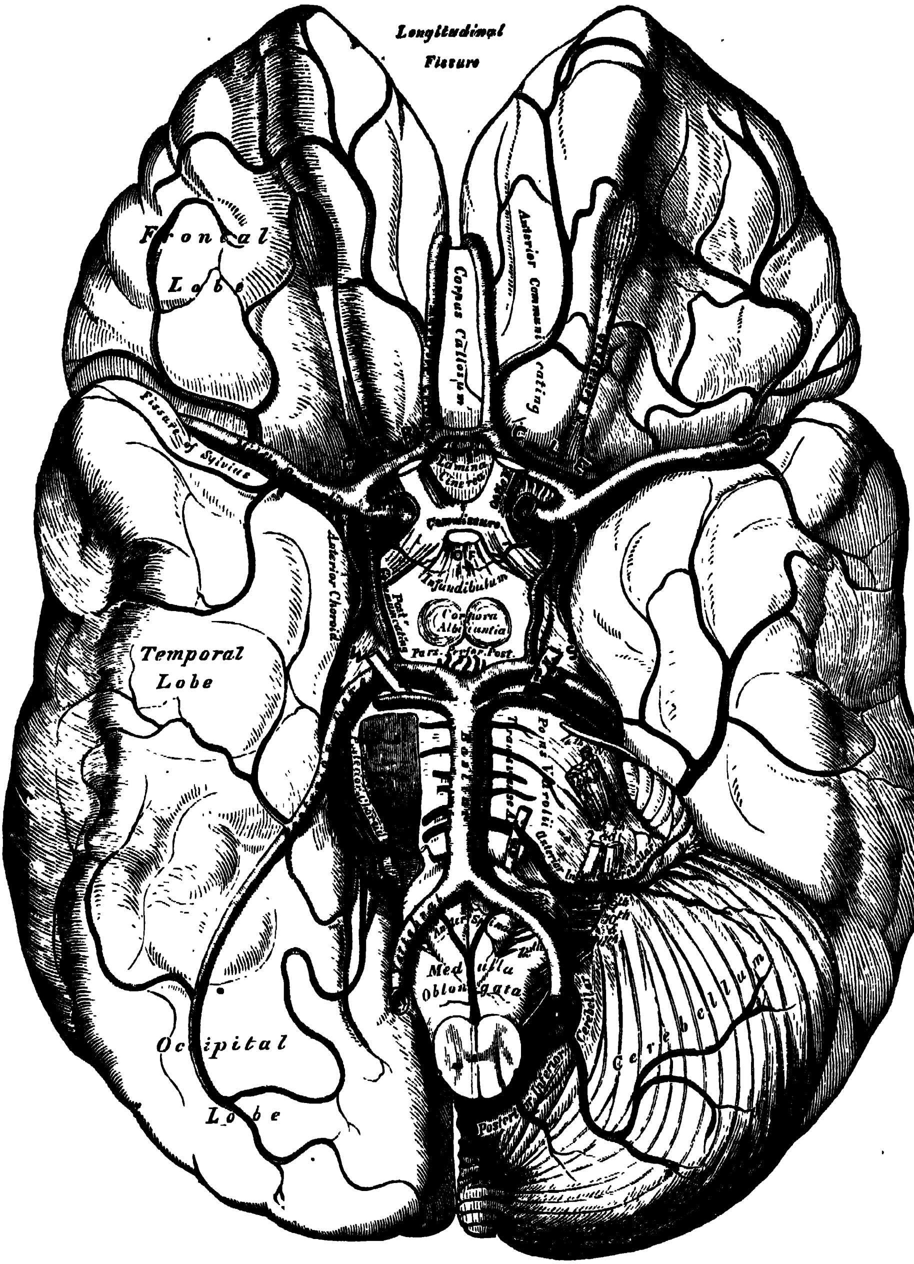
In its course the anterior cerebral artery gives off the following branches:

Antero-median ganglionic.	Anterior internal frontal.
Inferior internal frontal.	Middle internal frontal.
Posterior internal frontal.	

The *antero-median ganglionic* branches are a group of small arteries which arise at the commencement of the anterior cerebral artery; they pierce the anterior perforated space and lamina terminalis, and supply the rostrum of the corpus callosum, the septum pellucidum, and the head of the caudate nucleus. The *inferior internal frontal branches*, two or three in number, are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus, and internal orbital convolution. The *anterior internal frontal branches* supply a part of the marginal convolution, and send branches over the edge of the hemisphere to the superior and middle frontal convolutions and upper part of the ascending frontal convolution. The *middle internal frontal branches* supply the corpus callosum,

the callosal convolution, the inner surface of the superior frontal convolution, and the upper part of the ascending frontal convolution. The *posterior internal frontal branches* supply the lobus quadratus and adjacent outer surface of the hemisphere.

FIG. 582.—The arteries of the base of the brain. The right half of the cerebellum and pons have been removed.

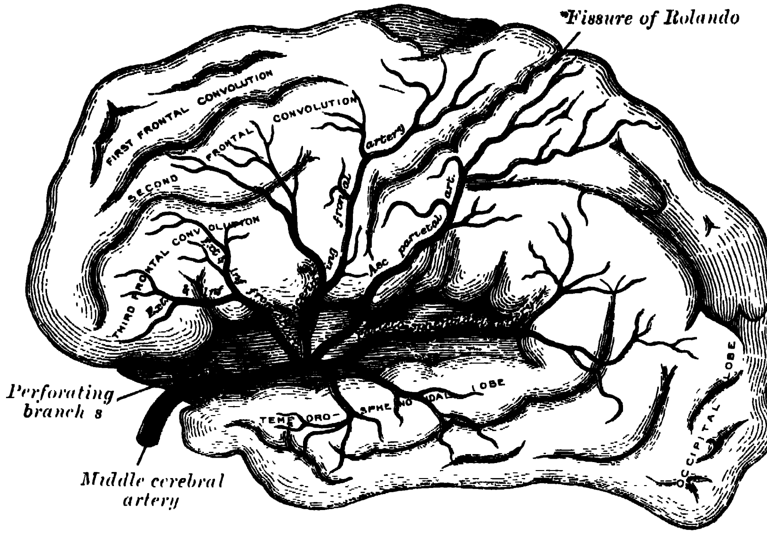


N.B.—It will be noticed that in the illustration the two anterior cerebral arteries have been drawn at a considerable distance from each other; this makes the anterior communicating artery appear longer than it really is.

The *anterior communicating artery* is a short branch, about 4 mm. in length, but of moderate size, connecting together the two anterior cerebral arteries across

the longitudinal fissure. Sometimes this vessel is wanting, the two arteries joining together to form a single trunk, which afterwards divides ; or the vessel may be wholly, or partially, divided into two ; frequently it is longer and smaller than

FIG. 583.—The distribution of the middle cerebral artery. (After Charcot.)



usual. It gives off some of the antero-median ganglionic vessels, but these are principally derived from the anterior cerebral.

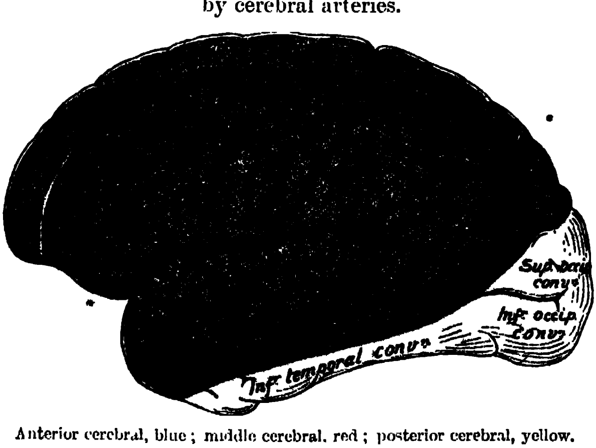
9. The **middle cerebral artery** (a. cerebri media) (fig. 583), the largest branch of the internal carotid, passes obliquely outwards along the fissure of Sylvius, and divides into its terminal branches opposite the island of Reil.

The branches of this vessel are the :

Antero-lateral ganglionic.	Ascending parietal.
Inferior external frontal.	Parieto-temporal.
Ascending frontal.	Temporal.

The *antero-lateral ganglionic branches*, a group of small arteries which arise at the commencement of the middle cerebral artery, are arranged in two sets :

FIG. 584.—Outer surface of cerebral hemisphere, showing areas supplied by cerebral arteries.

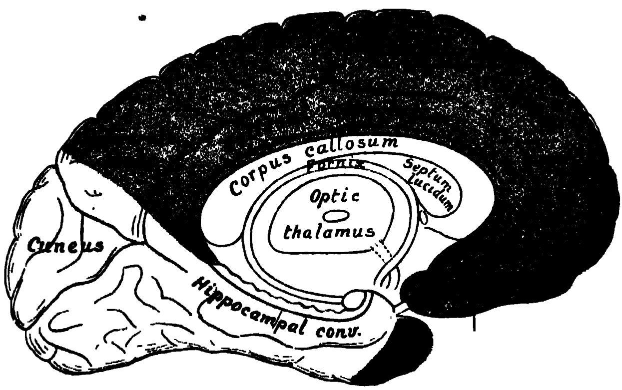


Anterior cerebral, blue ; middle cerebral, red ; posterior cerebral, yellow.

one, the *internal striate,* passes upwards through the inner segments of the lenticular nucleus, and supplies it, the caudate nucleus and the internal capsule ; the other, the *external striate,* ascends through the outer segment of the lenticular nucleus,

and supplies the caudate nucleus and the thalamus. One artery of this group is of larger size than the rest, and is of special importance, as being the artery in the brain most frequently ruptured; it has been termed by Charcot, the '*artery*

FIG. 585.—Mesial surface of cerebral hemisphere, showing areas supplied by cerebral arteries.



Anterior cerebral, blue; middle cerebral, red; posterior cerebral, yellow.

of cerebral hæmorrhage.' It passes up between the lenticular nucleus and the external capsule, and ultimately ends in the caudate nucleus. The *inferior external frontal* supplies the third or inferior frontal convolution (Broca's convolution) and

FIG. 586.—Upper surface of cerebral hemisphere, showing areas supplied by cerebral arteries.

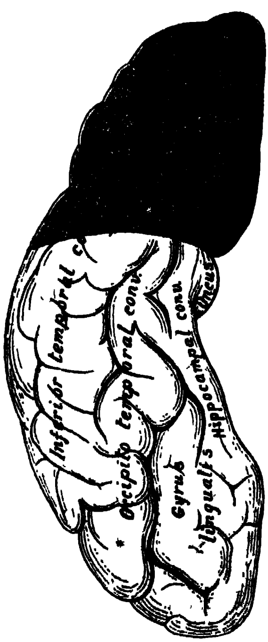
FIG. 587.—Under surface of cerebral hemisphere, showing areas supplied by cerebral arteries.



Anterior cerebral, blue; middle cerebral, red; posterior cerebral, yellow.

the outer part of the orbital surface of the frontal lobe. The *ascending frontal* supplies the ascending frontal convolution. The *ascending parietal* is distributed to the ascending parietal and the lower part of the superior parietal convolutions.

The *parieto-temporal* supplies the supra-marginal and angular gyri, and the posterior parts of the superior and middle temporal convolutions. The *temporal branches*, two or three in number, are distributed to the outer surface of the temporal lobe.

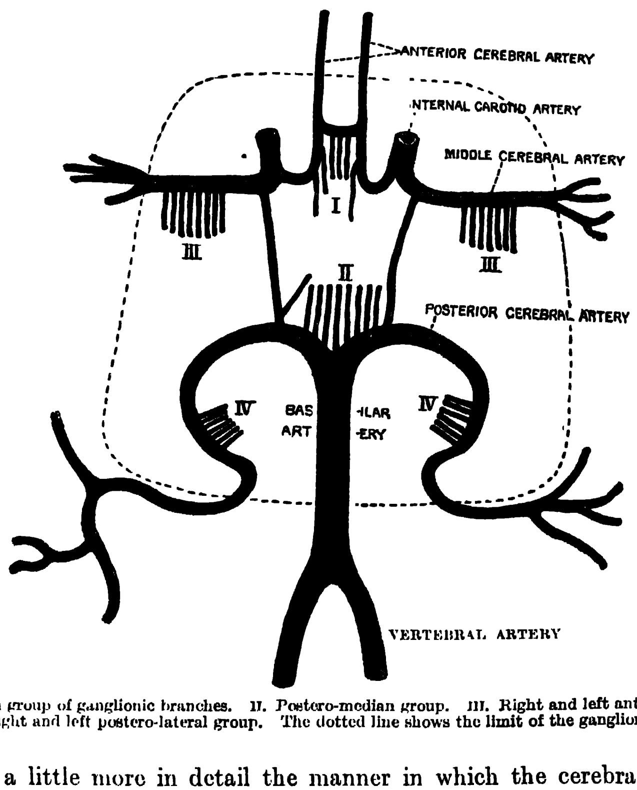
10. The **posterior communicating artery** (a. communicans posterior) runs backwards from the internal carotid, and anastomoses with the posterior cerebral, a branch of the basilar. This artery varies in size, being sometimes small, and occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other. From the posterior half of this vessel are given off a number of small branches, the *postero-median ganglionic branches*, which, with similar vessels from the posterior cerebral, pierce the posterior perforated space and supply the internal surfaces of the thalami and the walls of the third ventricle.

11. The **anterior choroidal** (a. chorioidea) is a small but constant branch, which arises from the internal carotid, near the posterior communicating artery. Passing backwards and outwards between the temporal lobe and the crus cerebri, it enters the descending horn of the lateral ventricle through the choroidal fissure and ends in the choroid plexus. It is distributed to the hippocampus major, fimbria, velum interpositum, and choroid plexus.

THE ARTERIES OF THE BRAIN

Investigations show that the mode of distribution of the vessels of the brain has an important bearing upon a considerable number of the pathological lesions which may occur in this part of the nervous system; it is therefore important

FIG. 588.—Diagram of the arterial circulation at the base of the brain. (After Charcot.)



I. Antero-median group of ganglionic branches. II. Postero-median group. III. Right and left antero-lateral group. IV. Right and left postero-lateral group. The dotted line shows the limit of the ganglionic circle.

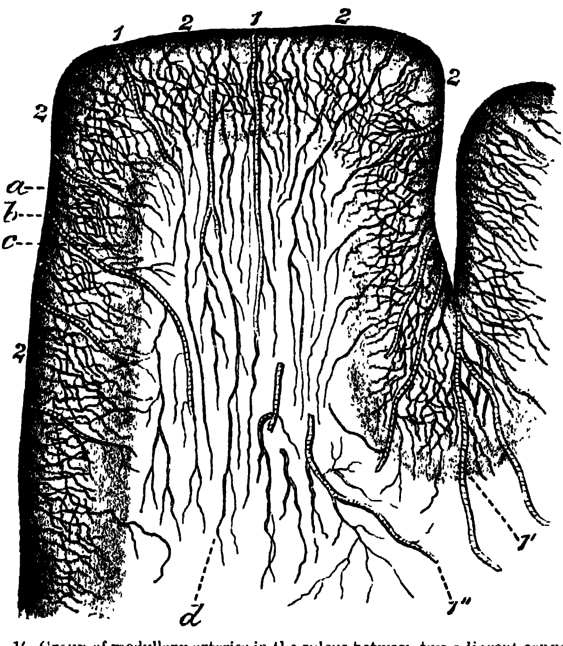
to consider a little more in detail the manner in which the cerebral vessels are distributed.

The cerebral arteries are derived from the internal carotid and vertebral, which at the base of the brain form a remarkable anastomosis known as the *circle*

of Willis (circulus arteriosus). It is formed in front by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind by the two posterior cerebral arteries, branches of the basilar, which are connected on either side with the internal carotid by the posterior communicating (figs. 582, 588). The parts of the brain included within this arterial circle are the lamina terminalis, the optic commissure, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space.

The three trunks which together supply each cerebral hemisphere arise from the circle of Willis. From its anterior part proceed the two anterior cerebrals; from its antero-lateral parts the middle cerebrals, and from its posterior part the posterior cerebrals. Each of these principal arteries gives origin to two different systems of secondary vessels. One of these is named the *central ganglionic system*, and the vessels belonging to it supply the central ganglia of the brain; the other is the *cortical system*, and its vessels ramify in the pia mater and supply the cortex and subjacent brain substance. These two systems do not communicate at any point of their peripheral distribution, but are entirely independent of each other,

FIG. 589.—Distribution of the cortical arteries. (After Charcot.)



1. Medullary arteries. 1′. Group of medullary arteries in the sulcus between two adjacent convolutions. 1″. Arteries situated among the short association fibres. 2, 2. Cortical arteries. *a*. Capillary network with fairly wide meshes, situated beneath the pia mater. *b*. Network with more compact, polygonal meshes, situated in the cortex. *c*. Transitional network with wider meshes. *d*. Capillary network in the white matter.

and there is between the parts supplied by the two systems a borderland of diminished nutritive activity, where, it is said, softening is especially liable to occur in the brains of old people.

The central ganglionic system.—All the vessels of this system are given off from the circle of Willis, or from the vessels close to it; so that if a circle be drawn parallel to and at a distance of about an inch from the circle of Willis, it will include the origins of all the arteries belonging to this system (fig. 588). These vessels form six principal groups: (I) the *antero-median group*, derived from the anterior cerebrals and anterior communicating; (II) the *postero-median group*, from the posterior cerebrals and posterior communicating; (III and IV) the right and left *antero-lateral groups*, from the middle cerebrals; and (V and VI) the right and left *postero-lateral groups*, from the posterior cerebrals, after they have wound round the crura cerebri. The vessels of this system are larger than those of the cortical system, and are what Cohnheim has designated 'terminal' arteries—that is to say, vessels which from their origin to their termination neither supply nor receive any anastomotic branch, so that, through any one of the vessels only a

limited area of the central ganglia can be injected, and the injection cannot be driven beyond the area of the part supplied by the particular vessel which is the subject of the experiment.

The cortical arterial system.—The vessels forming this system are the terminal branches of the anterior, middle, and posterior cerebral arteries. These vessels divide and ramify in the substance of the pia mater, and give off nutrient arteries which penetrate the brain cortex perpendicularly. The nutrient vessels are divisible into two classes, long and short. The *long*, or *medullary arteries*, pass through the grey matter and penetrate the subjacent white matter to the depth of about an inch and a half, without intercommunicating otherwise than by very fine capillaries, and thus constitute so many independent small systems. The *short vessels* are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the grey matter, the outer and inner zones being sparingly supplied with blood (fig. 589). The vessels of the cortical arterial system are not so strictly 'terminal' as those of the central ganglionic system, but they approach this type very closely, so that injection of one area from the vessel of another area, though possible, is frequently very difficult, and is only effected through vessels of small calibre. As a result of this, obstruction of one of the main branches, or its divisions, may have the effect of producing softening in a limited area of the cortex.

ARTERIES OF THE UPPER EXTREMITY

The artery which supplies the upper extremity continues as a single trunk from its commencement down to the elbow; but different portions of it have received different names, according to the regions through which they pass. That part of the vessel which extends from its origin to the outer border of the first rib is termed the *subclavian*; beyond this point to the lower border of the axilla, the artery is termed the *axillary*; and from the lower margin of the axillary space to the bend of the elbow, it is termed *brachial*; here, the trunk ends by dividing into two branches, the *radial* and *ulnar*.

Subclavian Arteries (fig. 590)

On the right side the **subclavian artery** (a. subclavia) arises from the innominate artery opposite the right sterno-clavicular articulation; on the left side it springs from the arch of the aorta. The two vessels, therefore, in the first part of their course, differ in length, direction, and relation with neighbouring structures.

In order to facilitate the description, more especially from a surgical point of view, each subclavian artery is divided into three parts. The first portion, on the right side, passes upwards and outwards from the origin of the vessel to the inner border of the Scalenus anticus. On the left side it ascends nearly vertically, to gain the inner border of that muscle. The second part passes outwards, behind the Scalenus anticus; and the third part extends from the outer margin of that muscle, beneath the clavicle, to the outer border of the first rib, where it becomes the axillary artery. The first portions of the two vessels differ so much in their course and relations with neighbouring parts, that they will be described separately. The second and third parts are practically alike on the two sides.

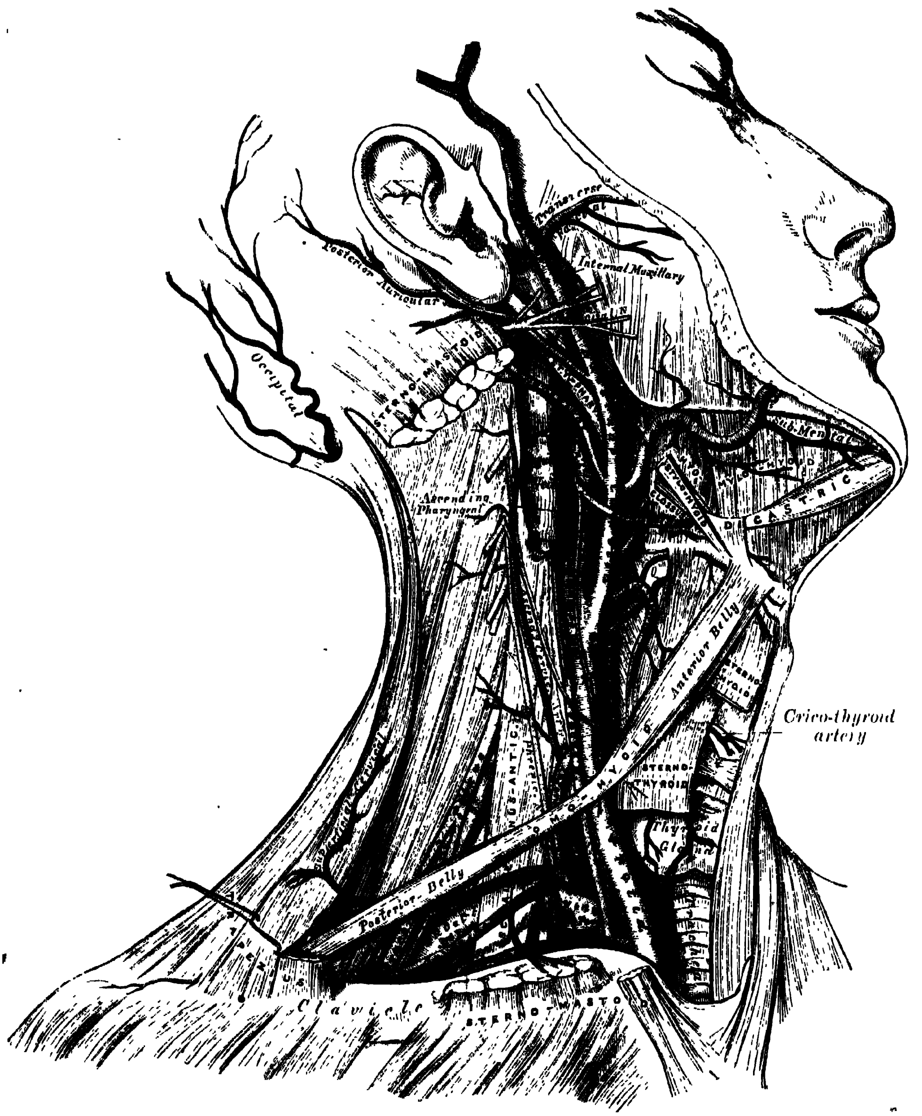
First Part of the Right Subclavian Artery (figs. 572, 590)

The first part of the **right subclavian artery** arises from the arteria innominata, opposite the upper part of the right sterno-clavicular articulation, and passes upwards and outwards to the inner margin of the Scalenus anticus muscle. It ascends a little above the clavicle, the extent to which it does so varying in different cases.

Relations.—It is covered, *in front*, by the integument, superficial fascia, Platysma, deep fascia, the clavicular origin of the Sterno-mastoid, the Sterno-hyoid, and Sterno-thyroid muscles, and another layer of the deep fascia. It is crossed by the internal jugular and vertebral veins, and by the pneumogastric

nerve and the cardiac branches of the pneumogastric and sympathetic. A loop of the sympathetic trunk also crosses the artery, forming a ring (*annulus Vieussenii*) around the vessel. The anterior jugular vein passes outwards in front of the artery, but is separated from it by the Sterno-hyoid and Sterno-thyroid muscles.

FIG. 590.—Superficial dissection of the right side of the neck, showing the carotid and subclavian arteries.



Below and behind the artery is the pleura, which separates it from the apex of the lung; *behind* is the gangliated cord of the sympathetic, the Longus colli muscle and the first thoracic vertebra. The right recurrent laryngeal nerve winds round the lower and back part of the vessel.

FIRST PART OF THE LEFT SUBCLAVIAN ARTERY (fig. 572)

The **first part of the left subclavian artery** arises from the arch of the aorta, behind the left common carotid, and at the level of the fourth thoracic vertebra; it ascends nearly vertically to the root of the neck and then arches outwards to the inner margin of the Scalenus anticus.

Relations.—It is in relation, *in front*, with the pneumogastric, cardiac, and phrenic nerves, which lie parallel with it, the left common carotid artery, left internal jugular and vertebral veins, and the commencement of the left innominate vein, and is covered by the Sterno-thyroid, Sterno-hyoid, and Sterno-mastoid muscles; *behind*, it is in relation with the œsophagus, thoracic duct, inferior cervical ganglion of the sympathetic, and Longus colli; higher up, however, the œsophagus and thoracic duct lie to its right side; the latter ultimately arching over the vessel to join the angle of union between the subclavian and internal jugular veins. To its *inner side* are the œsophagus, trachea, thoracic duct, and left recurrent laryngeal nerve; to its *outer side*, the left pleura and lung.

Second and Third Parts of the Subclavian Artery (fig. 590)

The **second portion** of the subclavian artery lies behind the Scalenus anticus muscle; it is very short, and forms the highest part of the arch described by the vessel.

Relations.—It is covered, *in front*, by the skin, superficial fascia, Platysma, deep cervical fascia, Sterno-mastoid, and Scalenus anticus. On the right side of the body the phrenic nerve is separated from the second part of the artery by the Scalenus anticus, while on the left side it crosses the first part of the artery immediately to the inner edge of the muscle. *Behind*, it is in relation with the pleura and the Scalenus medius. *Above* it, is the brachial plexus of nerves; *below*, the pleura. The subclavian vein lies below and in front of the artery, separated from it by the Scalenus anticus.

The **third portion** of the subclavian artery runs downwards and outwards from the outer margin of the Scalenus anticus to the outer border of the first rib, where it becomes the axillary artery. This is the most superficial portion of the vessel, and is contained in the subclavian triangle (see page 643).

Relations.—It is covered *in front*, by the skin, the superficial fascia, the Platysma, the descending clavicular branches of the cervical plexus, and the deep cervical fascia. The external jugular vein crosses its inner part and receives the suprascapular, transversalis colli and anterior jugular veins, which frequently form a plexus in front of the artery. Behind the veins, the nerve to the Subclavius muscle descends in front of the artery. The outer part of the artery lies behind the clavicle and the Subclavius muscle and is crossed by the suprascapular vessels. The subclavian vein lies in front of and at a slightly lower level than the artery. *Behind*, it lies on the lowest trunk of the brachial plexus, which intervenes between it and the Scalenus medius. *Above* and to its *outer* side, are the upper trunks of the brachial plexus, and the Omo-hyoid muscle. *Below*, it rests on the upper surface of the first rib, or on the cervical rib if one be present (page 210).

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The origin of the right subclavian from the innominate takes place, in some cases, above the sterno-clavicular articulation, and occasionally, but less frequently, below that joint. The artery may arise as a separate trunk from the arch of the aorta, and in such cases it may be either the first, second, third, or even the last branch derived from that vessel; in the majority however it is the first or last, rarely the second or third. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it gains its usual position by passing behind the right carotid; and when the last branch, it arises from the left extremity of the arch, and passes obliquely towards the right side, usually behind the trachea, œsophagus, and right carotid, sometimes between the œsophagus and trachea, to the upper border of the first rib, whence it follows its ordinary course. In very rare instances, this vessel arises from the thoracic aorta, as low down as the fourth thoracic vertebra. Occasionally, it perforates the Scalenus anticus; more rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the Scalenus anticus. The artery may ascend as high as an inch and a half above the clavicle, or any intermediate point between this and the upper border of the bone, the right subclavian usually ascending higher than the left.

The left subclavian is occasionally joined at its origin with the left carotid.

Surface Marking.—The course of the subclavian artery in the neck may be mapped out by describing a curve with its convexity upwards, at the base of the posterior triangle. The inner end of this curve corresponds to the sterno-clavicular joint, the outer end to the centre of the lower border of the clavicle. The curve is to be drawn with such an amount of convexity that its mid-point reaches half an inch above the upper border of the clavicle.

The left subclavian artery is more deeply placed than the right in the first part of its course, and, as a rule, does not reach quite as high a level in the neck. It should be borne in mind that the posterior border of the Sterno-mastoid muscle corresponds pretty closely to the outer border of the Scalenus anticus, so that the third portion of the artery, the part most accessible for operation, lies immediately external to the posterior border of the Sterno-mastoid.

Applied Anatomy.—An *aneurysm* may form on any part of the subclavian artery, except the intrathoracic portion of the left vessel, which is said never to be the seat of aneurysm. The most common site is, however, the third portion, especially on the right side, on account of the greater exposure to injury and the greater amount of use of the right upper extremity. In this situation it may cause pressure on the brachial plexus, producing pain and numbness in the arm and fingers, with loss of power or paralysis of the muscles of these parts. Œdema of the arm may result from pressure on the subclavian vein. The external jugular vein may become distended and varicose. The treatment is unsatisfactory, since proximal ligature cannot be undertaken with much chance of success. If constitutional treatment and direct pressure on the aneurysmal sac fail, the best treatment is excision of the sac, if it be small. In aneurysms of the first portion of this artery there is œdema of the head and face, with lividity, congestion of the brain, and semi-consciousness from pressure on the internal jugular vein; and spasmodic action of the Diaphragm from pressure on the phrenic nerve. The collateral circulation is so good that blocking of the subclavian artery by embolism or thrombosis often fails to give rise to any striking signs or symptoms, beyond occasional pains in the neck and shoulder and some degree of weakness and wasting in the muscles of the arm.

Compression of the subclavian artery is required in cases of operations about the shoulder, in the axilla, or at the upper part of the arm; and the student will observe that there is only one situation in which it can be effectually applied, viz. where the artery passes across the upper surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed, and the surgeon grasping the side of the neck should press with his thumb in the angle formed by the posterior border of the Sterno-mastoid with the upper border of the clavicle, downwards, backwards, and inwards against the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure may be made from before backwards, so as to compress the artery against the Scalenus medius and transverse process of the seventh cervical vertebra. In appropriate cases, a preliminary incision may be made through the cervical fascia, and the finger may be pressed down directly upon the artery.

Ligature of the subclavian artery may be required in cases of wounds, or of aneurysm in the axilla, or in cases of aneurysm on the cardiac side of the point of ligature; and the third part of the artery is that which is most favourable for an operation, on account of its being comparatively superficial, and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurysmal tumour in the axilla, the artery lies at a great depth from the surface, and this materially increases the difficulty of the operation. Under these circumstances, it becomes a matter of importance to consider the height to which this vessel reaches above the bone. In ordinary cases, its arch is about half an inch above the clavicle, occasionally as high as an inch and a half, and sometimes so low as to be on a level with its upper border. If the clavicle be displaced, these variations will necessarily make the operation more or less difficult, according as the vessel is less or more accessible. The vessel is also ligatured as a preliminary measure to the complete interscapulo-thoracic amputation of the upper extremity, in which case the suprascapular and transverse cervical arteries may, if found, be ligatured at the same time, making the 'fore-quarter' amputation an almost bloodless procedure.

The procedure in the operation of tying the third portion of the subclavian artery is as follows: The patient being placed on a table in the supine position, with the head drawn over to the opposite side, and the shoulder depressed as much as possible, the integument should be pulled downwards over the clavicle, and an incision made through it, upon that bone, from the anterior border of the Trapezius to the posterior border of the Sterno-mastoid. The object in drawing the skin downwards is to avoid any risk of wounding the external jugular vein, for as it perforates the deep fascia above the clavicle, it cannot be drawn downwards with the skin. The soft parts should now be allowed to glide up, and the cervical fascia divided upon a director, and if the interval between the Trapezius and Sterno-mastoid muscles be insufficient for the performance of the operation, a portion of one or both may be divided. The external jugular vein will now be seen towards the inner side of the wound; this and the suprascapular and transverse cervical veins which terminate in it should be held aside. If the external jugular vein be at all in the way and exposed to injury, it should be tied in two places and divided. The suprascapular artery should be avoided, and the Omo-hyoid muscle held aside if necessary. In the space beneath this muscle, careful search must be made for the vessel a deep layer of fascia and some connective tissue having been divided carefully, the outer margin of the Scalenus anticus muscle must be felt for, and the finger being guided by it to the

first rib, the pulsation of the subclavian artery will be felt as it passes over the rib. The sheath of the vessels having been opened, the aneurysm needle may then be passed around the artery from above downwards and inwards so as to avoid including any of the branches of the brachial plexus. If the clavicle be so raised by the tumour that the application of the ligature cannot be effected in this situation, the artery may be tied above the first rib, or even behind the Scalenus anticus muscle; the difficulties of the operation in such a case will be materially increased, on account of the greater depth of the artery, and the alteration in position of the surrounding parts.

The second part of the subclavian artery, from being that portion which rises highest in the neck, has been considered favourable for the application of the ligature when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the Scalenus anticus muscle, upon which lies the phrenic nerve, and at the inner side of which is situated the internal jugular vein; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact, below, with the pleura, which must also be avoided; and, lastly, the proximity of so many of its large branches arising internal to this point must be a still further objection to the operation. In cases, however, where the sac of an axillary aneurysm encroaches on the neck, it may be necessary to divide the outer half or two-thirds of the Scalenus anticus muscle, so as to place the ligature on the vessel at a greater distance from the sac. The operation is performed exactly in the same way as ligature of the third portion, until the Scalenus anticus is exposed, when it is to be divided on a director (never to a greater extent than its outer two-thirds), and it immediately retracts. The operation is therefore merely an extension of the operation for ligature of the third portion of the vessel.

In those cases of aneurysm of the axillary or subclavian artery which encroach upon the outer portion of the Scalenus anticus to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first portion of the subclavian artery. On the left side, this operation is almost impracticable; the great depth of the artery from the surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, present a series of difficulties which it is next to impossible to overcome.* On the right side, the operation is practicable, and has been performed on several occasions. The main objection to the operation in this situation is the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The operation may be performed in the following manner: The patient being placed on the table in the supine position, with the neck extended, an incision should be made along the upper border of the inner part of the clavicle, and a second along the inner border of the Sterno-mastoid, meeting the former at an angle. The attachments of both heads of the Sterno-mastoid must be divided on a director, and turned outwards; a few small arteries and veins, and occasionally the anterior jugular, must be avoided, or, if necessary, ligatured in two places and divided, and the Sterno-hyoid and Sterno-thyroid muscles divided in the same manner as the preceding muscle. After tearing through the deep fascia with the finger-nail, the internal jugular vein will be seen crossing the subclavian artery; this should be pressed aside, and the artery secured by passing the needle from below upwards, by which the pleura is more effectually avoided. The exact position of the vagus, the recurrent laryngeal, the phrenic and sympathetic nerves should be borne in mind, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a coagulum between the ligature and the origin of the vessel. It should be remembered that the right subclavian artery is occasionally deeply placed in the first part of its course, when it arises from the left side of the aortic arch, and passes in such cases behind the œsophagus, or between it and the trachea.

Collateral Circulation.—After ligature of the third part of the subclavian artery, the collateral circulation is established mainly by three sets of vessels, thus described in a dissection:

'1. A posterior set, consisting of the suprascapular and posterior scapular branches of the subclavian, anastomosing with the subscapular from the axillary.

'2. An internal set, produced by the connection of the internal mammary on the one hand, with the superior and long thoracic arteries, and the branches from the subscapular on the other.

'3. A middle or axillary set, consisting of a number of small vessels derived from branches of the subclavian, above, and, passing through the axilla, terminated either in the main trunk, or some of the branches of the axillary below. This last set presented most conspicuously the peculiar character of newly formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

'The chief agent in the restoration of the axillary artery below the tumour was the subscapular artery, which communicated most freely with the internal mammary, supra-

* The operation has, however, been performed by J. K. Rodgers, by Halsted, and by Schumpert.

scapular, and posterior scapular branches of the subclavian, from all of which it received so great an influx of blood as to dilate it to three times its natural size.' *

When a ligature is applied to the first part of the subclavian artery, the collateral circulation is carried on by: 1, the anastomosis between the superior and inferior thyroid; 2, the anastomosis of the two vertebrals; 3, the anastomosis of the internal mammary with the deep epigastric and the aortic intercostals; 4, the superior intercostal anastomosing with the aortic intercostals; 5, the profunda cervicis anastomosing with the princeps cervicis; 6, the scapular branches of the thyroid axis anastomosing with the branches of the axillary; and 7, the thoracic branches of the axillary anastomosing with the aortic intercostals.

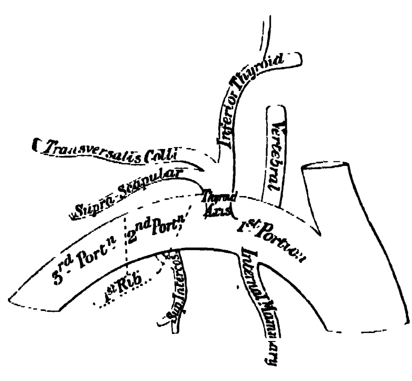
Branches.—The branches given off from the subclavian artery are:

Vertebral.	Internal mammary.
Thyroid axis.	Superior intercostal.

On the left side all four branches generally arise from the first portion of the vessel; but on the right side (fig. 591) the superior intercostal usually springs from the second portion of the vessel. On both sides of the body, the first three branches arise close together at the inner margin of the Scalenus anticus; in the majority of cases, a free interval of from half an inch to an inch exists between the commencement of the artery and the origin of the nearest branch.

1. The **vertebral artery** (a. vertebralis) is the first branch of the subclavian, and arises from the upper and back part of the first portion of the vessel. It is surrounded by a plexus of nerve fibres derived from the inferior cervical ganglion of the sympathetic trunk, and ascends through the foramina in the transverse processes of the upper six cervical vertebræ; † it then winds behind the superior articular process of the atlas and, entering the skull through the foramen magnum, unites, at the lower border of the pons Varolii, with the vessel of the opposite side to form the basilar artery.

Fig. 591.—Plan of the branches of the right subclavian artery.



Relations.—The vertebral artery may be divided into four parts. The *first part* runs upwards and backwards between the Longus colli and the Scalenus anticus. In front of it are the internal jugular and vertebral veins, and it is crossed by the inferior thyroid artery; the left vertebral is crossed by the thoracic duct also. Behind it are the transverse process of the seventh cervical vertebra and the sympathetic cord. The *second part* runs upwards through the foramina in the transverse processes of the upper six cervical vertebræ, and is surrounded by a plexus of veins which unite to form the vertebral vein at the lower part of the neck. It is situated in front of the trunks of the cervical nerves, and pursues an almost vertical course as far as the transverse process of the atlas, above which it runs upwards and outwards to the foramen in the transverse process of the atlas. The *third part* issues from the latter foramen on the inner side of the Rectus lateralis muscle, and inclines backwards and inwards behind the superior articular process of the atlas; it lies in the groove on the upper surface of the posterior arch of the atlas, and enters the spinal canal by passing beneath the posterior occipito-atlantal ligament. This part of the artery is covered by the Complexus muscle and contained in the *suboccipital triangle*—a triangular space bounded by the Rectus capitis posticus major and the Superior and Inferior oblique muscles. The suboccipital nerve lies between the artery and the posterior arch

* *Guy's Hospital Reports*, vol. i. 1836. Case of axillary aneurysm, in which Aston Key had tied the subclavian artery on the outer edge of the Scalenus anticus, twelve years previously.

† The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra. Smyth, who tied this artery in the living subject, found it, in one of his dissections, passing into the foramen in the seventh vertebra.

of the atlas. The *fourth part* pierces the dura mater and inclines inwards to the front of the medulla oblongata; it is placed between the hypoglossal nerve and the anterior root of the suboccipital nerve and beneath the first digitation of the ligamentum denticulatum. At the lower border of the pons Varolii it unites with the vessel of the opposite side to form the basilar artery.

The branches of the vertebral artery may be divided into two sets—those given off in the neck, and those within the cranium.

Cervical Branches.	*Cranial Branches.*
Spinal.	Posterior meningeal.
Muscular.	Anterior spinal.
	Posterior spinal.
	Posterior inferior cerebellar.
	Bulbar.

Spinal branches (rami spinales) enter the spinal canal through the intervertebral foramina, and each divides into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord and its membranes, anastomosing with the other arteries of the spinal cord; the other divides into an ascending and a descending branch, which unite with similar branches from the arteries above and below, so that two lateral anastomotic chains are formed on the posterior surfaces of the bodies of the vertebræ, near the attachment of the pedicles. From these anastomotic chains branches are supplied to the periosteum and the bodies of the vertebræ, and others form communications with similar branches from the opposite side; from these communications small twigs arise which join similar branches above and below, to form a central anastomotic chain on the posterior surface of the bodies of the vertebræ.

Muscular branches are given off to the deep muscles of the neck, where the vertebral artery curves round the articular process of the atlas. They anastomose with the occipital, and with the ascending and deep cervical arteries.

The **posterior meningeal** (ramus meningeus) springs from the vertebral opposite the foramen magnum, ramifies between the bone and dura mater in the cerebellar fossa, and supplies the falx cerebelli. It is frequently represented by one or two small branches.

The **anterior spinal** (a. spinalis anterior) is a small branch, which arises near the termination of the vertebral, and, descending in front of the medulla oblongata, unites with its fellow of the opposite side at the level of the foramen magnum. One of these vessels is usually larger than the other, but occasionally they are about equal in size. The single trunk, thus formed, descends on the front of the spinal cord, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina; these branches are derived from the vertebral and ascending cervical of the inferior thyroid in the neck; from the intercostals in the thorax; and from the lumbar, ilio-lumbar, and lateral sacral arteries in the abdomen and pelvis. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extends as far as the lower part of the spinal cord, and is continued as a slender twig on the filum terminale. This vessel is placed in the pia mater along the anterior median fissure; it supplies that membrane, and the substance of the cord, and sends off branches at its lower part to be distributed to the cauda equina.

The **posterior spinal** (a. spinalis posterior) arises from the vertebral, at the side of the medulla oblongata; passing backwards to the posterior aspect of the spinal cord, it descends on the spinal cord, lying in front of the posterior roots of the spinal nerves, and is reinforced by a succession of small branches, which enter the spinal canal through the intervertebral foramina; by means of these it is continued to the lower part of the cord, and to the cauda equina. Branches from the posterior spinal arteries form a free anastomosis round the posterior roots of the spinal nerves, and communicate, by means of very tortuous transverse branches, with the vessels of the opposite side. Close to its origin each gives off an ascending branch, which terminates at the side of the fourth ventricle.

Applied Anatomy.—Bleeding into the spinal membranes or into the substance of the spinal cord itself is not common, but may occur from injuries received at birth when labour is unduly prolonged or instruments are used. It is also met with in chronic insanity, and in tetanus or strychnine poisoning.

The **posterior inferior cerebellar** (a. cerebelli inferior posterior) (fig. 582), the largest branch of the vertebral, winds backwards round the upper part of the medulla oblongata, passing between the origins of the pneumogastric and spinal accessory nerves, over the restiform body to the under surface of the cerebellum, where it divides into two branches. The internal branch is continued backwards to the notch between the two hemispheres of the cerebellum; while the external supplies the under surface of the cerebellum, as far as its outer border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from this artery supply the choroid plexus of the fourth ventricle.

The **bulbar arteries** are several minute vessels which spring from the vertebral and its branches and are distributed to the medulla oblongata.

The **basilar artery** (a. basilaris) (fig. 582), so named from its position at the base of the skull, is a single trunk formed by the junction of the two vertebral arteries; it extends from the posterior to the anterior border of the pons Varolii, lying in its median groove, under cover of the arachnoid. It ends by dividing into the two *posterior cerebral arteries.*

Its branches, on either side, are the following:

Transverse.	Anterior inferior cerebellar.
Auditory.	Superior cerebellar.
Posterior cerebral.	

The **transverse branches** (rami ad pontem) are a number of small vessels which come off at right angles on either side of the basilar artery and supply the pons Varolii and adjacent parts of the brain.

The **auditory** (a. auditiva interna), a long slender branch, arises from near the middle of the artery; it accompanies the corresponding auditory nerve into the internal auditory meatus, and is distributed to the internal ear.

The **anterior inferior cerebellar** (a. cerebelli inferior anterior) passes backwards, to be distributed to the anterior part of the under surface of the cerebellum, anastomosing with the posterior inferior cerebellar branch of the vertebral.

The **superior cerebellar** (a. cerebelli superior) arises near the termination of the basilar. It passes outwards, immediately behind the third nerve, which separates it from the posterior cerebral artery, winds round the crus cerebri, close to the fourth nerve, and, arriving at the upper surface of the cerebellum, divides into branches which ramify in the pia mater and anastomose with the branches of the inferior cerebellar artery. Several branches are given to the pineal gland, the valve of Vieussens, and the velum interpositum.

The **posterior cerebral** (a. cerebri posterior) is larger than the preceding, from which it is separated near its origin by the third nerve. Passing outwards, parallel to the superior cerebellar artery, and receiving the posterior communicating from the internal carotid, it winds round the crus cerebri, and reaches the under surface of the occipital lobe of the cerebrum, where it breaks up into branches for the supply of the temporal and occipital lobes.

The branches of the posterior cerebral artery are divided into two sets, ganglionic and cortical:

Ganglionic	Postero-median. Posterior choroidal. Postero-lateral.	Cortical	Anterior temporal. Posterior temporal. Calcarine. Parieto-occipital.

Ganglionic.—The *postero-median ganglionic branches* (fig. 582) are a group of small arteries which arise at the commencement of the posterior cerebral artery: these, with similar branches from the posterior communicating, pierce the posterior perforated space, and supply the internal surfaces of the thalami and the walls of the third ventricle. The *posterior choroidal branches* enter the interior of the brain beneath the splenium of the corpus callosum, and supply the velum interpositum and the choroid plexus. The *postero-lateral ganglionic branches* are small arteries which arise from the posterior cerebral artery after it has turned round the crus cerebri; they supply a considerable portion of the thalamus.

Cortical.—The cortical branches are: the *anterior temporal,* distributed to the anterior parts of the uncinate and occipito-temporal gyri; the *posterior temporal,*

to the occipito-temporal and the third temporal convolutions; the *calcarine* to the cuneate and lingual lobules and the back part of the outer surface of the occipital lobe; and the *parieto-occipital* to the cuneus and the quadrate lobe.

2. The **thyroid axis** (truncus thyreocervicalis) (fig. 590) is a short thick trunk, which arises from the front of the first portion of the subclavian artery, close to the inner border of the Scalenus anticus, and divides almost immediately into three branches, the *inferior thyroid*, *suprascapular*, and *transverse cervical*.

The **inferior thyroid artery** (a. thyreoidea inferior) passes upwards, in front of the vertebral artery and Longus colli muscle; then turns inwards behind the carotid sheath and its contents, and also behind the sympathetic cord, the middle cervical ganglion resting upon the vessel. Reaching the lower border of the lateral lobe of the thyroid gland it divides into two branches, which supply the postero-inferior parts of the gland, and anastomose with the superior thyroid, and with the corresponding artery of the opposite side. The recurrent laryngeal nerve passes upwards generally behind, but occasionally in front of, the artery.

The branches of the inferior thyroid are:

Inferior laryngeal.	Œsophageal.
Tracheal.	Ascending cervical.
Muscular.	

The **inferior laryngeal branch** (a. laryngea inferior) ascends upon the trachea to the back part of the larynx under cover of the Inferior constrictor, in company with the recurrent laryngeal nerve, and supplies the muscles and mucous membrane of this part, anastomosing with the branch from the opposite side, and with the laryngeal branch from the superior thyroid artery.

The **tracheal branches** (rami tracheales) are distributed upon the trachea, anastomosing below with the bronchial arteries.

The **œsophageal branches** (rami œsophagei) supply the œsophagus, and anastomose with the œsophageal branches of the aorta.

The **ascending cervical** (a. cervicalis ascendens) is a small branch which arises from the inferior thyroid, just where that vessel is passing behind the carotid sheath, and runs up on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the Scalenus anticus and Rectus capitis anticus major. It gives to the muscles of the neck branches which anastomose with branches of the vertebral, and it sends one or two twigs (rami spinales) into the spinal canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebræ, in the same manner as the lateral spinal branches from the vertebral. It anastomoses with the ascending pharyngeal and occipital arteries.

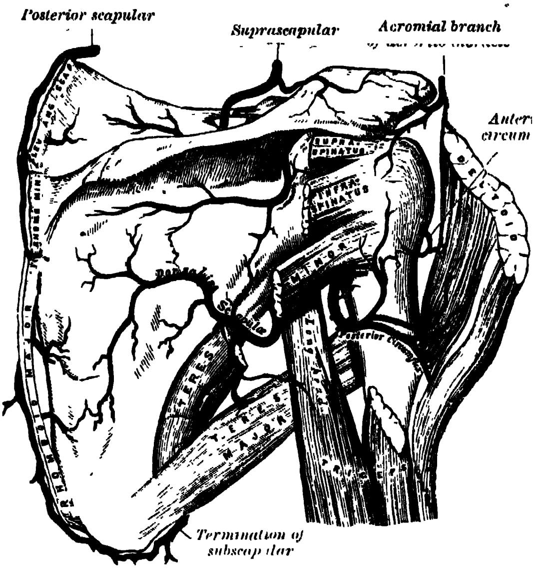
The **muscular branches** supply the depressors of the hyoid bone, the Longus colli, the Scalenus anticus, and the Inferior constrictor of the pharynx.

The **suprascapular artery** (a. transversa scapulæ) (fig. 592) passes at first downwards and outwards across the Scalenus anticus and phrenic nerve, being covered by the Sterno-mastoid; it then crosses the subclavian artery and the cords of the brachial plexus, and runs outwards, behind and parallel with the clavicle and Subclavius, and beneath the posterior belly of the Omo-hyoid, to the superior border of the scapula; it passes over the transverse ligament of the scapula, which separates it from the suprascapular nerve, and enters the supraspinous fossa. In this situation it lies close to the bone, and ramifies between it and the Supraspinatus, to which it supplies branches. It then descends behind the neck of the scapula, through the great scapular notch, to reach the infraspinous fossa, where it anastomoses with the dorsalis scapulæ and posterior scapular arteries. Besides distributing branches to the Sterno-mastoid, Subclavius, and neighbouring muscles, it gives off a *suprasternal branch*, which crosses over the sternal end of the clavicle to the skin of the upper part of the chest; and a *supra-acromial branch*, which pierces the Trapezius and supplies the skin over the acromion, anastomosing with the acromio-thoracic artery. As the artery passes over the transverse ligament of the scapula, a branch of it descends into the subscapular fossa, ramifies beneath the Subscapularis, and anastomoses with the posterior and subscapular arteries. It also sends articular branches to the acromio-clavicular and shoulder joints, and a nutrient artery to the clavicle.

The **transverse cervical artery** (a. transversa colli), larger than the suprascapular, passes transversely outwards, across the upper part of the subclavian

triangle, to the anterior margin of the Trapezius muscle, beneath which it divides into two branches, the *superficial cervical* and the *posterior scapular.* It crosses in front of the phrenic nerve and Scaleni muscles, and in front of or between the divisions of the brachial plexus, and is covered by the Platysma, Sterno-mastoid, Omo-hyoid, and Trapezius muscles.

Fig. 592.—The scapular and circumflex arteries.



The **superficial cervical** (ramus ascendens) ascends beneath the anterior margin of the Trapezius, distributing branches to it, and to the neighbouring muscles and glands in the neck, and anastomoses with the superficial branch of the arteria princeps cervicis.

The **posterior scapular** (ramus descendens) (fig. 592) passes beneath the Levator anguli scapulæ to the superior angle of the scapula, and then descends along the posterior border of that bone as far as the inferior angle. It is covered by the Rhomboid muscles, supplying them and the Latissimus dorsi and Trapezius, and anastomosing with the suprascapular and subscapular arteries, and with the posterior branches of some of the intercostal arteries.

Peculiarities.—The superficial cervical frequently arises as a separate branch from the thyroid axis; and the posterior scapular, from the third, more rarely from the second, part of the subclavian.

3. The **internal mammary** (a. mammaria interna) (fig. 593) arises from the under surface of the first portion of the subclavian artery, opposite the thyroid axis. It descends behind the cartilages of the upper six ribs at a distance of about half an inch from the margin of the sternum, and at the level of the sixth intercostal space divides into the *musculo-phrenic* and *superior epigastric* arteries.

Relations.—It is directed at first downwards, forwards, and inwards behind the inner end of the clavicle, the subclavian and internal jugular veins, and the first costal cartilage. As it enters the thorax it is crossed from without inwards by the phrenic nerve, and passes forwards close to the outer side of the innominate vein. Below the first costal cartilage it descends almost vertically to its point of bifurcation. It is covered in front by the Pectoralis major and the cartilages of the upper six ribs with their intervening intercostal muscles, and is crossed by the terminal portions of the upper six intercostal nerves. *Behind*, it rests on the pleura, as far as the third costal cartilage; below this level, upon the Triangularis sterni muscle. It is accompanied by a pair of veins: these unite above to form a single vessel, which passes to the inner side of the artery and ends in the corresponding innominate vein.

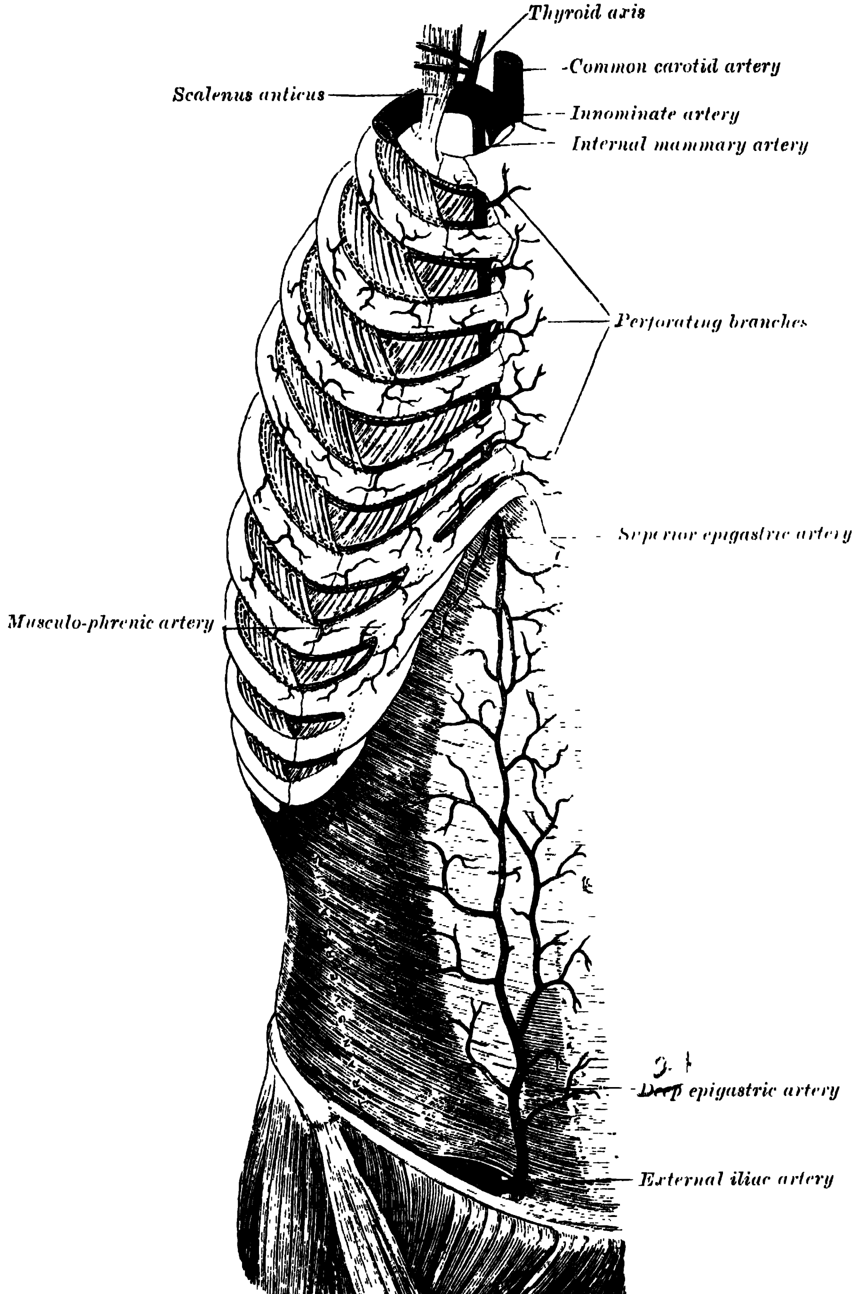
The branches of the internal mammary are:

Pericardiophrenic ~~Comes nervi phrenici.~~	Anterior intercostal.
Mediastinal.	Perforating.
Pericardial.	Musculo-phrenic.
Sternal.	Superior epigastric.

The comes nervi phrenici (a. pericardiacophrenica) is a long slender branch, which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragm, to which it is distributed; it anastomoses with the other phrenic arteries from the internal mammary and abdominal aorta.

The **mediastinal branches** (aa. mediastinales anteriores) are small vessels, distributed to the areolar tissue and lymphatic glands in the anterior mediastinum, and to the remains of the thymus gland.

FIG. 593.—The internal mammary artery and its branches.



The **pericardial branches** supply the upper part of the anterior surface of the pericardium, the lower part receiving branches from the musculo-phrenic artery.

The **sternal branches** (rami sternales) are distributed to the Triangularis sterni, and to the posterior surface of the sternum.

The mediastinal, pericardial, and sternal branches, together with some twigs from the comes nervi phrenici, anastomose with branches from the intercostal and bronchial arteries, and form a minute plexus beneath the pleura, which has been named by Turner the *subpleural mediastinal plexus*.

The **anterior intercostal branches** (rami intercostales) supply the upper five or six intercostal spaces. Two in number in each space, these small vessels pass outwards, one lying near the lower margin of the rib above, and the other near the upper margin of the rib below, and anastomose with the intercostal arteries from the aorta. They are at first situated between the pleura and the Internal intercostal muscles, and then between the Internal and External intercostal muscles. They supply the Intercostal muscles and, by branches which perforate the External intercostal muscle, the Pectoral muscles and the mammary gland.

The **perforating branches** (rami perforantes) correspond to the five or six upper intercostal spaces. They pass forwards through the intercostal spaces, and, curving outwards, supply the Pectoralis major and the integument. Those which correspond to the second, third, and fourth spaces are distributed to the mammary gland, and during lactation are of large size.

The **musculo-phrenic** (a. musculophrenica) is directed obliquely downwards and outwards, behind the cartilages of the false ribs, perforates the Diaphragm at the eighth or ninth costal cartilage, and terminates, considerably reduced in size, opposite the last intercostal space. It gives off anterior intercostal arteries to the seventh, eighth, and ninth intercostal spaces; these diminish in size as the spaces decrease in length, and are distributed in a manner precisely similar to the anterior intercostals from the internal mammary. The musculo-phrenic also gives branches to the lower part of the pericardium, and others which run backwards to the Diaphragm, and downwards to the abdominal muscles.

The **superior epigastric** (a. epigastrica superior) continues in the original direction of the internal mammary; it descends through the cellular interval between the costal and sternal attachments of the Diaphragm, and enters the sheath of the Rectus abdominis muscle, at first lying behind the muscle, and then perforating and supplying it, and anastomosing with the deep epigastric artery from the external iliac. Some vessels perforate the anterior wall of the sheath of the Rectus, and supply the muscles of the abdomen and the integument, and a small branch, which passes inwards upon the side of the ensiform appendix, anastomoses in front of that cartilage with the artery of the opposite side. It also gives some twigs to the Diaphragm, while from the artery of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

Applied Anatomy.—The course of the internal mammary artery may be defined by a line drawn half an inch outside and parallel with the sternal margin. The vessel is liable to be wounded in stabs of the chest-wall and in the operation of paracentesis pericardii (page 600). It is most easily reached by a transverse incision in the second intercostal space.

4. The **superior intercostal** (truncus costocervicalis) (fig. 580) arises from the upper and back part of the subclavian artery, behind the Scalenus anticus on the right side, and internal to that muscle on the left side. Passing backwards, it gives off the *profunda cervicis*, and then descends behind the pleura in front of the necks of the first and second ribs, and anastomoses with the first aortic intercostal. As it crosses the neck of the first rib it lies to the inner side of the anterior division of the first thoracic nerve, and to the outer side of the first thoracic ganglion of the sympathetic.

In the first intercostal space, it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the highest aortic intercostal. This branch is not constant, but is more commonly found on the right side; when absent, its place is supplied by an intercostal branch from the aorta. Each intercostal gives off a branch to the posterior spinal muscles, and a small one which passes through the corresponding intervertebral foramen to the spinal cord and its membranes.

The **profunda cervicis** (a. cervicalis profunda) arises, in most cases, from the superior intercostal, and is analogous to the posterior branch of an aortic intercostal artery: occasionally it is a separate branch from the subclavian artery. Passing backwards, above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the neck of the first rib, it runs up

the back of the neck, between the Complexus and Semispinalis colli, as high as the axis, supplying these and adjacent muscles, and anastomosing with the deep branch of the arteria princeps cervicis of the occipital, and with branches which pass outwards from the vertebral. It gives off a special branch which enters the spinal canal through the intervertebral foramen between the seventh cervical and first thoracic vertebræ.

The Axilla

The **axilla** is a pyramidal space, situated between the upper lateral part of the chest and the inner side of the arm.

Boundaries.—Its *apex*, which is directed upwards towards the root of the neck, corresponds to the interval between the first rib, the upper border of the scapula, and the clavicle, and through it the axillary vessels and nerves pass. The *base*, directed downwards, is formed by the integument and a thick layer of fascia, the *axillary fascia*, extending between the lower border of the Pectoralis major in front, and the lower border of the Latissimus dorsi behind; it is broad internally, at the chest, but narrow and pointed externally, at the arm. The *anterior wall* is formed by the Pectoralis major and minor muscles, the former covering the whole of the anterior wall, the latter only its central part. The space between the inner border of the Pectoralis minor and the clavicle is occupied by the costo-coracoid membrane. The *posterior wall*, which extends somewhat lower than the anterior, is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the *inner side* are the first four ribs with their corresponding Intercostal muscles, and part of the Serratus magnus. On the *outer side*, where the anterior and posterior walls converge, the space is narrow, and bounded by the humerus, the Coraco-brachialis, and the Biceps.

Contents.—It contains the axillary vessels, and the brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymphatic glands, together with a quantity of fat and loose areolar tissue. The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axilla, from its apex to its base, and are placed much nearer to the anterior than to the posterior wall, the vein lying to the inner or thoracic side of the artery and partially concealing it. At the fore part of the axilla, in contact with the Pectoral muscles, are the thoracic branches of the axillary artery, and along the lower margin of the Pectoralis minor the long thoracic artery extends to the side of the chest. At the back part, in contact with the lower margin of the Subscapularis, are the subscapular vessels and nerves; winding around the outer border of this muscle are the dorsalis scapulæ vessels; and, close to the neck of the humerus, the posterior circumflex vessels and the circumflex nerve curve backwards to the shoulder.

Along the inner or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. There are some important nerves, however, in this situation, viz. the posterior thoracic or external respiratory nerve, descending on the surface of the Serratus magnus, to which it is distributed; and the intercosto-humeral nerve or nerves, perforating the upper and anterior part of this wall, and passing across the axilla to the inner side of the arm.

The position and arrangement of the lymphatic glands are described on a subsequent page.

Applied Anatomy.—The axilla is a space of considerable surgical importance. It transmits the large vessels and nerves to the upper extremity, and these may be the seat of injury or disease: it contains numerous lymphatic glands which may require removal; in it is a quantity of loose connective and adipose tissue which may be readily infiltrated with blood or inflammatory exudation; and it may be the seat of rapidly growing tumours. Moreover, it is covered at its base by thin skin, which is largely supplied with sebaceous and sweat glands, and is frequently the seat of small cutaneous abscesses and boils.

Penetrating wounds in the axilla are sometimes accompanied by extensive hæmorrhage, either from wound of the main vessels, or of one of the large branches of the axillary artery, *e.g.* the long thoracic or the subscapular. Where the blood cannot find an easy exit externally, it collects in the axillary space and forms a large swelling which projects in the floor of the axilla and also bulges forwards the Pectoralis major. The treatment consists in freely opening up the cavity and searching for and securing the bleeding vessel.

In *suppuration in the axilla*, the arrangement of the fasciæ plays a very important part in the direction which the pus takes. As described on page 529, the costo-coracoid membrane, after covering in the space between the clavicle and the upper border of the Pectoralis minor, splits to enclose this muscle, and, reblending at its lower border, becomes incorporated with the axillary fascia at the anterior fold of the axilla. This is known as the *clavipectoral fascia*. Suppuration may take place either superficial to or beneath this layer of fascia; that is, either between the Pectorals or below the Pectoralis minor: in the former case, the abscess would point either at the anterior border of the axillary fold, or in the groove between the Deltoid and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves, and ascend into the neck, that being the direction in which there is least resistance. Its progress towards the surface is prevented by the axillary fascia; its progress backwards, by the insertion of the Serratus magnus; forwards, by the clavipectoral fascia; inwards, by the wall of the thorax; and outwards, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinum. Some instances have been recorded where the pus found its way along the course of the vessels into the upper arm.

In opening an axillary abscess, the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. After an incision has been made through the skin and fascia it is well to use a director and dressing forceps in the manner directed by Hilton.

The relations of the vessels and nerves in the several parts of the axilla are important, for it is the almost universal plan, in the present day, to remove the glands from the axilla in operating for cancer of the breast. In performing such an operation, it is necessary to proceed with much caution in the direction of the outer wall and apex of the space, as here the axillary vessels are in danger of being wounded. The subscapular, dorsalis scapulæ, and posterior circumflex vessels on the posterior wall and the thoracic branches along the anterior wall must be avoided. In clearing out the axilla, the axillary vein should be first defined and traced up to the apex of the space by means of an elevator or other blunt instrument. The Pectoralis major is retracted by an assistant; or, as is more commonly the practice in the present day, the sternal origin of this muscle is first removed. This proceeding not only lessens the chance of recurrence of the disease, but also enables the surgeon to clear out the axillary cavity more thoroughly. When the apex of the space is reached all fat and glands must be carefully removed and the whole axilla cleared by separating the tissues along the inner and posterior walls, so that when the proceeding is completed the axilla is emptied of all its contents except the main vessels and nerves.

Axillary Artery

The **axillary artery** (a. axillaris) (fig. 594), the continuation of the subclavian, commences at the outer border of the first rib, and terminates at the lower border of the tendon of the Teres major muscle, where it takes the name of brachial. Its direction varies with the position of the limb: thus the vessel is nearly straight when the arm is directed at right angles with the trunk, concave upwards when the arm is elevated above this, and convex upwards and outwards when the arm lies by the side. At its commencement the artery is very deeply situated, but near its termination is superficial, being covered only by the skin and fascia. To facilitate the description of the vessel it is divided into three portions; the first part lies above, the second behind, and the third below the Pectoralis minor.

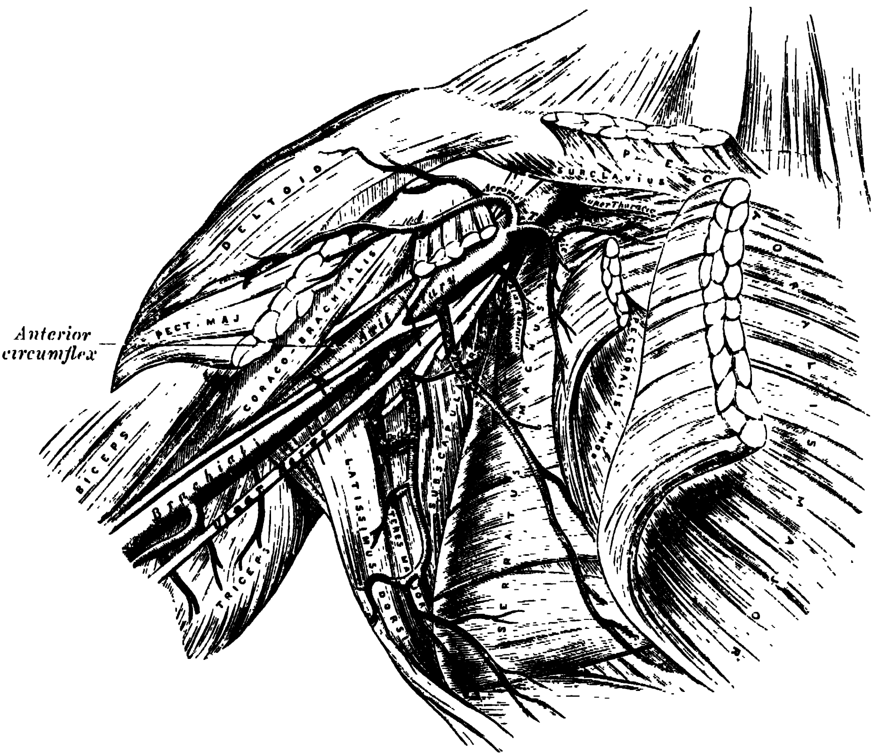
The **first portion** of the axillary artery is in relation, *in front*, with the clavicular portion of the Pectoralis major, the costo-coracoid membrane, the external anterior thoracic nerve, and the acromio-thoracic and cephalic veins; *behind*, with the first intercostal space, the corresponding Intercostal muscle, the first and second digitations of the Serratus magnus, and the posterior thoracic and internal anterior thoracic nerves; on its *outer side*, with the brachial plexus, from which it is separated by a little areolar tissue; on its *inner*, or thoracic side, with the axillary vein which overlaps the artery. It is enclosed, together with the axillary vein and the brachial plexus, in a fibrous sheath—the *axillary sheath*—continuous above with the deep cervical fascia.

The **second portion** of the axillary artery is covered, *in front*, by the Pectorales major and minor; *behind* it, is the posterior cord of the brachial plexus, and some areolar tissue which intervenes between it and the Subscapularis muscle; on the *inner side* is the axillary vein, separated from the artery by the inner cord of the brachial plexus and the internal anterior thoracic nerve; on the *outer side* is the outer cord of the brachial plexus. The brachial plexus of nerves thus surrounds

the artery on three sides, and separates it from direct contact with the vein and adjacent muscles.

The **third portion** of the axillary artery extends from the lower border of the Pectoralis minor to the lower border of the tendon of the Teres major. *In front*, it is covered by the lower part of the Pectoralis major above, but only by the integument and fascia below; *behind*, it is in relation with the lower part of the Subscapularis, and the tendons of the Latissimus dorsi and Teres major; on its

FIG. 594.—The axillary artery and its branches.



outer side is the Coraco-brachialis, and on its *inner*, or thoracic side, the axillary vein. The nerves of the brachial plexus bear the following relations to this part of the artery: on the *outer side* are the outer head and trunk of the median, and the musculo-cutaneous for a short distance; on the *inner side* the ulnar (between the vein and artery) and lesser internal cutaneous nerves (to the inner side of the vein); *in front* are the inner head of the median and the internal cutaneous, and *behind*, the musculo-spiral and circumflex, the latter only as far as the lower border of the Subscapularis.

Surface Marking.—The course of the axillary artery may be marked out by raising the arm to a right angle and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence caused by the Coraco-brachialis as it emerges from under cover of the anterior fold of the axilla. The third portion of the artery can be felt pulsating beneath the skin and fascia, at the junction of the anterior with the middle third of the space between the anterior and posterior folds of the axilla, close to the inner border of the Coraco-brachialis.

Applied Anatomy.—*Compression* of the vessel may be required in the removal of tumours, or in amputation of the upper part of the arm; and the only situation in which this can be effectually made is in the lower part of its course; by pressing on it in this situation from within outwards against the humerus, the circulation may be effectually arrested.

With the exception of the popliteal, the axillary artery is perhaps more frequently lacerated than any other artery in the body by violent movements, especially in those cases where its coats are diseased. It has occasionally been ruptured in attempts to

reduce old dislocations of the shoulder-joint. This lesion is most likely to occur during the preliminary breaking down of adhesions, in cases where the artery has become fixed to the capsule of the joint. Aneurysm of the axillary artery sometimes occurs: a large number of the cases are traumatic in their origin, due to the injuries to which the artery is exposed in the varied, extensive, and often violent movements of the limb.

The *application of a ligature to the axillary artery* may be required in cases of aneurysm of the upper part of th[illegible]chial, or as a distal operation for aneurysm of the subclavian; and there are onl[illegible]ns in which it can be secured, viz. in the first and in the third parts o[illegible] axillary artery at its central part is so deeply seated, and, at the [illegible] closely surrounded with large nervous trunks, that the application [illegible]here would be almost impracticable.

In the *third* [illegible]rse the operation is most simple, and may be performed in the following m[illegible] The patient being placed on a bed, and the arm separated from the side, with the hand supinated, an incision about two inches in length is made through the integument forming the floor of the axilla, a little nearer to the anterior than to the posterior fold of the axilla. After carefully dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; the former is displaced to the outer, and the latter to the inner side of the arm, the elbow being at the same time bent so as to relax the structures and facilitate their separation; the ligature may be passed round the artery from the ulnar to the radial side. This portion of the artery is occasionally crossed by a muscular slip, the *axillary arch* (page 490), derived from the Latissimus dorsi.

The *first portion* of the axillary artery may be tied in cases of aneurysm encroaching so far upwards that a ligature cannot be applied in the lower part of its course. Notwithstanding that this operation has been performed in some few patients with success, its performance is attended with much difficulty and danger. The student will remark that, in this situation, it would be necessary to divide a thick muscle, and, after incising the costo-coracoid membrane, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to it particularly hazardous. Under such circumstances, it is an easier and, at the same time, more advisable operation, to tie the third part of the subclavian artery.

The first part of the axillary can be best secured by a curved incision with the convexity downwards from a point half an inch external to the sterno-clavicular joint to a point half an inch internal to the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and the incision carried through the superficial structures, care being taken of the cephalic vein at the outer angle of the incision. The clavicular origin of the Pectoralis major is then divided in the whole extent of the wound. The arm is now brought to the side, and the upper edge of the Pectoralis minor defined and drawn downwards. The costo-coracoid membrane is carefully divided on a director, close to the coracoid process, and the axillary sheath exposed; this is to be opened with especial care on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein.

Collateral circulation after ligature of the axillary artery.—If the artery be tied above the origin of the acromio-thoracic, the collateral circulation will be carried on by the same branches as after the ligature of the subclavian; if at a lower point, between the acromio-thoracic and subscapular arteries, the latter vessel, by its free anastomoses with the other scapular arteries, branches of the subclavian, will become the chief agent in carrying on the circulation; the long thoracic, if it be below the ligature, will materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the point included in the ligature is below the origin of the subscapular artery, it will most probably also be below the origins of the two circumflex arteries. The chief agents in restoring the circulation will then be the subscapular and the two circumflex arteries anastomosing with the superior profunda from the brachial. The cases in which the operation has been performed are few in number, and no published account of dissections of the collateral circulation appears to exist.

The branches of the axillary artery are:

From first part, Superior thoracic.

From second part { Acromio-thoracic. Long thoracic. Alar thoracic.

From third part { Subscapular. Posterior circumflex. Anterior circumflex.

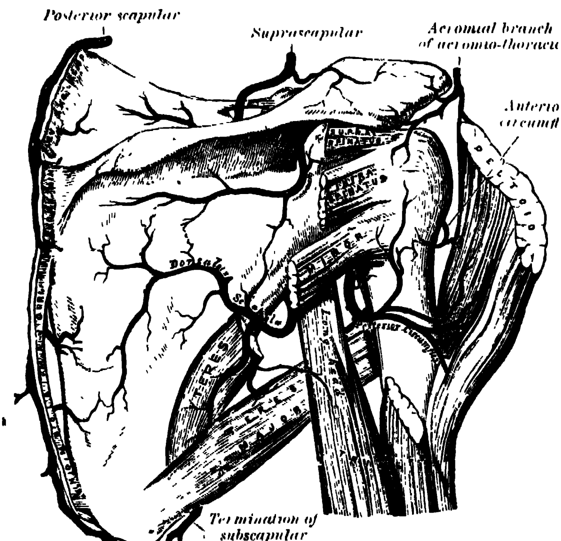
1. The **superior thoracic** (a. thoracalis suprema) is a small artery, which may arise by a common trunk with the acromio-thoracic. Running forwards and inwards along the upper border of the Pectoralis minor, it passes between it and the Pectoralis major to the side of the chest. It supplies these muscles, and

the parietes of the thorax, anastomosing with the internal mammary and intercostal arteries.

2. The **acromio-thoracic** (a. thoracoacromialis) is a short trunk, which arises from the fore part of the axillary artery, its origin being generally overlapped by the upper edge of the Pectoralis minor. Projecting forwards to the upper border of this muscle, it pierces the costo-coracoid membrane and divides into four branches—*pectoral*, *acromial*, *clavicular*, and *humeral*. The *pectoral branch* (ramus pectoralis) runs forwards and inwards between the two Pectoral muscles, and is distributed to them and to the mammary gland, anastomosing with the intercostal branches of the internal mammary. The *acromial branch* (ramus acromialis) is directed outwards towards the acromion, supplying the Deltoid muscle, and anastomosing, on the surface of the acromion, with the suprascapular and posterior circumflex arteries. The *clavicular branch* (ramus clavicularis) runs upwards and inwards to the sterno-clavicular joint, supplying this articulation, and the Subclavius muscle. The *humeral branch* (ramus deltoideus) passes, in the same groove as the cephalic vein, between the Pectoralis major and Deltoid, and gives branches to both muscles.

3. The **long thoracic** (a. thoracalis lateralis) passes downwards and inwards along the lower border of the Pectoralis minor to the side of the chest, supplying the Serratus magnus, the Pectoral muscles, and mammary gland, and sending branches across the axilla to the axillary glands and Subscapularis; it anastomoses with the internal mammary and intercostal arteries.

Fig. 595.—The scapular and circumflex arteries.



4. The **alar thoracic** is a small branch, which supplies the glands and areolar tissue of the axilla. Its place is frequently taken by branches from some of the other thoracic arteries.

5. The **subscapular** (a. subscapularis), the largest branch of the axillary artery, arises opposite the lower border of the Subscapularis, and passes downwards and backwards along this border to the inferior angle of the scapula, where it anastomoses with the long thoracic and intercostal arteries and with the posterior scapular branch of the transversalis colli, and terminates by supplying branches to the muscles in the neighbourhood. About an inch and a half from its origin it gives off a branch, the *dorsalis scapulæ*.

The **dorsalis scapulæ** (a. circumflexa scapulæ) is generally larger than the continuation of the subscapular. It curves round the axillary border of the scapula, leaving the axilla through the space between the Subscapularis above, the Teres major below, and the long head of the Triceps externally (fig. 595); it enters the infraspinous fossa under cover of the Teres minor, and anastomoses with the posterior scapular and suprascapular arteries. In its course it gives off two branches: one (*infrascapular*) enters the subscapular fossa beneath the Subscapularis which it supplies, anastomosing with the posterior scapular and suprascapular arteries; the other is continued along the axillary border of the scapula, between the Teres major and minor, and at the dorsal surface of the inferior angle anastomoses with the posterior scapular. In addition to these, small branches are distributed to the back part of the Deltoid muscle and the long head of the Triceps, anastomosing with an ascending branch of the superior profunda of the brachial.

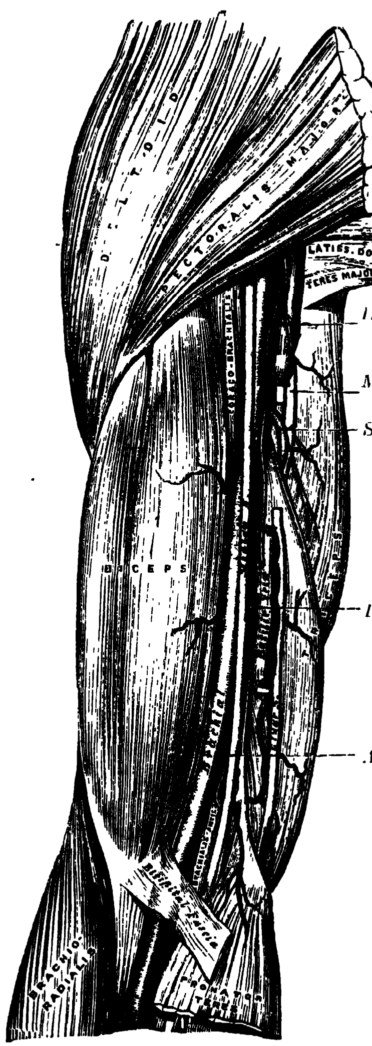
6. The **posterior circumflex** (a. circumflexa humeri posterior) (fig. 595) arises from the back part of the axillary artery opposite the lower border of the Subscapularis muscle, and runs backwards with the circumflex veins and nerve

through the quadrangular space bounded by the Teres major and minor, the scapular head of the Triceps and the humerus. It winds round the neck of the humerus and is distributed to the Deltoid muscle and shoulder-joint, anastomosing with the anterior circumflex and acromio-thoracic arteries, and with the superior profunda branch of the brachial artery.

7. The **anterior circumflex** (a. circumflexa humeri anterior) (fig. 595), considerably smaller than the preceding, arises nearly opposite it, from the outer side of the axillary artery. It passes horizontally outwards, beneath the Coraco-brachialis and short head of the Biceps, lying upon the fore part of the neck of the humerus. On reaching the bicipital groove, it gives off an ascending branch which ascends along the groove to supply the head of the humerus and the shoulder-joint. The trunk of the vessel is then continued outwards beneath the Deltoid, which it supplies, and anastomoses with the posterior circumflex artery.

Peculiarities.—The branches of the axillary artery vary considerably in different subjects. Occasionally the subscapular, circumflex, and profunda arteries arise from a common trunk, and when this occurs the branches of the brachial plexus surround this trunk instead of the main vessel. Sometimes the axillary artery divides into the radial and ulnar arteries, and occasionally it gives origin to the anterior interosseous artery of the forearm.

FIG. 596.—The brachial artery.



BRACHIAL ARTERY (fig. 596)

The **Brachial artery** (a. brachii) commences at the lower margin of the tendon of the Teres major, and, passing down the inner and anterior aspect of the arm, terminates about half an inch below the bend of the elbow, where it divides into the *radial* and *ulnar* arteries. At first the brachial artery lies internal to the humerus; but as it runs down the arm it gradually gets in front of the bone, and at the bend of the elbow it lies midway between the two condyles.

Relations.—The artery is superficial throughout its entire extent, being covered, *in front*, by the integument and the superficial and deep fasciæ; the bicipital fascia lies in front of it opposite the elbow and separates it from the vena mediana cubiti; the median nerve crosses it from without inwards opposite the insertion of the Coraco-brachialis. *Behind*, it is separated from the long head of the Triceps by the musculo-spiral nerve and superior profunda artery. It then lies upon the inner head of the Triceps, next upon the insertion of the Coraco-brachialis, and lastly on the Brachialis anticus. By its *outer side*, it is in relation with the commencement of the median nerve, and the Coraco-brachialis and Biceps,

the two muscles overlapping the artery to a considerable extent. By its *inner side*, its upper half is in relation with the internal cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on its inner side, but is separated from it in the lower part of the arm by the deep fascia. The artery is accompanied by two venæ comites, which lie in close contact with it, being connected together at intervals by short transverse communicating branches.

Anatomy of the Bend of the Elbow (anticubital fossa)

At the bend of the elbow the brachial artery sinks deeply into a triangular interval. The base of the triangle is directed upwards, and is represented by a line connecting the two condyles of the humerus; the sides are bounded, externally, by the inner edge of the Brachio-radialis, internally, by the outer margin of the Pronator teres; the floor is formed by the Brachialis anticus and Supinator brevis. This space contains the brachial artery, with its accompanying veins: the radial and ulnar arteries: the median and musculo-spiral nerves; and the tendon of the Biceps. The brachial artery occupies the middle line of the space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, *in front*, by the integument, the superficial fascia, and the vena mediana cubiti, the vein being separated from direct contact with the artery by the bicipital fascia. *Behind*, it lies on the Brachialis anticus, which separates it from the elbow-joint. The median nerve lies on the inner side of the artery, close to it above, but separated from it below by the coronoid origin of the Pronator teres. The tendon of the Biceps lies to the outer side of the artery, and still more externally is the musculo-spiral nerve which is situated upon the Supinator brevis, and concealed by the Brachio-radialis.

Peculiarities of the brachial artery as regards its Course.—The brachial artery, accompanied by the median nerve, may leave the inner border of the Biceps, and descend towards the inner epicondyle of the humerus; about two inches above the epicondyle it usually in such cases curves round a prominence of bone, the *supracondylar process*, from which a fibrous arch is in most cases thrown over the artery: it then inclines outwards, beneath or through the substance of the Pronator teres, to the bend of the elbow. This variation bears considerable analogy with the normal condition of the artery in some of the carnivora: it has been referred to in the description of the humerus (page 298).

As regards its division.—Occasionally, the artery is divided for a short distance at its upper part into two trunks, which are united below. A similar peculiarity may occur in the main vessel of the lower limb.

The vessels concerned in the high division of the brachial artery are three: viz. radial, ulnar, and interosseous. Most frequently the radial is given off high up, the other limb of the bifurcation consisting of the ulnar and interosseous. In some instances the ulnar arises from the brachial above the ordinary level, and the radial and interosseous form the other limb of the division; and occasionally the interosseous arises high up.

Sometimes, long slender vessels, *vasa aberrantia*, connect the brachial or the axillary artery with one of the arteries of the forearm, or branches from them. These vessels usually join the radial.

*Varieties in muscular relations.**—The brachial artery is occasionally concealed, in some part of its course, by muscular or tendinous slips derived from the Coraco-brachialis, Biceps, Brachialis anticus, or Pronator teres.

Surface Marking.—The direction of the brachial artery is marked by a line drawn along the inner edge of the Biceps from the insertion of the Teres major muscle to a point midway between the epicondyles of the humerus.

Applied Anatomy.—In spite of the fact that the brachial artery is very superficial and but little protected by surrounding tissues, it is seldom wounded. This, no doubt, is due to its situation on the inner side of the arm, which is little exposed to injury. *Compression* of the brachial artery is required in cases of amputation and some other operations in the arm and forearm, and may be effected in almost any part of the course of the artery. If pressure be made in the upper part of the limb, it should be directed from within outwards; if in the lower part, from before backwards, as the artery lies on the inner side of the humerus above, and in front of it below. The most favourable situation is about the middle of the arm, where the artery lies on the tendon of the Coraco-brachialis on the inner surface of the humerus.

The *application of a ligature* to the brachial artery may be required in cases of wound of the vessel, and in some cases of wound of the palmar arch. It is also sometimes necessary in cases of aneurysm of the brachial, radial, ulnar, or interosseous arteries. The

* See Struthers's *Anatomical and Physiological Observations.*

artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the inner margins of the Coraco-brachialis and Biceps, and the known course of the vessel; its pulsation should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position. It is essential in applying a ligature to this vessel that the arm should be held away from the side, and supported only from the elbow, for if the arm be allowed to rest on any firm structure the Triceps is pressed forwards and overlaps the vessel, thus making the operation much more difficult.

In the upper third of the arm the artery may be exposed in the following manner. The patient being placed supine upon a table, the affected limb should be raised from the side, and the hand supinated. An incision about two inches in length should be made on the inner side of the Coraco-brachialis muscle, and the subjacent fascia cautiously divided, so as to avoid wounding the internal cutaneous nerve or basilic vein, as the latter sometimes runs on the surface of the artery as high as the axilla. The fascia having been divided, it should be remembered that the ulnar and internal cutaneous nerves lie on the inner side of the artery, the median on the outer side, the latter nerve being occasionally superficial to the artery in this situation, and that the venæ comites are also in relation with the vessel, one on either side. These being carefully separated, the aneurysm needle should be passed round the artery from the inner to the outer side.

In the case of a high division, the two arteries are usually placed side by side; and if they are exposed in an operation, the surgeon should endeavour to ascertain, by alternately pressing on each vessel, which of the two communicates with the wound or aneurysm, when a ligature may be applied accordingly; or if pulsation or hæmorrhage ceases only when both vessels are compressed, both vessels must be tied, as it may be concluded that the two communicate above the seat of disease, or are reunited.

In the middle of the arm the brachial artery may be exposed by making an incision along the inner margin of the Biceps muscle. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and the fascia carefully divided, when the median nerve will be exposed lying upon (sometimes beneath) the artery; this being drawn inwards and the muscle outwards, the artery should be separated from its accompanying veins and secured. In this situation the inferior profunda may be mistaken for the main trunk, especially if enlarged from the collateral circulation having become established; this may be avoided by directing the incision externally towards the Biceps, rather than inwards or backwards towards the Triceps.

The lower part of the brachial artery is of interest from a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the vena mediana cubiti is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken, in opening the vein, not to carry the incision too deep, so as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the circumflex and subscapular arteries anastomosing with ascending branches from the superior profunda. If the brachial be tied *below* the origin of the profunda arteries, the circulation is maintained by the branches of the profundæ anastomosing with the recurrent radial, ulnar, and interosseous arteries.

The branches of the brachial artery are:

Superior profunda.	Inferior profunda.
Nutrient.	Anastomotica magna.
Muscular.	

1. The **superior profunda** (a. profunda brachii) arises from the inner and back part of the brachial, just below the lower border of the Teres major, and passes backwards to the interval between the outer and inner heads of the Triceps muscle, accompanied by the musculo-spiral nerve. It winds round the back of the shaft of the humerus in the spiral groove, between the outer head of the Triceps and the bone, to the external intermuscular septum where it divides into two terminal branches. One of these pierces the septum, and descends, in company with the musculo-spiral nerve, to the space between the Brachialis anticus and Brachio-radialis, where it anastomoses with the recurrent branch of the radial artery; the other, much larger, descends behind the external intermuscular septum to the back of the elbow-joint, where it anastomoses with the posterior interosseous recurrent, the posterior ulnar recurrent, the anastomotica magna, and inferior profunda (fig. 597). The superior profunda supplies the Triceps muscle and gives off a nutrient artery which enters the humerus at the upper end of the musculo-spiral groove. Near its commencement it sends a branch upwards

between the external and long heads of the Triceps muscle to anastomose with the posterior circumflex artery; and, while in the groove, a small branch which accompanies a branch of the musculo-spiral nerve through the substance of the Triceps muscle and ends in the Anconeus below the outer epicondyle of the humerus.

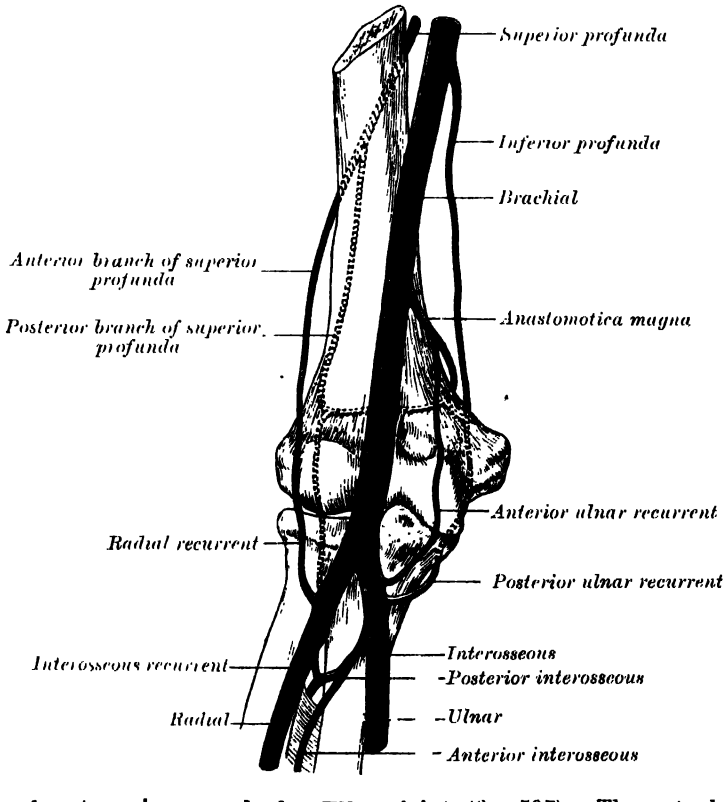
2. The **nutrient artery** of the shaft of the humerus arises about the middle of the arm and enters the nutrient canal near the insertion of the Coraco-brachialis muscle.

3. The **inferior profunda** (a. collateralis ulnaris superior), of small size, arises a little below the middle of the arm. It pierces the internal intermuscular septum, and descends on the surface of the inner head of the Triceps muscle, to the space between the inner epicondyle and olecranon, accompanied by the ulnar nerve, and terminates by anastomosing with the posterior ulnar recurrent and anastomotica magna. It sometimes sends a branch in front of the internal epicondyle, to anastomose with the anterior ulnar recurrent.

4. The **anastomotica magna** (a. collateralis ulnaris inferior) arises about two inches above the elbow-joint. It passes transversely inwards upon the Brachialis anticus, and piercing the internal intermuscular septum, winds round the back part of the humerus between the Triceps and the bone, forming, by its junction with the posterior branch of the superior profunda, an arch above the olecranon fossa. As the vessel lies on the Brachialis anticus, branches ascend to join the inferior profunda; others descend in front of the inner epicondyle, to anastomose with the anterior ulnar recurrent. Behind the internal epicondyle a branch is given off to anastomose with the inferior profunda and posterior ulnar recurrent arteries and supply the Triceps.

5. The **muscular** are three or four large branches, which are distributed to the muscles in the course of the artery. They supply the Coraco-brachialis, Biceps, and Brachialis anticus.

FIG. 597.—Diagram of the anastomosis around the elbow-joint.

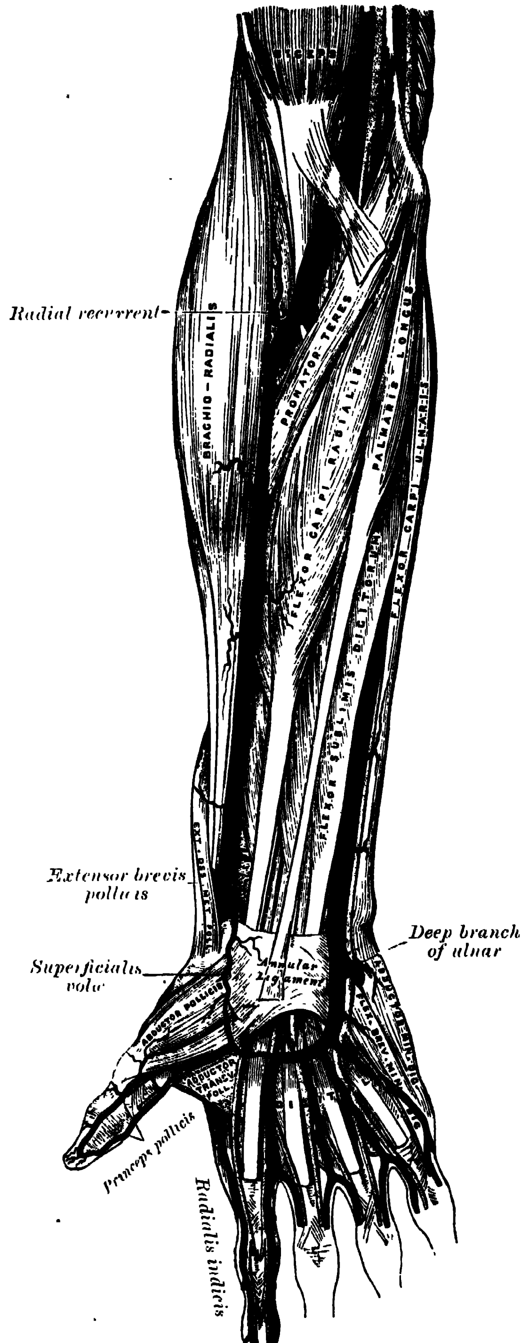


The **Anastomosis around the Elbow-joint** (fig. 597).—The vessels engaged in this anastomosis may be conveniently divided into those situated *in front* of,

and those *behind* the internal and external epicondyles. The branches anastomosing *in front* of the internal epicondyle are: the anterior branch of the anastomotica magna, the anterior ulnar recurrent, and the anterior branch of the inferior profunda. Those *behind* the internal epicondyle are: the anastomotica magna, the posterior ulnar recurrent, and the posterior terminal branch of the inferior profunda. The branches anastomosing *in front* of the external epicondyle are: the radial recurrent and the anterior terminal branch of the superior profunda. Those *behind* the external epicondyle (perhaps more properly described as being situated between the external epicondyle and the olecranon) are: the anastomotica magna, the interosseous recurrent, and the posterior terminal branch of the superior profunda. There is also a large arch of anastomosis above the olecranon, formed by the interosseous recurrent joining with the anastomotica magna and posterior ulnar recurrent (fig. 600).

From this description it will be observed that the anastomotica magna is the vessel most engaged, the only part of the anastomosis in which it is not employed being that in front of the external epicondyle.

Fig. 598.—The radial and ulnar arteries.



Radial Artery (fig. 598)

The **radial artery** (a. radialis) appears, from its direction, to be the continuation of the brachial, but it is smaller in calibre than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes along the radial side of the forearm to the wrist. It then winds backwards, round the outer side of the carpus, beneath the Extensor tendons of the thumb to the upper end of the space between the metacarpal bones of the thumb and index finger, and, finally, passes forwards between the two heads of the First dorsal interosseous muscle, into the palm of the hand, where it crosses the metacarpal bones to the ulnar border of the hand, to form the deep palmar arch. At its termination, it anastomoses with the deep branch of the ulnar artery. The relations of this

vessel may thus be conveniently divided into three parts, viz. in the forearm, at the back of the wrist, and in the hand.

Relations.—(*a*) *In the forearm* the artery extends from opposite the neck of the radius to the fore part of the styloid process, being placed to the inner side of the shaft above, and in front of it below. It is overlapped in the upper part of its course by the fleshy belly of the Brachio-radialis muscle; throughout the rest of its course it is superficial, being covered by the integument and the superficial and deep fasciæ. In its course downwards, it lies upon the tendon of the Biceps, the Supinator brevis, the Pronator teres, the radial origin of the Flexor sublimis digitorum, the Flexor longus pollicis, the Pronator quadratus, and the lower extremity of the radius. In the upper third of its course it lies between the Brachio-radialis and the Pronator teres; in its lower two-thirds, between the tendons of the Brachio-radialis and Flexor carpi radialis. The radial nerve lies close to the outer side of the artery in the middle third of its course; and some filaments of the musculo-cutaneous nerve, after piercing the deep fascia, run along the lower part of the artery as it winds round the wrist. The vessel is accompanied by venæ comites throughout its whole course.

(*b*) *At the wrist* as it winds round the outer side of the carpus, from the styloid process to the first interosseous space, it lies upon the external lateral ligament, and then upon the scaphoid and trapezium, being covered by the Extensor tendons of the thumb, subcutaneous veins, some filaments of the radial nerve, and the integument. It is accompanied by two veins, and a filament of the musculo-cutaneous nerve.

(*c*) *In the hand*, it passes from the upper end of the first interosseous space, between the heads of the Abductor indicis or First dorsal interosseous muscle, transversely across the palm, to the base of the metacarpal bone of the little finger, where it anastomoses with the deep branch from the ulnar artery, completing the *deep palmar arch* (arcus volaris profundus). It lies upon the carpal extremities of the metacarpal bones and the Interossei, being covered by the Adductor obliquus pollicis, the flexor tendons of the fingers, and the Lumbricales. Alongside of it, but running in the opposite direction—that is to say, from within outwards—is the deep branch of the ulnar nerve.

Peculiarities.—The origin of the radial artery, according to Quain, is, in nearly one case in eight, higher than usual; more often it arises from the axillary or upper part of the brachial, than from the lower part of the latter vessel. In the forearm it deviates less frequently from its normal position than the ulnar. It has been found lying on the deep fascia instead of beneath it. It has also been observed on the surface of the Brachio-radialis, instead of under its inner border; and in turning round the wrist, it has been seen lying on, instead of beneath, the Extensor tendons of the thumb.

Surface Marking.—The position of the radial artery in the forearm is represented by a line drawn from the outer border of the tendon of the Biceps in the centre of the hollow in front of the elbow-joint to the inner side of the fore part of the styloid process of the radius, with the limb in the position of supination.

Applied Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded by the hand being driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, &c. The injury may be followed by a traumatic aneurysm, for which the operation of laying open the sac and securing the vessel above and below is required.

The operation of tying the radial artery is required in cases of wounds either of its trunk, or of some of its branches, or for aneurysm: and the vessel may be exposed in any part of its course through the forearm without the division of any muscular fibres. The operation in the middle or inferior third of the forearm is easily performed; but in the upper third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel, and from its being overlapped by the Brachio-radialis.

To tie the artery in the upper third, an incision three inches in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided, and the Brachio-radialis drawn a little outwards, the artery will be exposed. The venæ comites should be carefully separated from the vessel and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the inner margin of the Brachio-radialis. In this situation, the radial nerve lies in close relation with the outer side of the artery, and should, as well as the veins, be carefully avoided.

In the lower third, the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Brachio-radialis and Flexor carpi radialis.

The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

In the forearm.	*At the wrist.*	*In the hand.*
Radial recurrent.	Posterior radial carpal.	Princeps pollicis.
Muscular.	First dorsal interosseous.	Radialis indicis.
Anterior radial carpal.	Dorsales pollicis.	Perforating.
Superficialis volæ.	Dorsalis indicis.	Palmar interosseous.
		Recurrent.

The **radial recurrent** (a. recurrens radialis) is given off immediately below the elbow. It ascends between the branches of the musculo-spiral nerve, lying on the Supinator brevis and then between the Brachio-radialis and Brachialis anticus, supplying these muscles and the elbow-joint, and anastomosing with the anterior terminal branch of the superior profunda.

The **muscular branches** (rami musculares) are distributed to the muscles on the radial side of the forearm.

The **anterior radial carpal** (ramus carpeus volaris) is a small vessel which arises near the lower border of the Pronator quadratus, and, running inwards in front of the carpus, anastomoses with the anterior carpal branch of the ulnar artery. In this way an arterial anastomosis, the *anterior carpal arch*, is formed in front of the wrist: it is joined by branches from the anterior interosseous above, and by recurrent branches from the deep palmar arch below, and gives off twigs which descend to supply the articulations of the wrist and carpus.

The **superficialis volæ** (ramus volaris superficialis) arises from the radial artery, just where this vessel is about to wind round the outer side of the wrist. Running forwards, it passes through, occasionally over, the muscles of the thumb, which it supplies, and sometimes anastomoses with the terminal portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size: usually it is very small, and terminates in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The **posterior radial carpal** (ramus carpeus dorsalis) is a small vessel which arises beneath the Extensor tendons of the thumb; crossing the carpus transversely towards the inner border of the hand, it anastomoses with the posterior carpal branch of the ulnar, forming the *posterior carpal arch*, which is joined by the termination of the anterior interosseous artery. From this arch are given off two slender *dorsal interosseous arteries*, which run forwards on the Third and Fourth dorsal interossei and bifurcate into dorsal digital branches which supply the adjacent sides of the middle, ring, and little fingers respectively, communicating with the collateral digital branches of the superficial palmar arch. Near their origins they anastomose with the deep palmar arch by the *superior perforating arteries*, and near their points of bifurcation with the digital vessels of the superficial palmar arch by the *inferior perforating arteries*.

The **first dorsal interosseous** arises beneath the Extensor tendons of the thumb, sometimes with the posterior radial carpal; running forwards on the Second dorsal interosseous muscle it divides into two dorsal digital branches, which supply the adjoining sides of the index and middle fingers; it forms anastomoses similar to those of the other two dorsal interosseous arteries.

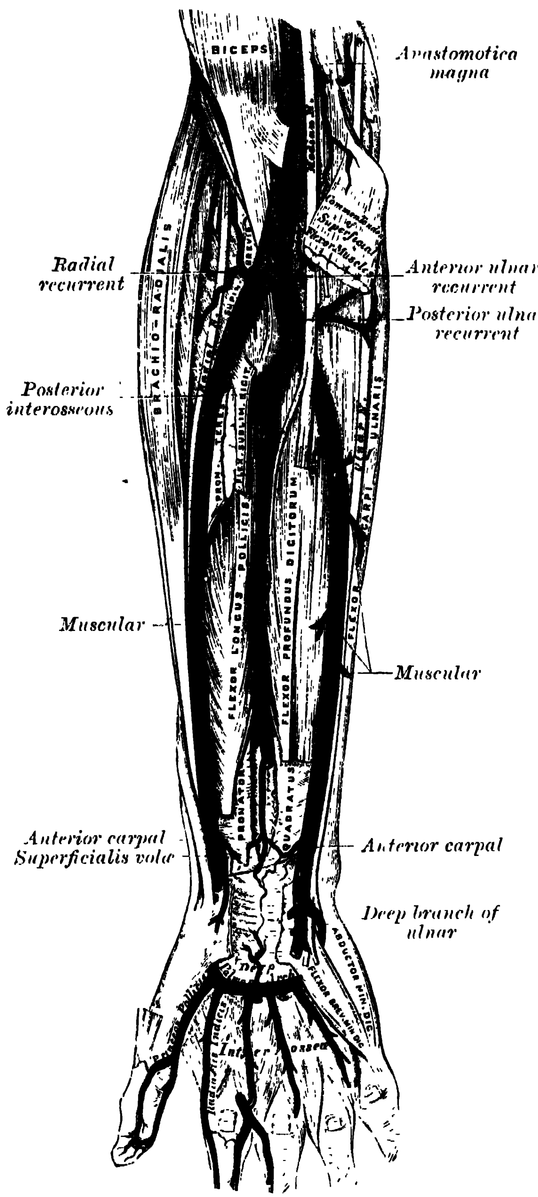
The **dorsales pollicis** are two small vessels which run along the sides of the dorsal aspect of the thumb. They usually arise separately, but occasionally by a common trunk, near the base of the first metacarpal bone.

The **dorsalis indicis**, also a small branch, runs along the radial side of the back of the index finger, sending a few branches to the Abductor indicis.

The **princeps pollicis** (a. princeps pollicis) arises from the radial just as it turns inwards to the deep part of the hand; it descends between the Abductor indicis and Adductor obliquus pollicis, along the ulnar side of the metacarpal bone of the thumb to the base of the first phalanx, where it lies beneath the tendon of the Flexor longus pollicis and divides into two branches. These make their appearance between the inner and outer insertions of the Adductor obliquus pollicis, and run along the sides of the palmar aspect of the thumb, forming on the palmar surface of the last phalanx an arch, from which branches are distributed to the integument and subcutaneous tissue of the thumb.

The **radialis indicis** (a. volaris indicis radialis) arises close to the preceding, descends between the Abductor indicis and Adductor transversus pollicis, and runs along the radial side of the index finger to its extremity, where it anastomoses with the collateral digital artery from the superficial palmar arch. At the lower border of the Adductor transversus pollicis, this vessel anastomoses with the princeps pollicis, and gives a communicating branch to the superficial palmar arch.

Fig. 599.—Ulnar and radial arteries. Deep view.



The **perforating arteries** (rami perforantes), three in number, pass backwards from the deep palmar arch, through the second, third, and fourth interosseous spaces and between the heads of the corresponding Interossei, to anastomose with the dorsal interosseous arteries.

The **palmar interosseous** (aa. metacarpeæ volares), three or four in number, arise from the convexity of the deep palmar arch; they run downwards upon the Interossei, and anastomose at the clefts of the fingers with the digital branches of the superficial arch.

The **recurrent branches** arise from the concavity of the deep palmar arch. They ascend in front of the wrist, supplying the carpal articulations and anastomosing with the anterior carpal arch.

Ulnar Artery (fig. 599)

The **ulnar artery** (a. ulnaris), the larger of the two terminal branches of the brachial, commences a little below the bend of the elbow, and, passing obliquely downwards and inwards, reaches the inner side of the forearm at a point about midway between the elbow and the wrist. It then runs along the ulnar border to the wrist, crosses the annular ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches, which enter into the formation of the superficial and deep palmar arches.

Relations. (*a*) *In the forearm.*—In its *upper half*, it is deeply seated, being covered by all the superficial Flexor muscles, except the Flexor carpi ulnaris; it lies upon the Brachialis anticus and Flexor profundus digitorum muscles. The median nerve is in relation with the inner side of the artery for about an inch and then crosses the vessel, being separated from it by the deep head of the Pronator

teres. In the *lower half* of the forearm, it lies upon the Flexor profundus, being covered by the integument, and the superficial and deep fasciæ, and is placed between the Flexor carpi ulnaris and Flexor sublimis digitorum muscles. It is accompanied by two venæ comites, and is overlapped in its middle third by the Flexor carpi ulnaris; the ulnar nerve lies on its inner side for the lower two-thirds of its extent, and a small branch from the nerve descends on the lower part of the vessel to the palm of the hand.

(*b*) *At the wrist* (fig. 598) the ulnar artery is covered by the integument and fascia, and lies upon the anterior annular ligament. On its inner side is the pisiform bone, and, somewhat behind the artery, the ulnar nerve. The nerve and artery are crossed by a band of fibres, which extends from the pisiform bone to the anterior annular ligament.

Peculiarities.—The ulnar artery has been found to vary in its origin nearly in the proportion of one in thirteen cases; it may arise lower than usual, about two or three inches below the elbow, but usually much higher, the brachial being more often the source of origin than the axillary. Variations in the position of this vessel are more common than in the radial. When its origin is normal, the course of the vessel is rarely changed. When it arises high up, it is almost invariably superficial to the Flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases, its position was subcutaneous in the upper part of the forearm, and subaponeurotic in the lower part.

Surface Marking.—On account of the curved direction of the ulnar artery, the line on the surface of the limb which indicates its course is somewhat complicated. First, draw a line from the front of the internal epicondyle of the humerus to the radial side of the pisiform bone; the lower two-thirds of this line represent the course of the middle and lower thirds of the artery. Secondly, draw a line from the centre of the hollow in front of the elbow-joint to the junction of the upper and middle thirds of the first line; this represents the course of the upper third of the artery.

Applied Anatomy.—The application of a ligature to this vessel is required in cases of wound of the artery, or of its branches, or in consequence of aneurysm. In the upper half of the forearm the artery is deeply seated beneath the superficial Flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the internal epicondyle of the humerus to the outer side of the pisiform bone, so that the centre of the incision is three fingers' breadth below the internal epicondyle. The skin and superficial fascia having been divided, and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other Flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed lying on the Flexor profundus digitorum, and must be drawn aside. Some little distance below the nerve, the artery will be found accompanied by its venæ comites, and may be ligatured, the needle being passed from within outwards. In the middle and lower thirds of the forearm, this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris: when the deep fascia is divided, and the Flexor carpi ulnaris and the Flexor sublimis separated from each other, the vessel will be exposed, accompanied by its venæ comites, the ulnar nerve lying on its inner side. The veins being separated from the artery, the ligature should be passed from the ulnar to the radial side, taking care to avoid the ulnar nerve.

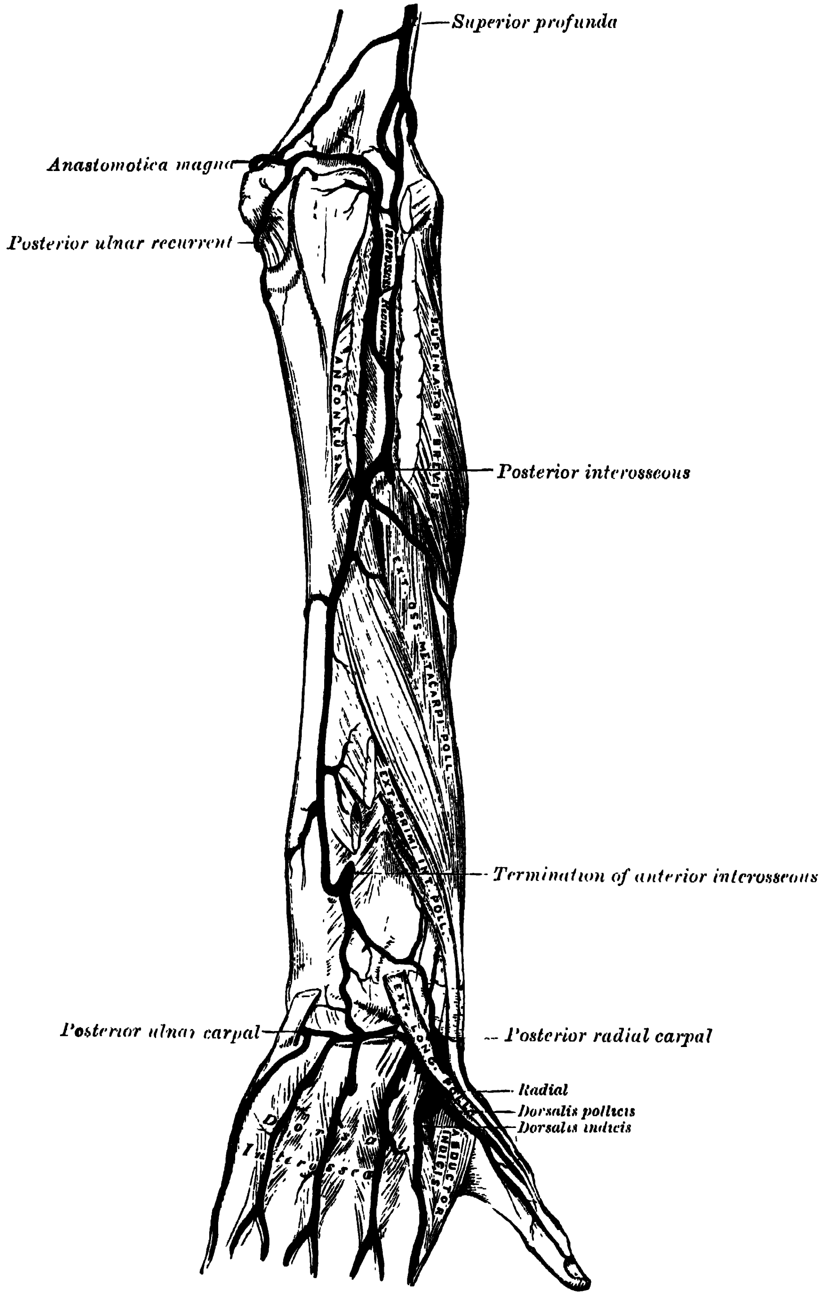
The branches of the ulnar artery may be arranged in the following groups:

In the forearm	Recurrent	Anterior.
		Posterior.
	Interosseous	Anterior interosseous.
		Posterior interosseous.
	Muscular.	
At the wrist	Anterior ulnar carpal.	
	Posterior ulnar carpal.	
In the hand	Profunda.	
	Superficial palmar arch.	

The **recurrent branches** (aa. recurrentes ulnares) are two in number, anterior and posterior. The *anterior ulnar recurrent* arises immediately below the elbow-joint, runs upwards and inwards between the Brachialis anticus and Pronator teres, supplies twigs to those muscles, and, in front of the inner epicondyle, anastomoses with the anastomotica magna and inferior profunda. The *posterior ulnar recurrent* is much larger, and arises somewhat lower than the preceding.

It passes backwards and inwards, beneath the Flexor sublimis, and ascends behind the inner epicondyle of the humerus. In the interval between this process and the olecranon, it lies beneath the Flexor carpi ulnaris, and ascending between the heads of that muscle, in relation with the ulnar nerve, it supplies

FIG. 600.—Arteries of the back of the forearm and hand.



the neighbouring muscles and the elbow-joint, and anastomoses with the inferior profunda, anastomotica magna, and interosseous recurrent arteries (fig. 600).

The **interosseous** (a. interossea communis) (fig. 599) is a short trunk about half an inch in length, and of considerable size, which arises immediately below

the tuberosity of the radius, and, passing backwards to the upper border of the interosseous membrane, divides into two branches, the *anterior* and *posterior interosseous arteries.*

The **anterior interosseous** (a. interossea volaris) (fig. 599) passes down the forearm on the anterior surface of the interosseous membrane. It is accompanied by the interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor profundus digitorum and Flexor longus pollicis, giving off in this situation *muscular* branches, and the *nutrient* arteries of the radius and ulna. At the upper border of the Pronator quadratus, a branch descends beneath that muscle, to anastomose in front of the carpus with the anterior carpal arch. The continuation of the artery passes behind the Pronator quadratus, and, piercing the interosseous membrane, reaches the back of the forearm, and anastomoses with the posterior interosseous artery (fig. 600). It then descends, in company with the terminal portion of the posterior interosseous nerve, to the back of the wrist to join the posterior carpal arch. The anterior interosseous gives off a long, slender branch, the *comes nervi mediani* (a. mediana), which accompanies the median nerve, and gives offsets to its substance; this artery is sometimes much enlarged, and runs with the nerve into the palm of the hand.

The **posterior interosseous** (a. interossea dorsalis) passes backwards through the interval between the oblique ligament and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator brevis and the Extensor ossis metacarpi pollicis, and runs down the back of the forearm between the superficial and deep layers of muscles, to both of which it distributes branches (fig. 600). Where it lies upon the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis, it is accompanied by the posterior interosseous nerve. At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery, and with the posterior carpal arch. It gives off, near its origin, the *interosseous recurrent branch* (a. interossea recurrens), which ascends to the interval between the external epicondyle and olecranon, on or through the fibres of the Supinator brevis, but beneath the Anconeus, and anastomoses with the posterior branch of the superior profunda, and with the posterior ulnar recurrent and anastomotica magna.

The **muscular branches** are distributed to the muscles along the ulnar side of the forearm.

The **anterior ulnar carpal** (ramus carpeus volaris) is a small vessel which crosses the front of the carpus beneath the tendons of the Flexor profundus, and anastomoses with a corresponding branch of the radial artery.

The **posterior ulnar carpal** (ramus carpeus dorsalis) arises immediately above the pisiform bone, and winds backwards beneath the tendon of the Flexor carpi ulnaris; it passes across the dorsal surface of the carpus beneath the Extensor tendons, to anastomose with a corresponding branch of the radial artery, and complete the *posterior carpal arch.* Immediately after its origin, it gives off a small branch, which runs along the ulnar side of the fifth metacarpal bone, and supplies the ulnar side of the dorsal surface of the little finger.

The **profunda branch** (ramus volaris profundus) (fig. 599) passes between the Abductor minimi digiti and Flexor brevis minimi digiti, near their origins; it anastomoses with the termination of the radial artery, and completes the deep palmar arch.

The **superficial palmar arch** (arcus volaris superficialis) (fig. 598) is formed by the ulnar artery in the hand, and is usually completed on the outer side by a branch from the radialis indicis, but sometimes by the superficialis volæ or by a branch from the princeps pollicis of the radial artery. The arch passes across the palm, describing a curve, with its convexity downwards.

Relations.—The superficial palmar arch is covered by the skin, the Palmaris brevis and the palmar fascia. It lies upon the annular ligament, the Flexor brevis and Opponens minimi digiti, the tendons of the Flexor sublimis digitorum, the Lumbrical muscles, and the divisions of the median and ulnar nerves.

Four digital arteries (aa. digitales volares communes) (fig. 598) are given off from the convexity of this arch. The innermost accompanies the inner digital branch of the ulnar nerve, and runs along the ulnar side of the little finger; it is joined by a twig from the deep palmar arch or from the innermost palmar interosseous artery. The three outer run downwards in front of the three inner interosseous spaces, superficial to the corresponding nerves and Lumbrical muscles.

A little above the interdigital clefts they are joined by the palmar interosseous arteries, and by the inferior perforating branches of the dorsal interosseous arteries. Each then divides into *collateral digital arteries* (aa. digitales volares propriæ) for the supply of the contiguous sides of the index, middle, ring, and little fingers. These collateral branches lie behind the corresponding digital nerves; they anastomose freely in the subcutaneous tissue of the finger-tip, and by smaller branches near the interphalangeal joints. Each gives off a couple of dorsal branches which anastomose with the dorsal digital arteries, and supply the soft parts on the back of the second and third phalanges, including the matrix of the finger-nail.

Surface Marking.—The superficial palmar arch is represented by a curved line, starting from the outer side of the pisiform bone, and carried downwards and outwards as far as the base of the thumb, with the convexity towards the fingers. The lowest point of the arch is usually on a level with the lower border of the outstretched thumb.

The deep palmar arch is situated about half an inch nearer to the carpus.

Applied Anatomy.—Wounds of the palmar arches are of special interest, and are always difficult to deal with. When the superficial arch is wounded it is generally possible, enlarging the wound when necessary, to secure the vessel and tie it on both sides of the bleeding point; or in cases where it is found impossible to encircle the vessel with a ligature, a pair of Wells's artery clips may be applied and left on for twenty-four or forty-eight hours. Failing this, the wound may be plugged with gauze and an outside dressing carefully bandaged on. The plug should be allowed to remain untouched for three or four days. It is useless in these cases to ligature one of the arteries of the forearm alone, and indeed simultaneous ligature of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, upon the failure of pressure to arrest hæmorrhage, it is expedient to apply a ligature to the brachial artery. When an incision for deep-seated suppuration in the tendon-sheath is required, the situation of the superficial arch must always be borne in mind, and the incisions placed either above or below it. The position of the digital branches of the artery must also be remembered, and incisions must be made opposite the heads of the metacarpal bones and not between them.

ARTERIES OF THE TRUNK

The Descending Aorta

The **descending aorta** is divided into two portions, the *thoracic* and *abdominal*, in correspondence with the two great cavities of the trunk in which it is situated.

The Thoracic Aorta

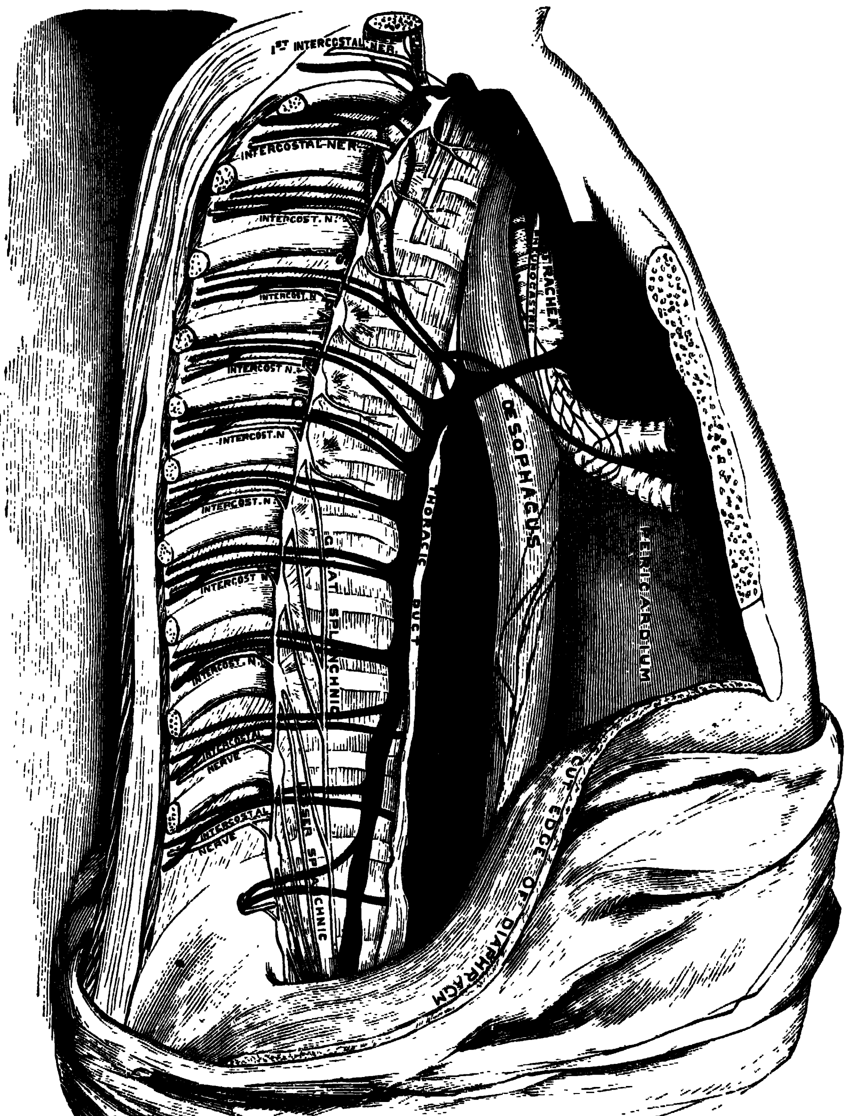
The **thoracic aorta** (aorta thoracalis) is contained in the back part of the posterior mediastinum. It commences at the lower border of the fourth thoracic vertebra, and terminates in front of the lower border of the twelfth at the aortic opening in the Diaphragm. At its commencement, it is situated on the left side of the vertebral column; it approaches the median line as it descends; and, at its termination, lies directly in front of the column. Its direction being influenced by the vertebral column, upon which it rests, the vessel describes a curve which is concave forwards. As the branches given off from it are small, its diminution in size is inconsiderable.

Relations.—It is in relation, *in front*, from above downwards, with the root of the left lung, the pericardium, the œsophagus, and the Diaphragm; *behind*, with the vertebral column, and the azygos minor veins; on the *right side*, with the vena azygos major, and thoracic duct; on the *left side*, with the left pleura and lung. The œsophagus, with its accompanying nerves, lies on the right side of the aorta above; but at the lower part of the thorax it is placed in front of the aorta, and, close to the Diaphragm, is situated to its left side.

Peculiarities.—The aorta is occasionally found to be obliterated at the junction of the arch with the thoracic aorta, just below the ductus arteriosus. Whether this is the result of disease, or of congenital malformation, is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation. The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the 'Pathological Transactions,' vols. viii. and x. In the former, Sydney Jones thus sums up the detailed description of the anastomosing vessels: 'The principal

communications by which the circulation was carried on, were—Firstly, the internal mammary, anastomosing with the intercostal arteries, with the phrenic of the abdominal aorta by means of the musculo-phrenic and comes nervi phrenici, and largely with the deep epigastric. Secondly, the superior intercostal, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyroid, by means of a branch about the size of an ordinary radial, forming a communication with the first aortic intercostal. Fourthly,

Fig. 601.—Thoracic aorta from right side.



the transversalis colli, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest were large, and anastomosed freely with the lateral branches of the intercostals.' In the second case Wood describes the anastomoses in a somewhat similar manner, adding the remark, that 'the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis ; while the supply to the lower extremities had passed through the internal mammary and epigastrics.'

In a few cases an apparently double descending thoracic aorta has been found, the two vessels lying side by side, and eventually fusing to form a single tube in the lower part of the thorax or in the abdomen. One of them is the aorta, the other represents a dissecting aortic aneurysm which has become canalised, opening above and below into the true aorta, and at first sight presenting the appearances of a proper blood-vessel.

Applied Anatomy.—The effects likely to be produced by aneurysm of the thoracic aorta, a disease of common occurrence, must now be considered. When the great depth of the vessel from the surface, and the number of important structures which surround it on every side are remembered, it may easily be conceived what a variety of obscure symptoms are likely to arise from disease of this part of the arterial system, and how they may be mistaken for those of other affections. Aneurysm of the thoracic aorta most usually extends backwards, along the left side of the vertebral column, producing absorption of the bodies of the vertebræ, with curvature of the column; while the irritation or pressure on the spinal cord will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumour may project backwards on either side of the vertebral column, beneath the integument, as a pulsating swelling, simulating abscess connected with diseased bone; or it may displace the œsophagus, and compress the lungs on one or the other side. If the tumour extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; it may displace or compress the œsophagus, causing pain and difficulty of swallowing, as in stricture of that tube; and ultimately even open into it by ulceration, producing fatal hæmorrhage. If the disease extend to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity, or into the trachea or lung; and lastly, it may open into the posterior mediastinum. Pressure on one of the bronchi, usually the left, will cause cough, and in time set up bronchiectasis; pressure on the left pulmonary plexus has been said to give rise to asthmatic attacks. Of late years, the diagnosis of thoracic aneurysm has been much facilitated by the employment of the *x*-rays, by means of which the outline of the sac may be demonstrated.

Branches of the Thoracic Aorta

Visceral	Pericardial. Bronchial. Œsophageal. Mediastinal.	Parietal	Intercostal. Subcostal. Superior phrenic.

The **pericardial** (rami pericardiaci) are a few small vessels, irregular in their origin, distributed to the pericardium.

The **bronchial arteries** (aa. bronchiales) vary in number, size, and origin. There is as a rule only one *right bronchial artery*, which arises from the first aortic intercostal, or from the upper left bronchial artery. The *left bronchial arteries* are usually two in number, and arise from the thoracic aorta. The upper left bronchial arises opposite the fifth thoracic vertebra, the lower just below the level of the left bronchus. Each vessel runs on the back part of its bronchus, dividing and subdividing along the bronchial tubes, supplying them, the cellular tissue of the lungs, the bronchial glands, and the œsophagus.

The **œsophageal arteries** (aa. œsophageæ), usually four or five in number, arise from the front of the aorta, and pass obliquely downwards to the œsophagus, forming a chain of anastomoses along that tube, anastomosing with the œsophageal branches of the inferior thyroid arteries above, and with ascending branches from the phrenic and gastric arteries below.

The **mediastinal branches** (rami mediastinales) are numerous small vessels which supply the glands and loose areolar tissue in the posterior mediastinal space.

Intercostal arteries (aa. intercostales). There are usually nine pairs of aortic intercostal arteries. They arise from the back of the aorta, and are distributed to the nine lower intercostal spaces, the first two spaces being supplied by the superior intercostal branch of the subclavian. The *right* aortic intercostals are longer than the left, on account of the position of the aorta on the left side of the vertebral column; they pass across the bodies of the vertebræ behind the œsophagus, thoracic duct, and vena azygos major, and are covered by the right lung and pleura. The *left* aortic intercostals run backwards on the sides of the vertebræ and are covered by the left lung and pleura; the two upper vessels are crossed by the left superior intercostal vein, the lower vessels by the azygos minor veins. The further course of the intercostal arteries is practically the same on both sides. Opposite the heads of the ribs the sympathetic cord passes downwards in front of them, and the splanchnic nerves also descend in front of the lower arteries. Each artery crosses

the corresponding intercostal space obliquely towards the angle of the upper rib, and thence is continued forward in the subcostal groove. It is placed at first between the pleura and the posterior intercostal membrane, then it pierces this membrane, and lies between it and the External intercostal muscle as far as the rib angle ; from this onward it runs between the External and Internal intercostal muscles, and anastomoses in front with the anterior intercostal branch of the internal mammary or musculo-phrenic. Each artery is accompanied by a vein and a nerve, the former being above and the latter below the artery, except in the upper spaces, where the nerve is at first above the artery. The highest aortic intercostal artery anastomoses with the superior intercostal, and may form the chief supply of the second intercostal space. The two lower intercostal arteries are continued anteriorly from the intercostal spaces into the abdominal wall, and anastomose with the subcostal, superior epigastric and lumbar arteries.

Each intercostal artery gives off the following branches :

Posterior or dorsal.	Collateral intercostal.
Muscular.	Lateral cutaneous.

The *posterior* or *dorsal branch* (ramus posterior) runs with the posterior division of a spinal nerve and passes backwards through a small opening which is bounded above and below by the necks of the ribs and adjacent transverse processes, internally by the vertebral body, and externally by the anterior costo-transverse ligament. It gives off a *spinal branch*, which enters the spinal canal through the intervertebral foramen and is distributed to the spinal cord and its membranes, and to the bodies of the vertebræ, in the same manner as the lateral spinal branches from the vertebral.

The *collateral intercostal branch* comes off from the intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with the anterior intercostal branch of the internal mammary.

Muscular branches (rami musculares) are given to the Intercostal and Pectoral muscles and to the Serratus magnus ; they anastomose with the superior and long thoracic branches of the axillary artery.

The *lateral cutaneous branches* (rami cutanei laterales) accompany the lateral cutaneous branches of the intercostal nerves, and divide into anterior and posterior branches.

Mammary branches are given off by the intercostal arteries in the third, fourth, and fifth spaces. They supply the mammary gland, and increase considerably in size during the period of lactation.

Applied Anatomy.—The position of the intercostal vessels should be borne in mind in performing the operation of paracentesis thoracis. The puncture should never be made nearer the middle line posteriorly than the angle of the rib, as the artery crosses the space internal to this point. In the lateral portion of the chest, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

The **subcostal arteries**, so named because they lie below the last ribs, constitute the lowest pair of branches derived from the thoracic aorta, and are in series with the intercostal arteries. Each passes along the lower border of the twelfth rib behind the kidney and in front of the Quadratus lumborum muscle, and is accompanied by the twelfth thoracic nerve. It then pierces the posterior aponeurosis of the Transversalis abdominis, and, passing forward between this muscle and the Internal oblique, anastomoses with the superior epigastric, lower intercostal, and lumbar arteries.

The **superior phrenic branches** (aa. phrenicæ superiores) are small branches arising from the lower part of the thoracic aorta ; they are distributed to the posterior part of the upper surface of the Diaphragm, and anastomose with the musculo-phrenic and comes nervi phrenici arteries.

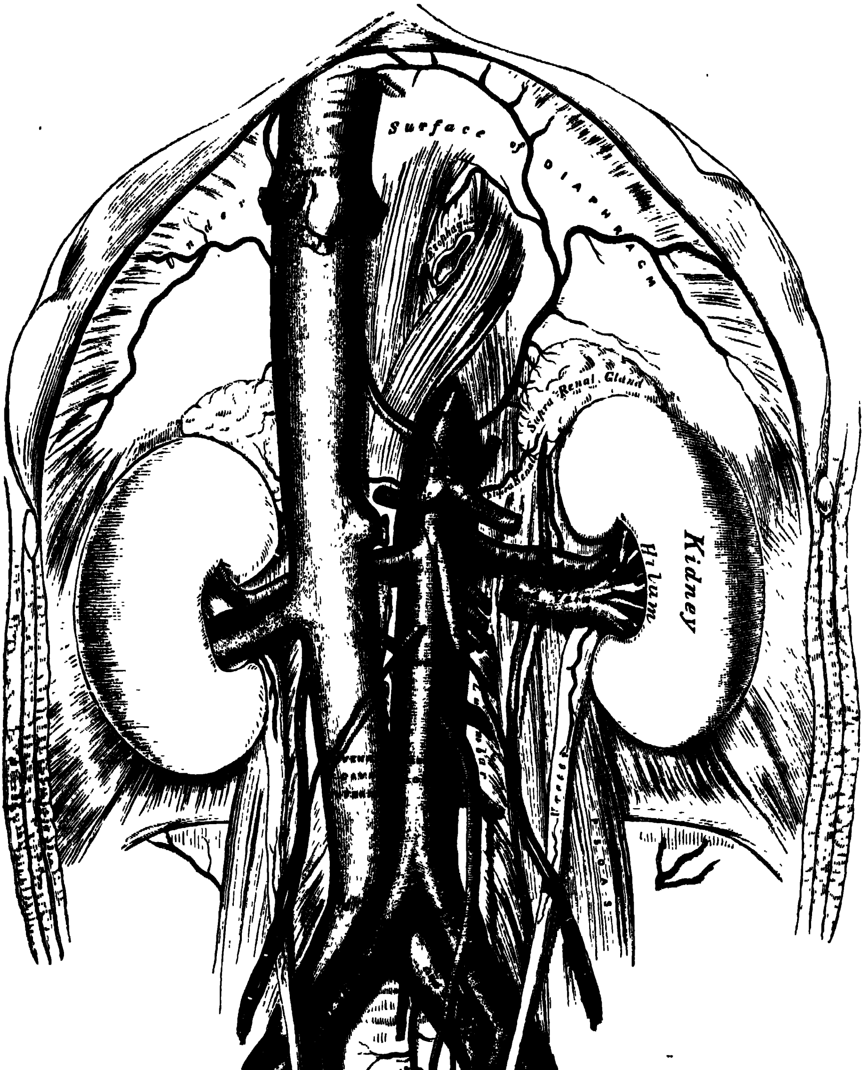
A small *aberrant* artery is sometimes found arising from the right side of the thoracic aorta near the origin of the right bronchial. It passes upwards and to the right behind the trachea and the œsophagus, and may anastomose with the right superior intercostal artery. It represents the remains of the right dorsal aortic trunk, and in a small proportion of cases is enlarged to form the first part of the right subclavian artery.

The Abdominal Aorta (fig. 602)

The **abdominal aorta** (aorta abdominalis) commences at the aortic opening of the Diaphragm, in front of the lower border of the body of the

last thoracic vertebra, and, descending a little to the left side of the vertebral column, terminates on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line,* by dividing into the two common

FIG. 602.—The abdominal aorta and its branches.



iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebræ, the curve which it describes is convex forwards, the summit of the convexity corresponding to the third lumbar vertebra.

Relations.—The abdominal aorta is covered, *in front*, by the lesser omentum and stomach, behind which are the branches of the cœliac axis, and the solar plexus; below these, by the splenic vein, the pancreas, the left renal vein, the third portion of the duodenum, the mesentery, and aortic plexus. *Behind*, it is separated from the lumbar vertebræ and intervening discs by the anterior

* Lord Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it 'either absolutely, or almost absolutely, mesial in 15, while in 13 it deviated more or less to the left, and in two was slightly to the right.'—*System of Surgery*, edited by T. Holmes, 2nd ed. vol. v. p. 652.

common ligament and left lumbar veins. On the *right side* it is in relation above with the vena azygos major, receptaculum chyli, thoracic duct, and the right crus of the Diaphragm—the last separating it from the upper part of the inferior vena cava, and from the right semilunar ganglion; the inferior vena cava is in contact with the aorta below. On the *left side* are the left crus of the Diaphragm, the left semilunar ganglion, the fourth part of the duodenum, and some coils of the small intestine.

Surface Marking.—In order to map out the abdominal aorta on the surface of the abdomen, a line must be drawn from the middle line of the body, on a level with the seventh costal cartilages, downwards and slightly to the left, so that it just skirts the umbilicus, to a zone drawn round the body opposite the highest point of the crest of the ilium. This point is generally half an inch below and to the left of the umbilicus, but as the position of this structure varies with the obesity of the individual, it is not a reliable landmark for the situation of the bifurcation of the aorta.

Applied Anatomy.—The abdominal aorta may be the seat of an aneurysm either at its upper part, close to and often involving the cœliac axis, or at its lower part, near the bifurcation. Occasionally aneurysms are met with on some of the branches of the aorta, the mesenteric or splenic, quite independent of the main trunk.

When an aneurysmal sac is connected with the back part of the abdominal aorta, it usually produces absorption of the bodies of the vertebræ, and forms a pulsating tumour that presents itself in the left hypochondriac or epigastric regions, and is accompanied by symptoms of disturbance in the alimentary canal. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumour pressing on or displacing the branches of the solar plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumour: hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (generally of the left side). This form of aneurysm usually bursts into the peritoneal cavity, or behind the peritoneum, in the left hypochondriac region; or it may form a large aneurysmal sac, extending down as low as Poupart's ligament.

When an aneurysmal sac is connected with the front of the aorta near the cœliac axis, it forms a pulsating tumour in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the alimentary canal, as sickness, dyspepsia, or constipation, and accompanied by pain, which is constant, but nearly always fixed, in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurysm may burst into the peritoneal cavity, behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it rarely extends backwards so as to affect the spine.

Occlusion of the abdominal aorta by thrombosis or embolism is rare, but produces very severe symptoms when it does occur. The patient complains of intense pain in the legs; pallor of the legs, followed by coldness, lividity, paresis, paralysis, and finally gangrene, are likely to succeed, death usually supervening within a fortnight.

The abdominal aorta has been tied several times, and although none of the patients permanently recovered, still, as one case lived forty-eight days, the possibility of the re-establishment of the circulation may be considered to be proved.

Collateral Circulation.—The collateral circulation would be carried on by the anastomoses between the internal mammary and the deep epigastric; by the free communication between the superior and inferior mesenterics, if the ligature were placed above the latter vessel; or by the anastomosis between the inferior mesenteric and the internal pudic, when (as is more common) the point of ligature is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac.

Branches of the Abdominal Aorta

The branches of the abdominal aorta may be divided into three sets visceral, parietal, and terminal.

Visceral Branches.	*Parietal Branches.*
Cœliac axis { Gastric. Hepatic. Splenic.	Inferior phrenic. Lumbar. Middle sacral.
Superior mesenteric.	
Inferior mesenteric.	
Suprarenal.	
Renal.	*Terminal Branches.*
Spermatic or Ovarian.	Common iliacs.

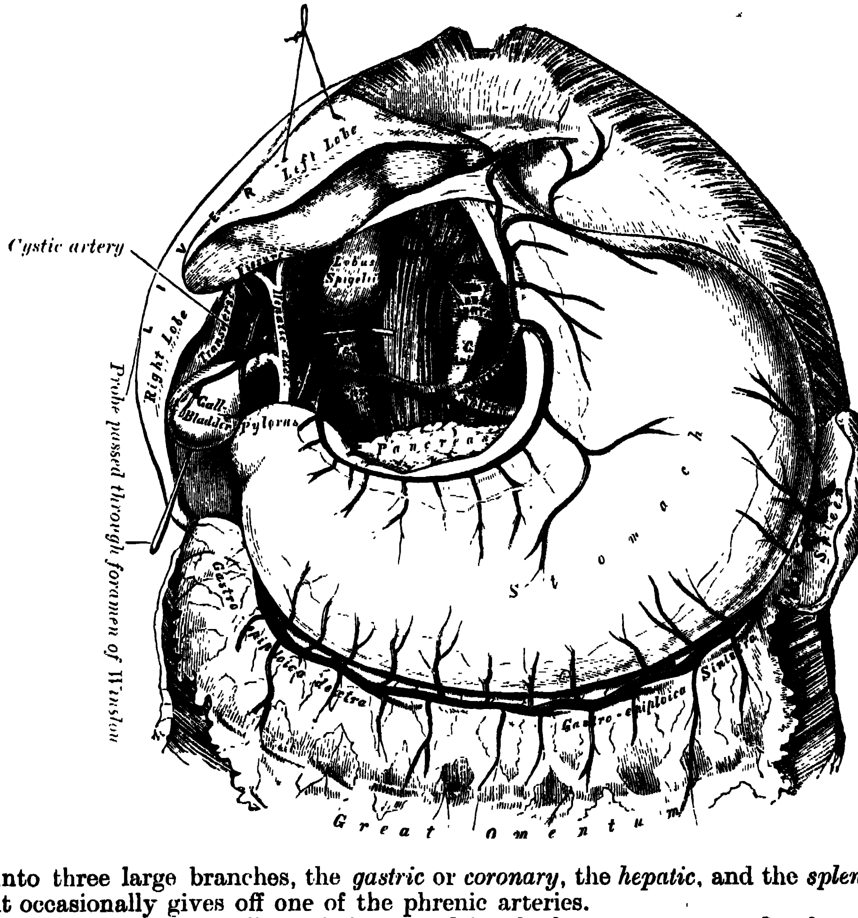
Of the visceral branches, the cœliac axis and the superior and inferior mesenteric arteries are single, while the suprarenal, renal, and spermatic or

ovarian are paired. The inferior phrenic and lumbar are paired parietal branches; the middle sacral is unpaired.

Cœliac Axis (fig. 603)

The **cœliac axis artery** (a. cœliaca) is a short thick trunk, about half an inch in length, which arises from the aorta, close to the margin of the opening in the Diaphragm, and, passing nearly horizontally forwards, divides

Fig. 603.—The cœliac axis and its branches; the liver has been raised, and the lesser omentum and anterior layer of the great omentum removed.



into three large branches, the *gastric* or *coronary*, the *hepatic*, and the *splenic*; it occasionally gives off one of the phrenic arteries.

Relations.—The cœliac axis is covered by the lesser omentum. On the *right side*, it is in relation with the right semilunar ganglion and the lobus Spigelii; on the *left side*, with the left semilunar ganglion and cardiac end of the stomach. *Below*, it is in relation to the upper border of the pancreas, and the splenic vein.

1. The **gastric** or **coronary artery** (a. gastrica sinistra), the smallest of the three branches of the cœliac axis, passes upwards and to the left, behind the lesser sac of the peritoneum, to the cardiac orifice of the stomach, where it distributes branches to the œsophagus (rami oesophagei), which anastomose with the aortic œsophageal arteries; others supply the cardiac end of the stomach, anastomosing with branches of the splenic artery. It then runs from left to right, along the lesser curvature of the stomach to the pylorus, between the layers of the lesser omentum; it gives branches to both surfaces of the organ and at its termination anastomoses with the pyloric branch of the hepatic.

2. The **hepatic artery** (a. hepatica), in the adult, is intermediate in size between the gastric and splenic; in the fœtus, it is the largest of the

three branches of the cœliac axis. It is first directed forwards and to the right, to the upper margin of the first part of the duodenum, forming the lower boundary of the foramen of Winslow. It then passes upwards between the layers of the lesser omentum, and in front of the foramen of Winslow, to the transverse fissure of the liver, where it divides into two branches, right and left, which supply the corresponding lobes of that organ, accompanying the ramifications of the portal vein and hepatic ducts. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the common bile-duct and portal vein, the duct lying to the right of the artery, and the vein behind.

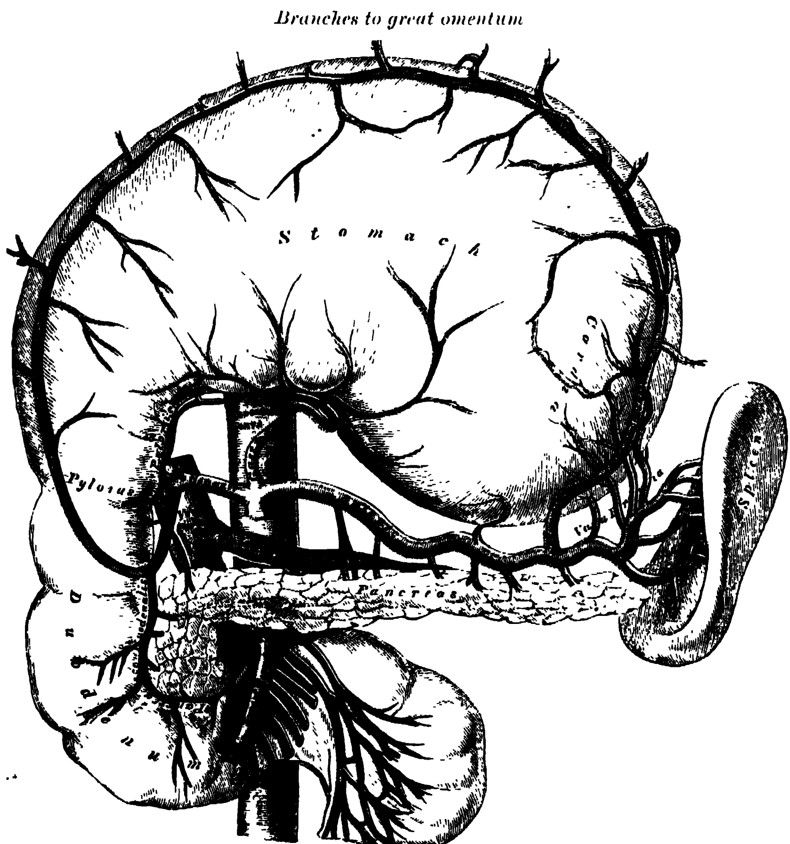
Its branches are:

Pyloric.
Gastro-duodenal { Right gastro-epiploic. / Superior pancreatico-duodenal.
Cystic.

The **pyloric** (a. gastrica dextra) arises from the hepatic, above the pylorus, descends to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches, and anastomosing with the gastric branches of the coronary artery.

The **gastro-duodenal** (a. gastroduodenalis) (fig. 604) is a short but large branch, which descends, near the pylorus, behind the first portion of the duodenum, and

Fig. 604.—The cœliac axis and its branches; the stomach has been raised and the peritoneum removed.



divides at the lower border of this viscus into two branches, the *right gastro-epiploic* and the *superior pancreatico-duodenal*. Previous to its division it gives off two

or three small inferior pyloric branches to the pyloric end of the stomach and pancreas.

The **right gastro-epiploic** (a. gastroepiploica dextra) runs from right to left along the greater curvature of the stomach, between the layers of the great omentum, anastomosing about the middle of the lower border of the stomach with the ~~right~~ gastro-epiploic from the splenic artery. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, while others descend to supply the great omentum.

The **superior pancreatico-duodenal** (a. pancreaticoduodenalis superior) descends between the contiguous margins of the duodenum and pancreas. It supplies both these organs, and anastomoses with the inferior pancreatico-duodenal branch of the superior mesenteric artery, and with the pancreatic branches of the splenic.

The **cystic** (a. cystica) (fig. 603), usually a branch of the right hepatic, passes downwards and forwards along the neck of the gall-bladder, and divides into two branches, one of which ramifies on its free surface, the other between it and the surfaces of the liver.

3. The **splenic artery** (a. lienalis), in the adult, is the largest of the three branches of the cœliac axis, and is remarkable for the extreme tortuosity of its course. It passes horizontally to the left side, behind the peritoneum and along the upper border of the pancreas, accompanied by the splenic vein, which lies below it; it crosses in front of the upper part of the left kidney, and, on arriving near the spleen, divides into branches, some of which enter the hilus of that organ between the two layers of the lieno-renal ligament to be distributed to its structure; some are distributed to the pancreas, while others pass to the greater curvature of the stomach between the layers of the gastro-splenic omentum. Its branches are:

Pancreatic. Vasa brevia.
Left gastro-epiploic.

The **pancreatic** (rami pancreatici) are numerous small branches derived from the splenic as it runs behind the upper border of the pancreas, supplying its middle and left parts. One of these, larger than the rest, is sometimes given off from the splenic near the left extremity of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the **pancreatica magna**. These vessels anastomose with the pancreatic branches of the pancreatico-duodenal arteries, derived from the hepatic on the one hand and the superior mesenteric on the other.

The **vasa brevia** (aa. gastricæ breves) consist of from five to seven small branches, which arise either from the end of the splenic artery, or from its terminal branches. They pass from left to right, between the layers of the gastro-splenic omentum, and are distributed to the greater curvature of the stomach, anastomosing with branches of the coronary and left gastro-epiploic arteries.

The **left gastro-epiploic** (a. gastroepiploica sinistra), the largest branch of the splenic, runs from left to right along the greater curvature of the stomach, between the layers of the great omentum, and anastomoses with the right gastro-epiploic. In its course it distributes several ascending branches to both surfaces of the stomach; others descend to supply the omentum.

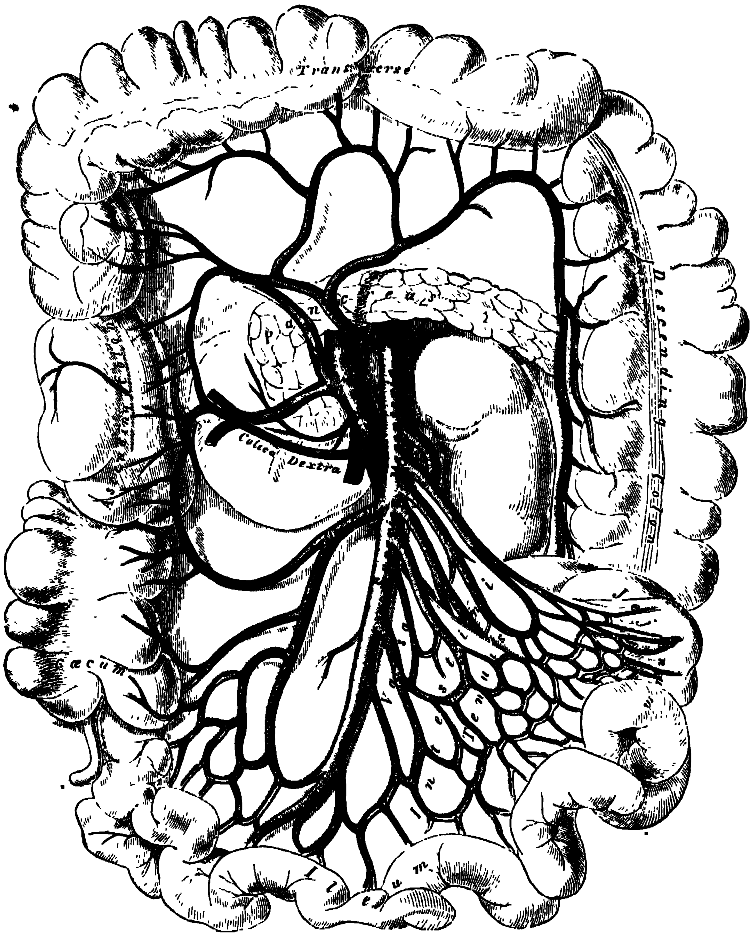
Applied Anatomy.—Embolism of branches of the splenic artery is tolerably common in heart disease, the embolus coming from the left side of the heart. It is characterised by the occurrence of a sudden sharp pain or 'stitch' in the splenic region, with subsequent local enlargement of the spleen from the formation of an infarct in its substance.

Superior Mesenteric Artery (fig. 605)

The **superior mesenteric artery** (a. mesenterica superior) is a vessel of large size which supplies the whole length of the small intestine, except the first part of the duodenum: it also supplies the cæcum and the ascending and transverse parts of the colon. It arises from the front of the aorta, about half an inch below the cœliac axis, and is covered at its origin by the splenic vein and the neck of the pancreas. It passes downwards and forwards, in front of the lower part of the head of the pancreas and third portion of the duodenum, and descends between the layers of the mesentery to the right

iliac fossa, where, considerably diminished in size, it anastomoses with one of its own branches, viz. the ileo-colic. In its course it forms an arch, the convexity of which is directed forwards and downwards to the left side,

FIG. 605.—The superior mesenteric artery and its branches.



the concavity backwards and upwards to the right. It is accompanied by the superior mesenteric vein, which lies to its right side, and it is surrounded by the superior mesenteric plexus of nerves. Its branches are :

Inferior pancreatico-duodenal.	Ileo-colic.
Vasa intestini tenuis.	Right colic.
Middle colic.	

The **inferior pancreatico-duodenal** (a. pancreaticoduodenalis inferior) is given off from the superior mesenteric or from its first intestinal branch, opposite the upper border of the third part of the duodenum. It courses to the right between the head of the pancreas and duodenum, and then ascends to anastomose with the superior pancreatico-duodenal artery. It distributes branches to the head of the pancreas and to the second and third portions of the duodenum.

The **vasa intestini tenuis** (aa. intestinales) arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum and ileum. They run parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with adjacent branches, forming a series of arches, the convexities of which are directed towards the intestine. From this first set of arches branches

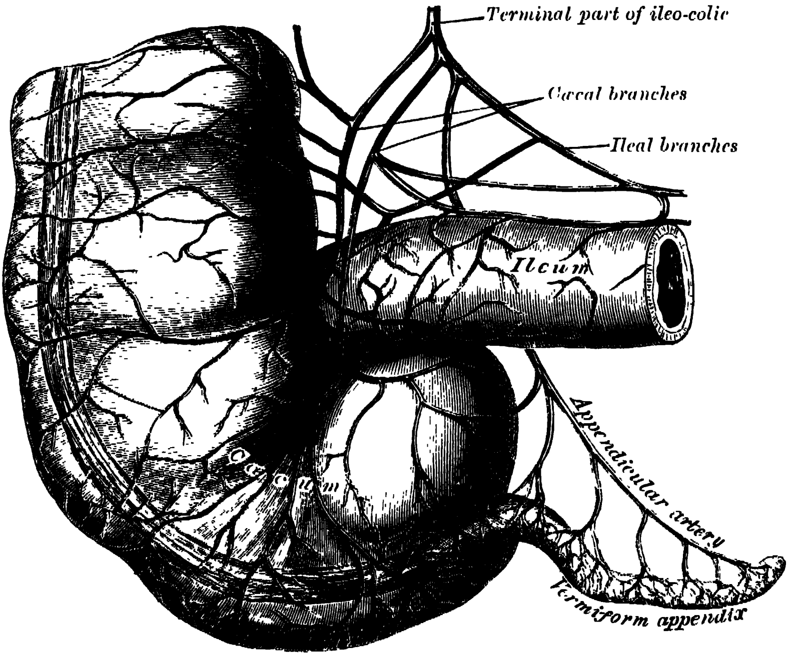
arise, which unite with similar branches from above and below, and thus a second series of arches is formed; and from these latter, a third, a fourth, or even a fifth series of arches may be constituted, diminishing in size the nearer they approach the intestine. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying between its coats. Throughout their course small branches are given off to the lymphatic glands and other structures between the layers of the mesentery.

The **ileo-colic** (a. ileocolica) is the lowest branch given off from the concavity of the superior mesenteric artery. It passes downwards and to the right behind the peritoneum towards the right iliac fossa, where it divides into two branches. Of these the inferior division anastomoses with the termination of the superior mesenteric artery; the superior division anastomoses with the right colic.

The descending branch of the ileo-colic runs towards the upper border of the ileo-cæcal junction and supplies the following branches:

(*a*) *colic*, which passes upwards on the ascending colon; (*b*) *anterior and posterior cæcal*, which are distributed to the front and back of the cæcum; (*c*) *appendicular* (a. appendicularis) which passes downwards behind the termination of the ileum and

FIG. 606.—Arteries of cæcum and vermiform appendix.



runs in the meso-appendix close to its free margin for the supply of the vermiform appendix; and (*d*) *ileal*, which runs upwards and to the left on the lower part of the ileum, and anastomoses with the termination of the superior mesenteric (fig. 606).

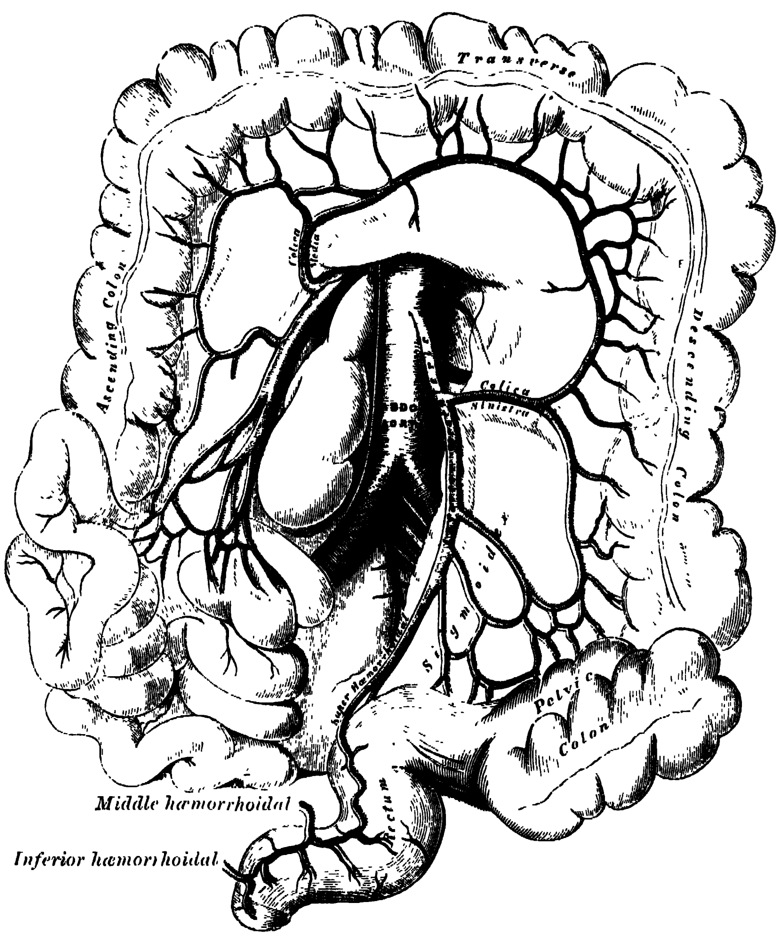
The **right colic** (a. colica dextra) arises from about the middle of the concavity of the superior mesenteric artery; it passes to the right behind the peritoneum, and in front of the right spermatic or ovarian vessels, the right ureter and the Psoas, towards the middle of the ascending colon, where it divides into a descending branch, which anastomoses with the ileo-colic, and an ascending branch, which anastomoses with the middle colic. These branches form arches, from the convexity of which vessels are distributed to the ascending colon.

The **middle colic** (a. colica media) arises from the upper part of the concavity of the superior mesenteric, and, passing downwards and forwards between the layers of the transverse mesocolon, divides into two branches, right and left; the former anastomoses with the right colic; the latter with the left colic, a branch of the inferior mesenteric. From the arches thus formed, branches are distributed to the transverse colon.

INFERIOR MESENTERIC ARTERY (fig. 607)

The **inferior mesenteric artery** (a. mesenterica inferior) supplies the descending, iliac, and pelvic portions of the colon, and the greater part of the rectum. It is smaller than the superior mesenteric, and arises from the front and towards the left side of the aorta, between one and two inches above the division into the common iliacs. It passes downwards to the left iliac fossa, and then descends, between the layers of the pelvic mesocolon, into the pelvis, under the name of the *superior hæmorrhoidal artery*. It lies at first in

FIG. 607.—The inferior mesenteric artery and its branches.



close relation with the left side of the aorta, and then passes as the superior hæmorrhoidal in front of the left common iliac artery. Its branches are:

Left colic. Sigmoid. Superior hæmorrhoidal.

The **left colic** (a. colica sinistra) passes behind the peritoneum, in front of the left kidney, to reach the descending colon; it divides into an ascending branch which runs between the two layers of the transverse mesocolon and anastomoses with the middle colic, and a descending branch which anastomoses with the upper sigmoid artery. From the arches formed by these anastomoses branches are distributed to the descending colon.

The **sigmoid arteries** (aa. sigmoideæ) run obliquely downwards and outwards behind the peritoneum and in front of the Psoas and ureter to the iliac colon. They divide into branches which supply the lower part of the descending colon, the

iliac colon, and the pelvic colon; anastomosing above with the left colic, and below with the superior hæmorrhoidal artery.

The **superior hæmorrhoidal** (a. hæmorrhoidalis superior), the continuation of the inferior mesenteric, descends into the pelvis between the layers of the mesentery of the pelvic colon, crossing, in its course, the ureter and left common iliac vessels. It divides, opposite the third sacral vertebra, into two branches, which descend one on either side of the rectum, and about four or five inches from the anus break up into several small branches. These pierce the muscular coat of the bowel and run downwards, as straight vessels, placed at regular intervals from each other in the wall of the gut between its muscular and mucous coats, to the level of the internal sphincter; here they form a series of loops around the lower end of the rectum, and communicate with the middle hæmorrhoidal branches of the internal iliac, and with the inferior hæmorrhoidal branches of the internal pudic.

Applied Anatomy.—Embolism of the mesenteric arteries produces acute and severe symptoms, of which the chief are abdominal pain and tenderness, nausea and vomiting, diarrhœa or constipation, and intestinal obstruction; blood is found in the stools of nearly half the patients.

Suprarenal Arteries (fig. 602)

The **suprarenal arteries** (aa. suprarenales) are two small vessels which arise, one from either side of the aorta, opposite the superior mesenteric artery. They pass obliquely upwards and outwards, over the crura of the Diaphragm, to the under surface of the suprarenal glands, to which they are distributed, anastomosing with suprarenal branches of the inferior phrenic and renal arteries. In the adult these arteries are of small size; in the fœtus they are as large as the renal arteries.

Renal Arteries (fig. 602)

The **renal arteries** (aa. renales) are two large trunks, which arise from the sides of the aorta, immediately below the superior mesenteric artery. Each is directed outwards across the crus of the Diaphragm, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava. The left is somewhat higher than the right. Before reaching the hilus of the kidney, each artery divides into four or five branches; the greater number of these lie between the renal vein and ureter, the vein being in front, the ureter behind, but one branch is usually situated behind the ureter. Each vessel gives off some small branches to the suprarenal gland, the ureter, and the surrounding cellular tissue and muscles. One or two accessory renal arteries are frequently found, more especially on the left side: they usually arise from the aorta, and may come off above or below the main artery, the former being the more common position. Instead of entering the kidney at the hilus, they usually pierce the upper or lower part of the gland.

Spermatic and Ovarian Arteries

The **spermatic arteries** (aa. spermaticæ internæ) (fig. 602) are distributed to the testes. They are two slender vessels of considerable length, and arise from the front of the aorta a little below the renal arteries. Each artery passes obliquely outwards and downwards behind the peritoneum, resting on the Psoas magnus, the right spermatic lying in front of the inferior vena cava and behind the terminal part of the ileum, the left behind the iliac colon. It crosses obliquely over the ureter and the lower part of the external iliac artery to reach the internal abdominal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous, and divides into several branches. Two or three of these accompany the vas deferens, and supply the epididymis, anastomosing with the artery of the vas deferens; others pierce the back part of the tunica albuginea, and supply the substance of the testis. The spermatic artery supplies one or two small branches to the ureter, and in the inguinal canal gives one or two twigs to the Cremaster.

The **ovarian arteries** (aa. ovaricæ) are the corresponding arteries in the female to the spermatic in the male. They supply the ovaries, are shorter than the spermatic, and do not pass out of the abdominal cavity. The origin and course of the first part of each artery are the same as those of the spermatic, but on arriving at the margin of the pelvis the ovarian artery passes inwards, between the two layers of the broad ligament of the uterus, to be distributed to the ovary. Small branches are given to the ureter and the Fallopian tube; and one passes on to the side of the uterus, and anastomoses with the uterine artery. Other offsets are continued along the round ligament, through the inguinal canal, to the integument of the labium and groin.

At an early period of fœtal life, when the testes or ovaries lie by the side of the vertebral column, below the kidneys, the spermatic or ovarian arteries are short; but as these organs descend into the scrotum or pelvis, the arteries become gradually lengthened.

Inferior Phrenic Arteries (fig. 602)

The **inferior phrenic arteries** (aa. phrenicæ inferiores) are two small vessels, which present much variety in their origin. They may arise separately from the front of the aorta, immediately above the cœliac axis, or by a common trunk, which may spring either from the aorta or from the cœliac axis. Sometimes one is derived from the aorta, and the other from one of the renal arteries. In only one out of thirty-six cases examined did these arteries arise as two separate vessels from the aorta. They diverge from one another across the crura of the Diaphragm, and then pass obliquely upwards and outwards upon its under surface. The left phrenic passes behind the œsophagus, and runs forwards on the left side of the œsophageal opening. The right phrenic passes behind the inferior vena cava, and ascends along the right side of the aperture which transmits that vein. Near the back part of the central tendon each vessel divides into an internal and an external branch. The internal branch runs forwards, supplying the Diaphragm, and anastomosing with its fellow of the opposite side, and with the musculo-phrenic and comes nervi phrenici branches of the internal mammary. The external branch passes towards the side of the thorax, and anastomoses with the lower intercostal arteries, and with the musculo-phrenic. The internal branch of the right phrenic gives off a few vessels to the inferior vena cava; and the left one, some branches to the œsophagus. Each vessel also sends glandular branches to the suprarenal gland of its own side. The spleen and the liver also receive a few branches from the left and right vessels respectively.

Lumbar Arteries

The **lumbar arteries** (aa. lumbales) are in series with the intercostals. They are usually four in number on either side, and arise from the back part of the aorta, opposite the bodies of the upper four lumbar vertebræ. A fifth pair, small in size, is occasionally present: it arises from the middle sacral artery. They run outwards and backwards on the bodies of the lumbar vertebræ, behind the sympathetic cord, to the intervals between the adjacent transverse processes, and are then continued into the abdominal wall. The arteries of the right side pass behind the inferior vena cava, and the upper two on each side run behind the corresponding crus of the Diaphragm. The arteries of both sides pass beneath the tendinous arches which give origin to the Psoas magnus, and are then continued behind this muscle and the lumbar plexus. They now cross the Quadratus lumborum, the upper three arteries running behind, the last usually in front of the muscle. At the outer border of the Quadratus lumborum they pierce the posterior aponeurosis of the Transversalis abdominis and are carried forwards between this muscle and the Internal oblique. They anastomose with the lower intercostals, the subcostal, the ilio-lumbar, the deep circumflex iliac, and the deep epigastric arteries.

Branches.—In the interval between the adjacent transverse processes each lumbar artery gives off a *dorsal branch* (ramus dorsalis) which is continued backwards between

the transverse processes and is distributed to the muscles and skin of the back. It gives off a *spinal branch* (ramus spinalis) which enters the spinal canal and is distributed in a similar manner to the lateral spinal branches of the vertebral (page 660). *Muscular branches* are supplied from each lumbar artery and from its dorsal branch to the neighbouring muscles.

Middle Sacral Artery

The **middle sacral artery** (a. sacralis media) is a small vessel, which arises from the back of the aorta, at or a little above its bifurcation. It descends upon the last lumbar vertebra, and along the middle line of the front of the sacrum, to the upper part of the coccyx ; it anastomoses with the lateral sacral arteries, and terminates in the coccygeal body. From it, minute branches pass to the posterior surface of the rectum. Other branches are given off on each side, which anastomose with the lateral sacral arteries, and send offsets into the anterior sacral foramina. It is crossed by the left common iliac vein, and is accompanied by a pair of venæ comites ; these unite to form a single vessel, which opens into the left common iliac vein.

Common Iliac Arteries (fig. 602)

The abdominal aorta divides, on the left side of the body of the fourth lumbar vertebra, into the two **common iliac arteries.** Each is about two inches in length. They diverge from the termination of the aorta, pass downwards and outwards to the margin of the pelvis, and divide, opposite the intervertebral disc between the last lumbar vertebra and the sacrum, into two branches, the *external* and *internal iliac arteries*: the former supplies the lower extremity; the latter, the viscera and parietes of the pelvis.

The **right common iliac** (fig. 608) is somewhat longer than the left, and passes more obliquely across the body of the last lumbar vertebra. *In front* of it are the peritoneum, the small intestines, branches of the sympathetic nerves, and, at its point of division, the ureter. *Behind*, it is separated from the bodies of the fourth and fifth lumbar vertebræ, and the intervening disc, by the two common iliac veins. On its *outer side*, it is in relation, above, with the inferior vena cava and the right common iliac vein; and, below, with the Psoas magnus muscle. On its *inner side*, above, is the left common iliac vein.

The **left common iliac** is in relation, *in front*, with the peritoneum, the small intestines, branches of the sympathetic nerves, and the superior hæmorrhoidal artery ; and is crossed at its point of bifurcation by the ureter. It rests on the bodies of the fourth and fifth lumbar vertebræ, and the intervening disc. The left common iliac vein lies partly on the *inner side* of, and partly behind the artery ; on its *outer side*, the artery is in relation with the Psoas magnus muscle.

Branches.—The common iliac arteries give off small branches to the peritoneum, Psoas magnus, ureters, and the surrounding cellular tissue, and occasionally give origin to the ilio-lumbar, or accessory renal arteries.

Peculiarities.—The *point of origin* varies according to the bifurcation of the aorta. In three-fourths of a large number of cases, the aorta bifurcated either upon the fourth lumbar vertebra, or upon the disc between it and the fifth ; the bifurcation being, in one case out of nine, below, and in one out of eleven above this point. In about eighty per cent. of the cases the aorta bifurcated within half an inch above or below the level of the crest of the ilium : more frequently below than above.

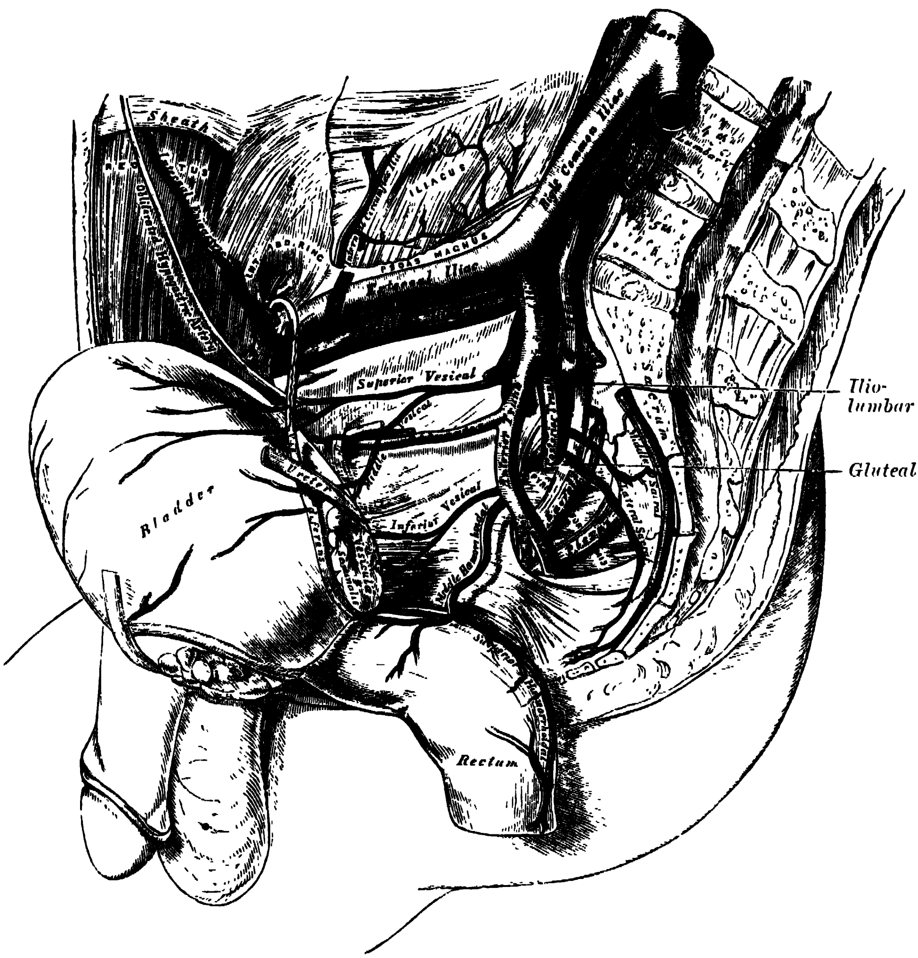
The *point of division* is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum ; being above that point in one case out of eight, and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

The *relative lengths*, also, of the two common iliac arteries vary. The right common iliac was the longer in sixty-three cases; the left in fifty-two ; while they were equal in fifty-three. The length of the arteries varied, in five-sevenths of the cases examined, from an inch and a half to three inches ; in about half of the remaining cases the artery was longer, and in the other half, shorter: the minimum length being less than half an inch, the maximum four and a half inches. In rare instances, the right common iliac has been found wanting, the external and internal iliacs arising directly from the aorta.

Surface Marking.—Draw a line between the highest points of the iliac crests: this is usually half an inch below the umbilicus; in this line take a point half an inch to the left of the middle line. From this draw two lines to points midway between the anterior superior iliac spines and the symphysis pubis. These two diverging lines will represent the course of the common and external iliac arteries. Draw a second line corresponding to the level of the anterior superior spines of the ilium: the portion of the diverging lines between these two levels on either side will represent the course of the common iliac artery; the portion below the lower zone, that of the external iliac artery.

Applied Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurysm or hæmorrhage, implicating the external or internal iliacs. The easiest and best method of tying the artery is by a transperitoneal route. The abdomen is opened, the intestines are drawn to one side and the peritoneum

Fig. 608.—Arteries of the pelvis.



covering the artery divided: the sheath is then opened and the needle passed from within outwards. On the right side great care must be exercised in passing the needle, since both the common iliac veins lie behind the artery. After the vessel has been tied, the incision in the peritoneum over the artery should be sutured. Formerly there were two different methods by which the common iliac artery was tied, without opening the peritoneal cavity: (1) an anterior or iliac incision, by which the vessel was approached more directly from the front; and (2) a posterior abdominal or lumbar incision, by which the vessel was reached from behind.

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are: the anastomoses of the hæmorrhoidal branches of the internal iliac with the superior hæmorrhoidal from the inferior mesenteric; of the uterine, ovarian, and vesical arteries of the opposite sides; of the

lateral sacral with the middle sacral artery; of the epigastric with the internal mammary, inferior intercostal, and lumbar arteries; of the circumflex iliac with the lumbar arteries; of the ilio-lumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the deep epigastric.

Internal Iliac Artery (fig. 608)

The **internal iliac** or **hypogastric artery** (a. hypogastrica) supplies the walls and viscera of the pelvis, the buttock, the generative organs, and the inner side of the thigh. It is a short, thick vessel, smaller than the external iliac, and about an inch and a half in length. It arises at the bifurcation of the common iliac, opposite the lumbo-sacral articulation, and, passing downwards to the upper margin of the great sacro-sciatic foramen, divides into two large trunks, an *anterior* and a *posterior*.

Relations.—It is in relation *in front* with the ureter, which separates it from the peritoneum; *behind*, with the internal iliac vein, the lumbo-sacral cord, and the Pyriformis muscle; on its *outer side*, near its origin, with the external iliac vein, which lies between it and the Psoas magnus muscle; lower down, with the obturator nerve.

In the fœtus, the internal iliac or hypogastric artery is twice as large as the external iliac, and is the direct continuation of the common iliac. It ascends along the side of the bladder, and runs upwards on the back of the anterior wall of the abdomen to the umbilicus, converging towards its fellow of the opposite side. Having passed through the umbilical opening, the two arteries, now termed *umbilical*, enter the umbilical cord, where they are coiled round the umbilical vein, and ultimately ramify in the placenta.

At birth, when the placental circulation ceases, the pelvic portion only of the hypogastric artery remains patent and constitutes the internal iliac artery and the first part of the superior vesical artery of the adult; the remainder of the vessel is converted into a solid fibrous cord, the *obliterated hypogastric artery* (ligamentum umbilicale laterale), which extends from the pelvis to the umbilicus.

Peculiarities as regards length.—In two-thirds of a large number of cases, the length of the internal iliac varied between an inch and an inch and a half; in the remaining third it was more frequently longer than shorter, the maximum length being three inches, the minimum half an inch.

The lengths of the common and internal iliac arteries bear an inverse proportion to each other, the internal iliac artery being long when the common iliac is short, and *vice versa*.

As regards its place of division.—The place of division of the internal iliac varies between the upper margin of the sacrum and the upper border of the sacro-sciatic foramen.

The right and left internal iliac arteries in a series of cases often differed in length, but neither seemed constantly to exceed the other.

Applied Anatomy.—The application of a ligature to the internal iliac artery may be required in cases of aneurysm or hæmorrhage affecting one of its branches. The vessel may be best secured by an abdominal section in the median line, and reaching the vessel through the peritoneal cavity. It should be remembered that the vein lies behind, and on the right side, a little external to the artery, and in close contact with it; the ureter, which lies in front, must also be avoided. The degree of facility in applying a ligature to this vessel will mainly depend upon its length. It has been seen that, in the great majority of the cases examined, the artery was short, varying from an inch to an inch and a half; in these cases, the artery is deeply seated in the pelvis: when, on the contrary, the vessel is longer, it is found partly above that cavity. If the artery be very short, as occasionally happens, it would be preferable to apply a ligature to the common iliac.

Collateral Circulation.—The circulation after ligature of the internal iliac artery is carried on by the anastomoses of the uterine and ovarian arteries; of the vesical arteries of the two sides; of the hæmorrhoidal branches of the internal iliac with those from the inferior mesenteric; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side, and with the epigastric and internal circumflex; of the circumflex and perforating branches of the profunda femoris with the sciatic; of the gluteal with the posterior branches of the sacral arteries; of the ilio-lumbar with the last lumbar; of the lateral sacral with the middle sacral; and of the circumflex iliac with the ilio-lumbar and gluteal.*

* For a description of a case in which Owen made a dissection ten years after ligature of the internal iliac artery, see *Med.-Chir. Trans.* vol. xvi.

The branches of the internal iliac are :

From the Anterior Trunk.	From the Posterior Trunk.
Superior vesical.	Ilio-lumbar.
Middle vesical.	Lateral sacral.
Inferior vesical.	Gluteal.
Middle hæmorrhoidal.	
Obturator.	
Internal pudic.	
Sciatic.	
Uterine } *In the female.*	
Vaginal } *In the female.*	

The **superior vesical** (a. vesicalis superior) supplies numerous branches to the upper part of the bladder. From one of these a slender vessel, the artery to the vas deferens, takes origin and accompanies the vas deferens in its course to the testis, where it anastomoses with the spermatic artery. Other branches supply the ureter. As already explained, the first part of the superior vesical artery represents the terminal section of the pervious portion of the hypogastric artery.

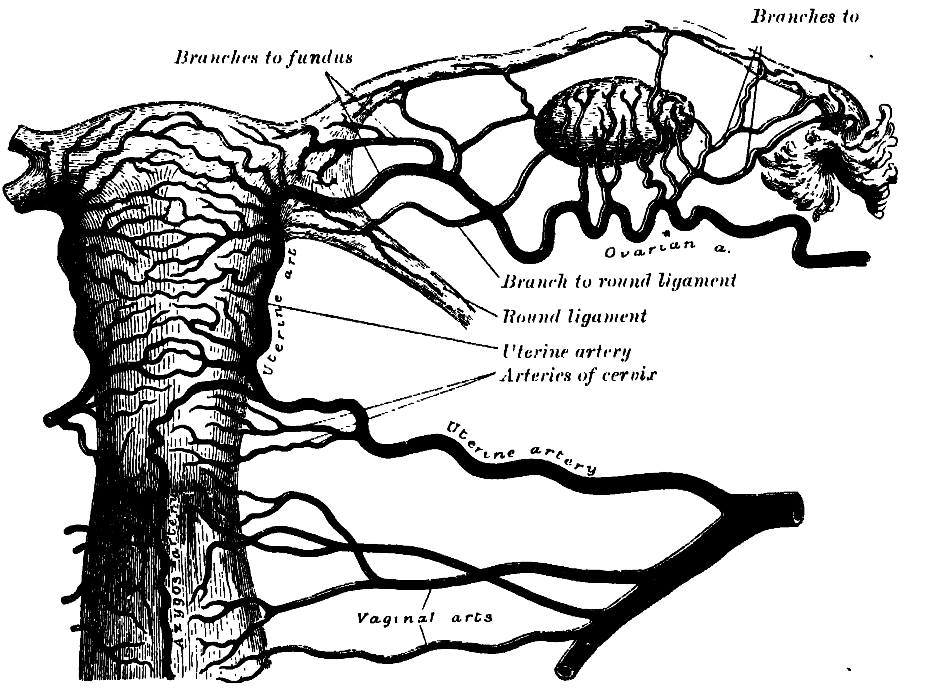
The **middle vesical** (a. vesicalis media), usually a branch of the superior, is distributed to the base of the bladder and under surface of the vesiculæ seminales.

The **inferior vesical** (a. vesicalis inferior) frequently arises in common with the middle hæmorrhoidal, and is distributed to the base of the bladder, the prostate gland, and the vesiculæ seminales. The branches to the prostate communicate with the corresponding vessels of the opposite side.

The **middle hæmorrhoidal** (a. hæmorrhoidalis media) usually arises together with the preceding vessel. It is distributed to the rectum, anastomosing with the inferior vesical and with the superior and inferior hæmorrhoidal arteries. It gives offsets to the seminal vesicle and prostate gland.

The **uterine** (a. uterina) (fig. 609) springs from the anterior division of the internal iliac and runs inwards on the Levator ani towards the cervix uteri ; about

Fig. 609.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)



three-quarters of an inch from the cervix it crosses above and in front of the ureter, to which it supplies a small branch. Reaching the side of the uterus it ascends

in a tortuous manner between the two layers of the broad ligament to the junction of the Fallopian tube and uterus. It then runs outwards towards the hilus of the ovary, and terminates by anastomosing with the ovarian artery. It supplies branches to the cervix uteri and others which descend on the vagina; the latter anastomose with branches of the vaginal arteries and form with them two median longitudinal vessels—the *azygos arteries of the vagina*—which run down one in front and the other on the back of the vagina. It supplies numerous branches to the body of the uterus, and from its terminal portion branches are distributed to the Fallopian tube and the round ligament of the uterus.

The **vaginal** (a. vaginalis) usually corresponds to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sends branches to the bulb of the vestibule, the neck of the bladder, and the contiguous part of the rectum. It assists in forming the azygos arteries of the vagina, and is frequently represented by two or three branches.

The **obturator** (a. obturatoria) passes forwards and downwards on the lateral wall of the pelvis, to the upper part of the obturator foramen, and, escaping from the pelvic cavity through a short canal, formed by a groove on the under surface of the ascending ramus of the pubis and the arched border of the obturator fascia, it divides into an internal and an external branch. In the pelvic cavity this vessel is in relation, externally, with the obturator fascia; internally, with the ureter, vas deferens, and peritoneum; while a little below it, is the obturator

Branches.—Inside the pelvis, the obturator artery gives off an *iliac branch* to the iliac fossa, which supplies the bone and the Iliacus muscle, and anastomoses with the ilio-lumbar artery; a *vesical branch*, which runs backwards to supply the bladder; and a *pubic branch*, which is given off from the vessel just before it leaves the pelvic cavity. The pubic branch ascends upon the back of the pubis, communicating with offsets from the deep epigastric artery, and with the corresponding vessel of the opposite side; it is sometimes placed on the inner side of the femoral ring.

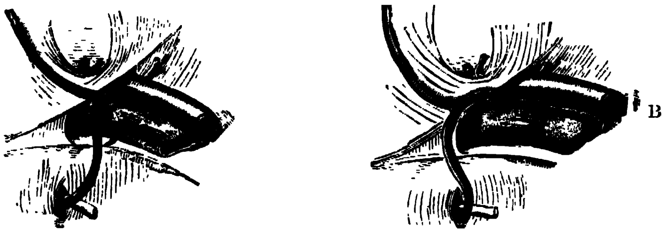
Outside the pelvis, the obturator artery divides into an *internal* and an *external branch*, which are deeply situated beneath the Obturator externus.

The *internal branch* curves downwards along the inner margin of the obturator foramen, lying beneath the Obturator externus muscle; it distributes branches to the Obturator externus, Pectineus, Adductors, and Gracilis, and anastomoses with the external branch, and with the internal circumflex artery.

The *external branch* curves round the outer margin of the foramen, also lying beneath the Obturator externus muscle, to the space between the Gemellus inferior and Quadratus femoris, where it divides into two branches. One, the smaller, courses inwards around the lower margin of the foramen and anastomoses with the internal branch and with the internal circumflex; the other inclines outwards in the groove below the acetabulum, and supplies the muscles attached to the tuberosity of the ischium and anastomoses with the sciatic artery. It sends through the cotyloid notch a branch to the hip-joint, which ramifies on the round ligament as far as the head of the femur.

Peculiarities.—The obturator artery sometimes arises from the main stem or from the posterior trunk of the internal iliac, or it may spring from the gluteal artery. Occasionally it arises from the external iliac. In about two out of every seven cases it springs from the deep epigastric and descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein,

FIG. 610.—Variations in origin and course of obturator artery.



and on the outer side of the femoral ring (fig. 610, A); in such cases it would not be endangered in the operation for femoral hernia. Occasionally, however, it curves inwards along the free margin of Gimbernat's ligament (fig. 610, B), and if in such circumstances a femoral hernia occurred, the vessel would almost completely encircle the neck of the hernial sac, and would be in great danger of being wounded if an operation were performed for strangulation.

The **internal pudic** (a. pudenda interna) is the smaller of the two terminal branches of the anterior trunk of the internal iliac, and supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is much smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The internal pudic artery in the male passes downwards and outwards to the lower border of the great sacro-sciatic foramen, and emerges from the pelvis between the Pyriformis and Coccygeus muscles; it then crosses the spine of the ischium, and enters the perinæum through the lesser sacro-sciatic foramen. The artery now crosses the Obturator internus muscle, along the outer wall of the ischio-rectal fossa, being situated about an inch and a half above the lower margin of the ischial tuberosity. It gradually approaches the margin of the ramus of the ischium and passes forwards between the two layers of the triangular ligament of the perinæum; it then runs forwards along the inner margin of the ramus of the pubis and about half an inch behind the sub-pubic ligament it pierces the superficial layer of the triangular ligament and divides into its two terminal branches, the *dorsal artery of the penis* and the *artery of the corpus cavernosum*.

Relations.—Within the pelvis, it lies in front of the Pyriformis muscle, the sacral plexus of nerves, and the sciatic artery, and on the outer side of the rectum (on the left side). As it crosses the spine of the ischium, it is covered by the Gluteus maximus and overlapped by the great sacro-sciatic ligament. Here the pudic nerve lies to the inner side and the nerve to the Obturator internus to the outer side of the vessel. In the perinæum it lies on the outer side of the ischio-rectal fossa, in a canal (*Alcock's canal*) formed by the splitting of the obturator fascia. It is accompanied by the pudic veins and the pudic nerve.

Peculiarities.—The internal pudic is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the *accessory pudic*, which generally arises from the internal pudic artery before its exit from the great sacro-sciatic foramen. It passes forwards along the lower part of the bladder and across the side of the prostate gland to the root of the penis, where it perforates the triangular ligament, and gives off the branches usually derived from the pudic artery. The deficiency most frequently met with is that in which the internal pudic ends as the artery of the bulb, the artery of the corpus cavernosum and the dorsal artery of the penis being derived from the accessory pudic. The pudic artery may also terminate as the superficial perineal, the artery of the bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudic artery is derived from one of the other branches of the internal iliac, most frequently the inferior vesical or the obturator.

Branches.—The branches of the internal pudic artery are:

Muscular.	Transverse perineal.
Inferior hæmorrhoidal.	Artery of the bulb.
Superficial perineal.	Artery of the corpus cavernosum.

Dorsal artery of the penis.

The *muscular branches* consist of two sets: one given off in the pelvis; the other, as the vessel crosses the ischial spine. The former consists of several small offsets which supply the Levator ani, the Obturator internus, the Pyriformis, and the Coccygeus muscles. The branches given off outside the pelvis are distributed to the adjacent part of the Gluteus maximus and external rotator muscles. They anastomose with branches of the sciatic artery.

The *inferior hæmorrhoidal* (a. hæmorrhoidalis inferior) (fig. 611) arises from the interna pudic as it passes above the tuberosity of the ischium. Piercing the wall of Alcock's canal it divides into two or three branches which cross the ischio-rectal fossa, and are distributed to the muscles and integument of the anal region, and send offshoots round the lower edge of the Gluteus maximus to the skin of the buttock. They anastomose with the corresponding vessels of the opposite side, with the superior and middle hæmorrhoidal, and with the transverse and superficial perineal arteries.

The *superficial perineal* (a. perinei) supplies the scrotum and the muscles and integument of the perinæum. It arises from the internal pudic, in front of the preceding branches, and turns upwards, crossing either over or under the Transversus perinæi muscle, and runs forwards, parallel to the pubic arch, in the interspace between the Ejaculator urinæ and Erector penis muscles, both of which it supplies, and is finally distributed to the skin and

dartos muscle of the scrotum. In its passage through the perinæum it lies under cover of the superficial perineal fascia.

FIG. 611.—The superficial branches of the internal pudic artery.

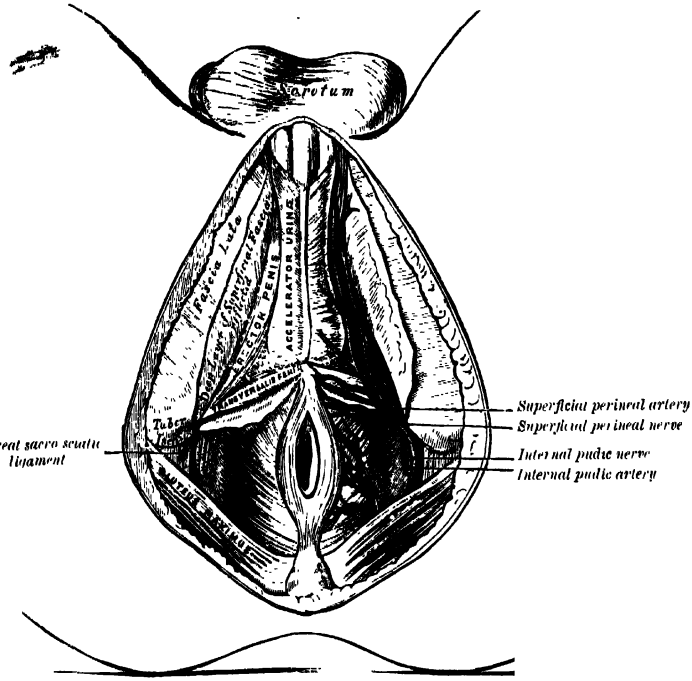


FIG. 612.—The deeper branches of the internal pudic artery.

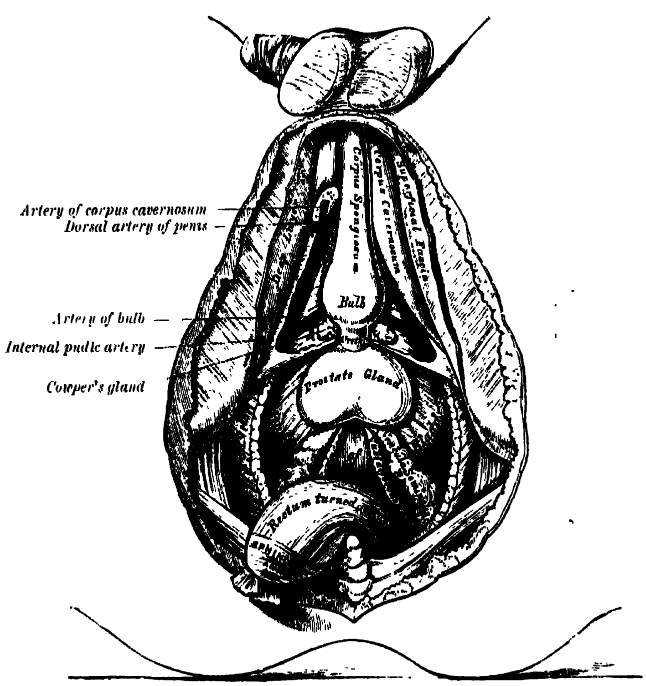
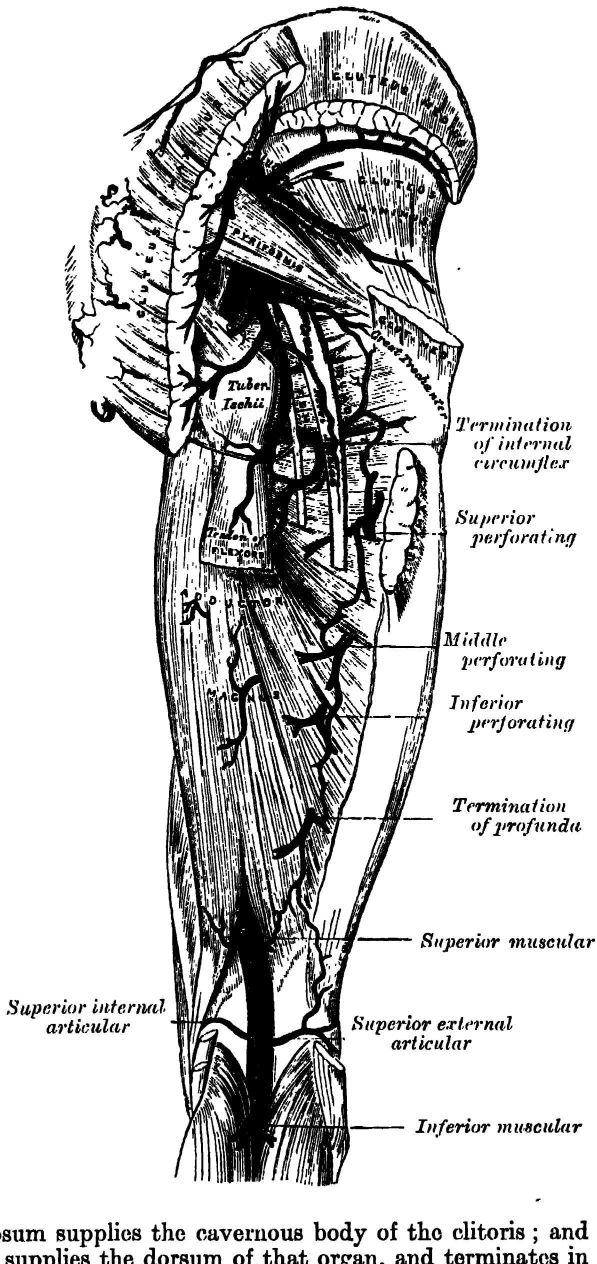


The *transverse perineal* is a small branch which arises either from the internal pudic, or from the superficial perineal artery as it crosses the Transversus perinæi muscle. It

runs transversely inwards along the cutaneous surface of the Transversus perinæi muscle, and anastomoses with the corresponding vessel of the opposite side and with the superficial perineal and inferior hæmorrhoidal arteries. It supplies the Transversus perinæi and the structures between the anus and the bulb of the urethra.

The *artery of the bulb* (a. bulbi urethræ) (fig. 612) is a short vessel of large calibre which arises from the internal pudic between the two layers of the triangular ligament; it passes nearly transversely inwards through the fibres of the Compressor urethræ muscle, pierces the superficial layer of the triangular ligament, and gives off branches which ramify in the bulb of the urethra. It is then continued forwards in the corpus spongiosum to the glans penis. It gives off a small branch to Cowper's gland.

Fig. 613.—The arteries of the gluteal and posterior femoral regions.



The *artery of the corpus cavernosum* (a. profunda penis), one of the terminal branches of the internal pudic, arises from that vessel while it is situated between the two layers of the triangular ligament; it pierces the superficial layer, and, entering the crus penis obliquely, runs forwards in the centre of the corpus cavernosum, to which its branches are distributed.

The *dorsal artery of the penis* (a. dorsalis penis) ascends between the crus and the pubic symphysis, and, piercing the triangular ligament, passes between the two layers of the suspensory ligament of the penis, and runs forwards on the dorsum of the penis to the glans, where it divides into two branches, which supply the glans and prepuce. On the penis, it lies between the dorsal nerve and deep dorsal vein, the former being on its outer side. It supplies the integument and fibrous sheath of the corpus cavernosum, sending branches through the sheath to anastomose with the preceding vessel.

The **internal pudic artery in the female** is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The superficial perineal artery supplies the labia pudendi; the artery of the bulb supplies the bulbus vestibuli and the erectile tissue of the vagina; the artery of the corpus cavernosum supplies the cavernous body of the clitoris; and the arteria dorsalis clitoridis supplies the dorsum of that organ, and terminates in the glans and in the membranous fold corresponding to the prepuce of the male.

The **sciatic artery** (a. glutæa inferior) (fig. 613), the larger of the two terminal branches of the anterior trunk of the internal iliac, is distributed chiefly on the buttock and back of the thigh. It passes down on the sacral plexus of nerves and the

Pyriformis muscle behind the internal pudic artery to the lower part of the great sacro-sciatic foramen, through which it escapes from the pelvis between the Pyriformis and Coccygeus. It then descends in the interval between the great trochanter of the femur and tuberosity of the ischium, accompanied by the sciatic nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh, supplying the skin, and anastomosing with branches of the perforating arteries.

Inside the pelvis it distributes branches to the Pyriformis, Coccygeus, and Levator ani muscles; some hæmorrhoidal branches, which supply the rectum, and occasionally take the place of the middle hæmorrhoidal artery; and vesical branches to the base and neck of the bladder, vesiculæ seminales, and prostate gland. *Outside the pelvis* it gives off the following branches:

Muscular.	Anastomotic.
Coccygeal.	Articular.
Comes nervi ischiadici.	Cutaneous.

The *muscular branches* supply the Gluteus maximus, anastomosing with the gluteal artery in the substance of the muscle; the external rotators, anastomosing with the internal pudic artery; and the muscles attached to the tuberosity of the ischium, anastomosing with the external branch of the obturator and the internal circumflex arteries.

The *coccygeal branch* runs inwards, pierces the great sacro-sciatic ligament, and supplies the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The *comes nervi ischiadici* (a. comitans n. ischiadici) is a long, slender vessel, which accompanies the great sciatic nerve for a short distance; it then penetrates it, and runs in its substance to the lower part of the thigh.

The *anastomotic* is directed downwards across the external rotators, and assists in forming the so-called *crucial anastomosis* by anastomosing with the superior perforating and internal and external circumflex arteries.

The *articular branch*, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

The *cutaneous branches* are distributed to the skin of the buttock and back of the thigh.

The **ilio-lumbar artery** (a. iliolumbalis), given off from the posterior trunk of the internal iliac, turns upwards and outwards behind the obturator nerve and the external iliac vessels, to the inner margin of the Psoas muscle, behind which it divides into a lumbar and an iliac branch.

The *lumbar branch* (ramus lumbalis) supplies the Psoas and Quadratus lumborum muscles, anastomoses with the last lumbar artery, and sends a small *spinal branch* through the intervertebral foramen between the last lumbar vertebra and the sacrum, into the spinal canal, to supply the cauda equina.

The *iliac branch* (ramus iliacus) descends to supply the Iliacus muscle; some offsets, running between the muscle and the bone, anastomose with the iliac branch of the obturator; one of these enters an oblique canal to supply the diploe, while others run along the crest of the ilium, distributing branches to the gluteal and abdominal muscles, and anastomosing in their course with the gluteal, circumflex iliac, and external circumflex arteries.

The **lateral sacral arteries** (aa. sacrales laterales) (fig. 608) are usually two in number on either side, superior and inferior.

The *superior*, which is of large size, passes inwards, and, after anastomosing with branches from the middle sacral, enters the first or second anterior sacral foramen, supplies branches to the contents of the sacral canal, and, escaping by the corresponding posterior sacral foramen, is distributed to the skin and muscles on the dorsum of the sacrum, anastomosing with the gluteal.

The *inferior* passes obliquely across the front of the Pyriformis muscle and sacral nerves to the inner side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the middle sacral and opposite lateral sacral artery. In its course it gives off branches, which enter the anterior sacral foramina; these, after supplying the contents of the sacral canal, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal.

The **gluteal artery** (a. glutæa superior) is the largest branch of the internal iliac, and appears to be the continuation of the posterior division of that vessel. It is a short, thick trunk, which runs backwards between the lumbo-sacral cord and the first sacral nerve, and, passing out of the pelvis above the upper border of the Pyriformis muscle, immediately divides into a *superficial* and a *deep branch*. Within

the pelvis it gives off a few muscular branches to the Iliacus, Pyriformis, and Obturator internus, and just previous to quitting that cavity, a nutrient artery which enters the ilium.

The *superficial branch* enters the deep surface of the Gluteus maximus, and divides into numerous branches, some of which supply the muscle, while others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the sacral arteries.

The *deep branch* lies under the Gluteus medius and almost immediately subdivides into two. Of these, the *superior division*, continuing the original course of the vessel, passes along the upper border of the Gluteus minimus to the anterior superior spine of the ilium, anastomosing with the circumflex iliac and ascending branches of the external circumflex artery. The *inferior division* crosses the Gluteus minimus obliquely to the trochanter major, distributing branches to the Gluteus muscles, and anastomoses with the external circumflex artery. Some branches pierce the Gluteus minimus to supply the hip-joint.

Surface Marking.—The three main branches of the internal iliac, the sciatic, internal pudic, and gluteal, may occasionally be the objects of surgical interference, and their positions are indicated on the surface in the following way. With the limb slightly flexed and rotated inwards draw a line from the posterior superior iliac spine to the posterior superior angle of the great trochanter: the point of emergence of the *gluteal artery* from the upper part of the great sacro-sciatic foramen will correspond with the junction of the upper with the middle third of this line. Draw a second line from the posterior superior iliac spine to the outer part of the tuberosity of the ischium; the junction of the lower with the middle third marks the point of emergence of the *sciatic* and *pudic arteries* from the great sacro-sciatic foramen.

Applied Anatomy.—Any of these three vessels may require ligaturing for a wound or for aneurysm, which is generally traumatic. The *gluteal* artery is ligatured by turning the patient two-thirds over on to his face and making an incision from the posterior superior spine of the ilium to the upper and posterior angle of the great trochanter. This must expose the Gluteus maximus muscle, and its fibres are to be separated through the whole thickness of the muscle and pulled apart with retractors. The contiguous margins of the Gluteus medius and Pyriformis are now to be separated from each other, and the artery will be exposed emerging from the sciatic notch. In ligature of the *sciatic* artery, the incision should be made parallel with that for ligature of the gluteal but an inch and a half lower down. After the fibres of the Gluteus maximus have been separated, the vessel is to be sought for at the lower border of the Pyriformis; the great sciatic nerve, which lies just above it, forms the chief guide to the artery.

External Iliac Artery (fig. 608)

The **external iliac artery** (a. iliaca externa) is larger than the internal iliac, and passes obliquely downwards and outwards along the inner border of the Psoas muscle, from the bifurcation of the common iliac to a point beneath Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, where it enters the thigh and becomes the femoral artery.

Relations.—*In front*, the artery is in relation with the peritoneum, subperitoneal areolar tissue, the termination of the ileum on the right side, and the ilio-pelvic colon on the left,* and a thin layer of fascia, derived from the iliac fascia, which surrounds the artery and vein. At its origin it is crossed by the ovarian vessels in the female, and occasionally by the ureter. The spermatic vessels lie for some distance upon it near its termination, and it is crossed in this situation by the genital branch of the genito-crural nerve and the deep circumflex iliac vein; the vas deferens in the male, and the round ligament in the female, curve down along its inner side. *Behind*, it is in relation with the inner border of the Psoas muscle, from which it is separated by the iliac fascia. At the upper part of its course, the external iliac vein lies partly behind it, but lower down lies entirely to its inner side. *Externally*, it rests against the Psoas magnus, from which it is separated by the iliac fascia. Numerous lymphatic vessels and glands lie on the front and on the inner side of the vessel.

Surface Marking.—The surface line indicating the course of the external iliac artery has been already given (see page 697).

Applied Anatomy.—The application of a ligature to the external iliac may be required in cases of aneurysm of the femoral artery, ilio-femoral aneurysm, or for a wound of the

artery. The vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the internal iliac, and near its lower end, which should also be avoided on account of the proximity of the deep epigastric and circumflex iliac vessels. The operation may be performed by opening the abdomen and incising the peritoneum over the artery (*transperitoneal*); or by an incision in the iliac region, dividing all the structures down to the peritoneum, which is then reflected inwards unopened from the iliac fossa until the artery is reached (*retroperitoneal*).

Transperitoneal ligature.—An incision four inches in length is made in the semilunar line, commencing about an inch below the umbilicus, and carried through the abdominal wall into the peritoneal cavity. The intestines are then pushed upwards and held out of the way by a broad abdominal retractor, and an incision made through the peritoneum at the margin of the pelvis in the course of the artery: the vessel is secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be, that if it is found necessary the common iliac artery can be ligatured instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligatured without in any way interfering with the sac of an aneurysm.

The retroperitoneal ligature may be performed either by the modified Abernethy's method, which consists in making an incision from an inch above and internal to the anterior superior spine of the ilium in a curved direction, with its convexity outwards and downwards to a point an inch and a half above the middle of Poupart's ligament; or by Astley Cooper's method, in which an incision is made in a curved direction from a little above and outside the external abdominal ring to an inch from the inner side of the anterior superior spinous process of the ilium. In both, the abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised towards the pelvis; and on introducing the finger to the bottom of the wound, the artery may be felt pulsating along the inner border of the Psoas muscle. The external iliac vein is generally found on the inner side of the artery, and must be cautiously separated from it by the finger-nail, or handle of the knife, and the aneurysm needle should be introduced on the inner side, between the artery and vein.

Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligature to the external iliac, are: the ilio-lumbar with the circumflex iliac; the gluteal with the external circumflex; the obturator with the internal circumflex; the sciatic with the superior perforating and circumflex branches of the profunda artery; and the internal pudic with the external pudic. When the obturator arises from the epigastric, it is supplied with blood by branches, from either the internal iliac, the lateral sacral, or the internal pudic. The epigastric receives its supply from the internal mammary and inferior intercostal arteries, and from the internal iliac by the anastomoses of its branches with the obturator.*

Branches.—Besides several small branches to the Psoas magnus and the neighbouring lymphatic glands, the external iliac gives off two branches of considerable size:

Deep epigastric   Deep circumflex iliac.

The **deep epigastric artery** (a. epigastrica inferior) arises from the external iliac, immediately above Poupart's ligament. It curves forwards below the peritoneum, and then ascends obliquely along the inner margin of the internal abdominal ring, between the transversalis fascia and peritoneum; continuing its course upwards, it pierces the transversalis fascia, and, passing in front of the semilunar fold of Douglas, ascends between the Rectus and the posterior lamella of its aponeurotic sheath. It finally divides into numerous branches, which anastomose, above the umbilicus, with the superior epigastric branch of the internal mammary and with the lower intercostal arteries (fig. 593). As the deep epigastric artery passes obliquely upwards and inwards from its origin it lies along the lower and inner margin of the internal abdominal ring, and behind the commencement of the spermatic cord. This part of the vessel is crossed by the vas deferens in the male and the round ligament of the uterus in the female.

The branches of the vessel are: the *cremasteric* (a. spermatica externa), which accompanies the spermatic cord, and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery (in the female it is very small and accompanies the round ligament); a *pubic branch* (ramus pubicus) which runs along Poupart's ligament, and then descends behind the pubis to the inner side of the femoral ring, and anastomoses with offsets from the obturator

* Sir Astley Cooper describes in vol. i. of the *Guy's Hospital Reports* the dissection of a limb eighteen years after successful ligature of the external iliac artery.

artery; *muscular branches*, some of which are distributed to the abdominal muscles and peritoneum, anastomosing with the lumbar and circumflex iliac arteries; branches which perforate the tendon of the External oblique, and supply the integument, anastomosing with branches of the superficial epigastric.

Peculiarities.—The origin of the deep epigastric may take place from any part of the external iliac between Poupart's ligament and a point two inches and a half above it; or it may arise below this ligament, from the femoral. It frequently arises from the external iliac, by a common trunk with the obturator. Sometimes it arises from the obturator, the latter vessel being furnished by the internal iliac, or it may be formed of two branches, one derived from the external iliac, the other from the internal iliac.

Applied Anatomy.—The deep epigastric artery follows a line drawn from the middle of Poupart's ligament towards the umbilicus; but shortly after this line crosses the linea semilunaris, the direction changes, and the course of the vessel is upwards along the line of junction of the inner with the middle third of the Rectus abdominis. It has important surgical relations, and is one of the principal means, through its anastomosis with the internal mammary, of establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the internal abdominal ring, and is therefore *internal* to an oblique inguinal hernia, but *external* to a direct inguinal hernia, as these emerge from the abdomen. It forms the outer boundary of Hesselbach's triangle, and is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The vas deferens hooks round its outer side.

The **deep circumflex iliac artery** (a. circumflexa ilium profunda) arises from the outer side of the external iliac nearly opposite the deep epigastric artery. It ascends obliquely outwards behind Poupart's ligament, contained in a fibrous sheath formed by the junction of the transversalis and iliac fasciæ, to the anterior superior spine of the ilium, where it anastomoses with the ascending branch of the external circumflex artery. It then pierces the transversalis fascia and passes along the inner surface of the crest of the ilium to about its middle, where it perforates the Transversalis, and runs backwards between that muscle and the Internal oblique, to anastomose with the ilio-lumbar and gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch, which ascends between the Internal oblique and Transversalis muscles, supplying them, and anastomosing with the lumbar and epigastric arteries.

ARTERIES OF THE LOWER EXTREMITY

The artery which supplies the greater part of the lower extremity is the direct continuation of the external iliac. It continues as a single trunk from Poupart's ligament to the lower border of the Popliteus muscle, where it divides into two branches, the *anterior* and *posterior tibial*. The upper part of the main trunk is named the *femoral*, the lower part the *popliteal*.

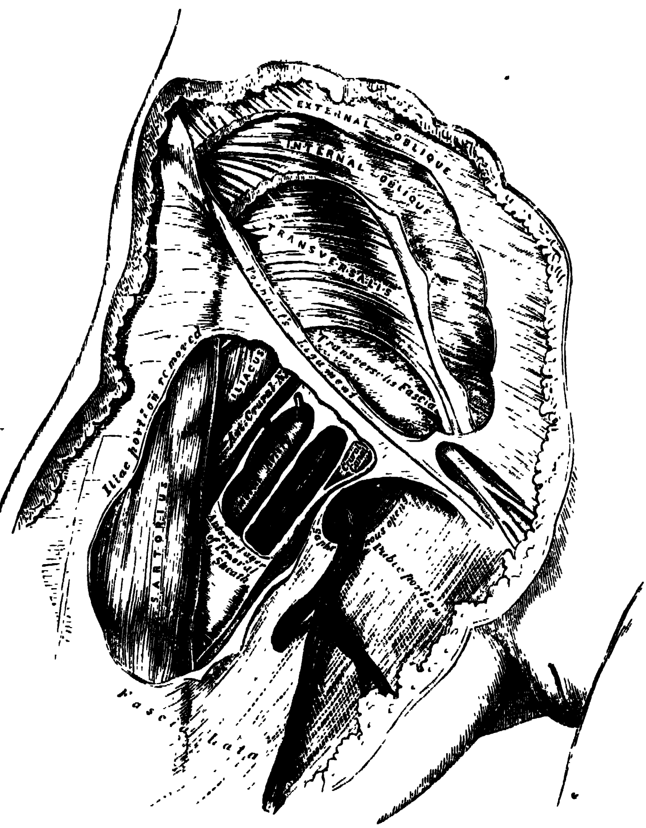
FEMORAL ARTERY (figs. 617, 618)

The **femoral artery** (a. femoralis) commences immediately behind Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and passes down the front and inner side of the thigh. It terminates at the junction of the middle with the lower third of the thigh where it passes through an opening in the Adductor magnus to become the popliteal artery. The vessel, at the upper part of the thigh, lies in front of the hip-joint, on a line with the innermost part of the head of the femur; in the lower part of its course it lies to the inner side of the shaft, and between these two parts, where it crosses the angle between the head and shaft, the vessel is some distance from the bone. The first inch and a half of the vessel is enclosed, together with the femoral vein, in a fibrous sheath—the *femoral sheath*. In the upper third of the thigh the femoral artery is contained in a triangular space, called *Scarpa's triangle*, and in the middle third of the thigh, in an aponeurotic canal, named *Hunter's canal*.

The **femoral sheath** (fig. 614) is formed by a prolongation downwards, behind Poupart's ligament, of the fasciæ which line the abdomen, the fascia transversalis being continued down in front of the femoral vessels and the

fascia transversalis behind them. The sheath assumes the form of a short funnel-shaped tube, the wide end of which is directed upwards, while the lower, narrow end fuses with the fascial investment of the vessels, about an inch and a half below the level of Poupart's ligament. It is strengthened in front by a band termed the *deep crural arch* (p. 516). The outer wall of the sheath is vertical and is perforated by the genital branch of the genito-crural nerve; the inner wall is directed obliquely downwards and outwards and is pierced by the internal saphenous vein and by some lymphatic vessels. The sheath is divided by two vertical partitions which stretch between its anterior and posterior walls. The outermost compartment contains the femoral artery and the middle the femoral vein, while the innermost and smallest compartment is named the *crural canal*, and contains some lymphatic vessels and a lymphatic

FIG. 614.—Femoral sheath laid open to show its three compartments.



gland imbedded in a small amount of areolar tissue. The crural canal is conical and measures about half an inch in length. Its base, directed upwards and named the *crural ring*, is oval in form, its long diameter being directed transversely and measuring about half an inch. The crural ring (figs. 615, 616) is bounded in front by Poupart's ligament, behind by the Pectineus muscle covered by the pubic portion of the fascia lata, internally by the crescentic base of Gimbernat's ligament, and externally by the fibrous septum on the inner side of the femoral vein. The spermatic cord in the male and the round ligament of the uterus in the female lie immediately above the anterior margin of the ring, while the deep epigastric artery is close to its upper and outer angle. The crural ring is closed by a somewhat condensed portion of the extra-peritoneal fatty tissue, named the *septum crurale*, the abdominal surface of which supports a small lymphatic gland and is covered by the parietal layer of the peritoneum. The septum crurale is pierced by numerous lymphatic vessels passing from the

deep inguinal to the external iliac glands, and the parietal peritoneum immediately above it presents a slight depression named the *femoral fossa*.

Fig. 615.—Structures passing behind Poupart's ligament.

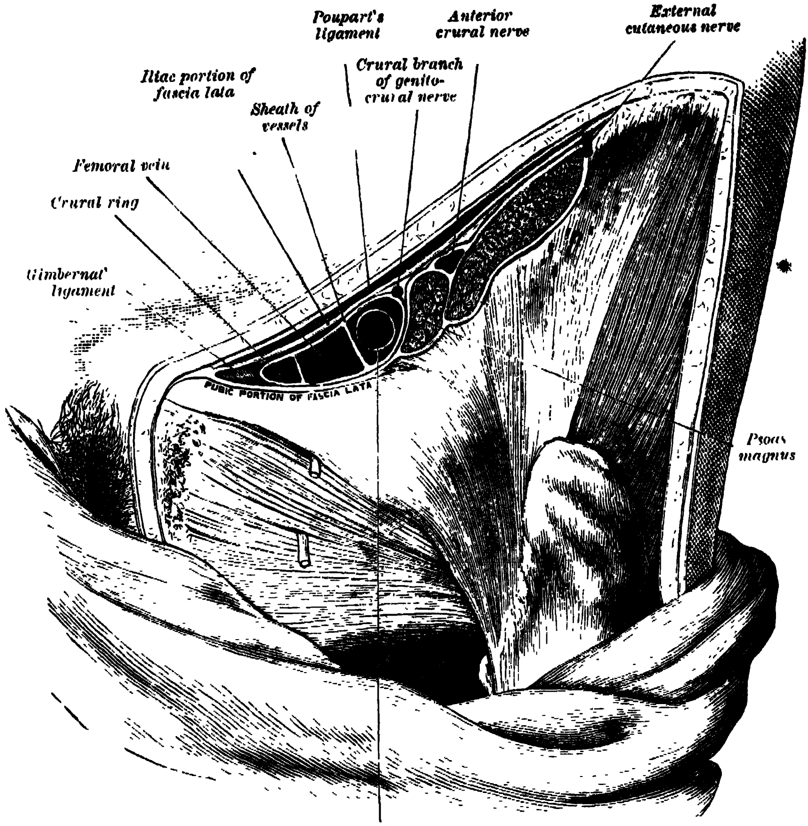


Fig. 616.—The relations of the crural and internal abdominal rings, seen from within the abdomen. Right side.

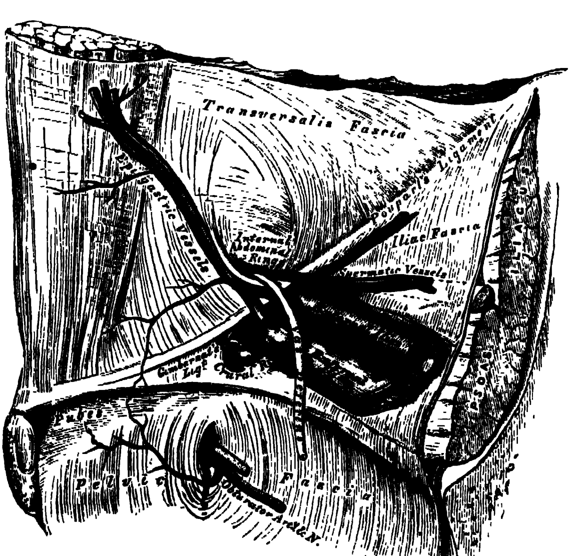
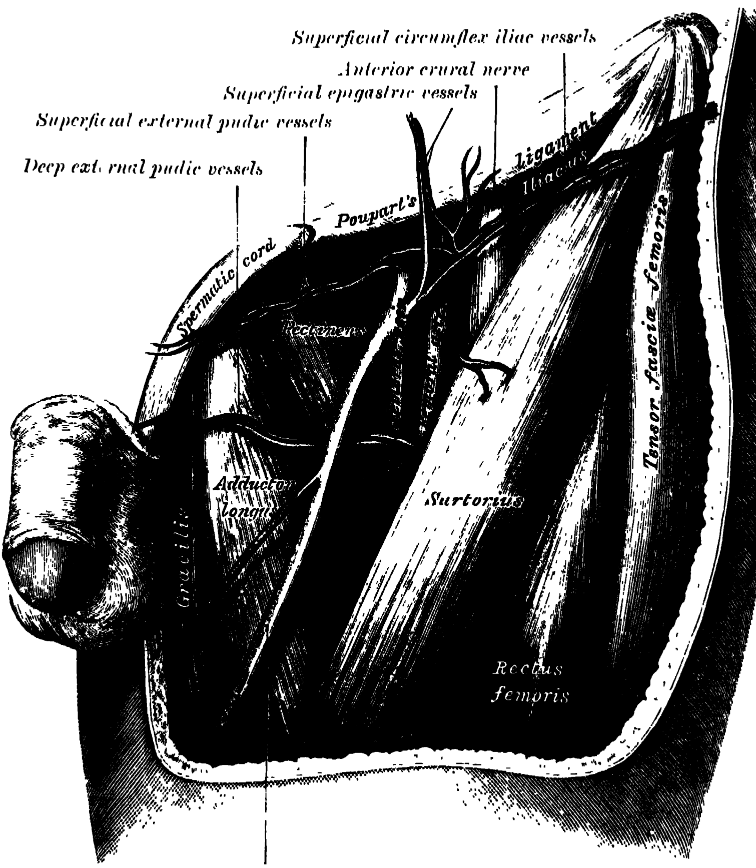


Scarpa's triangle (fig. 617) corresponds to the depression seen immediately below the fold of the groin. Its apex is directed downwards, and the sides are formed externally by the inner margin of the Sartorius, internally by the inner margin of the Adductor longus, and above by Poupart's ligament. The floor of the space is formed from without inwards by the Iliacus, Psoas, Pectineus, in some cases a small part of the Adductor brevis, and the Adductor longus; and it is divided into two nearly equal parts by the femoral vessels, which extend from near the middle of its base to its apex: the artery giving off in this situation its cutaneous and profunda branches, the vein receiving the deep femoral and internal saphenous tributaries. On the outer side of the femoral artery is the anterior crural nerve dividing into

FIG. 617.—Scarpa's triangle.



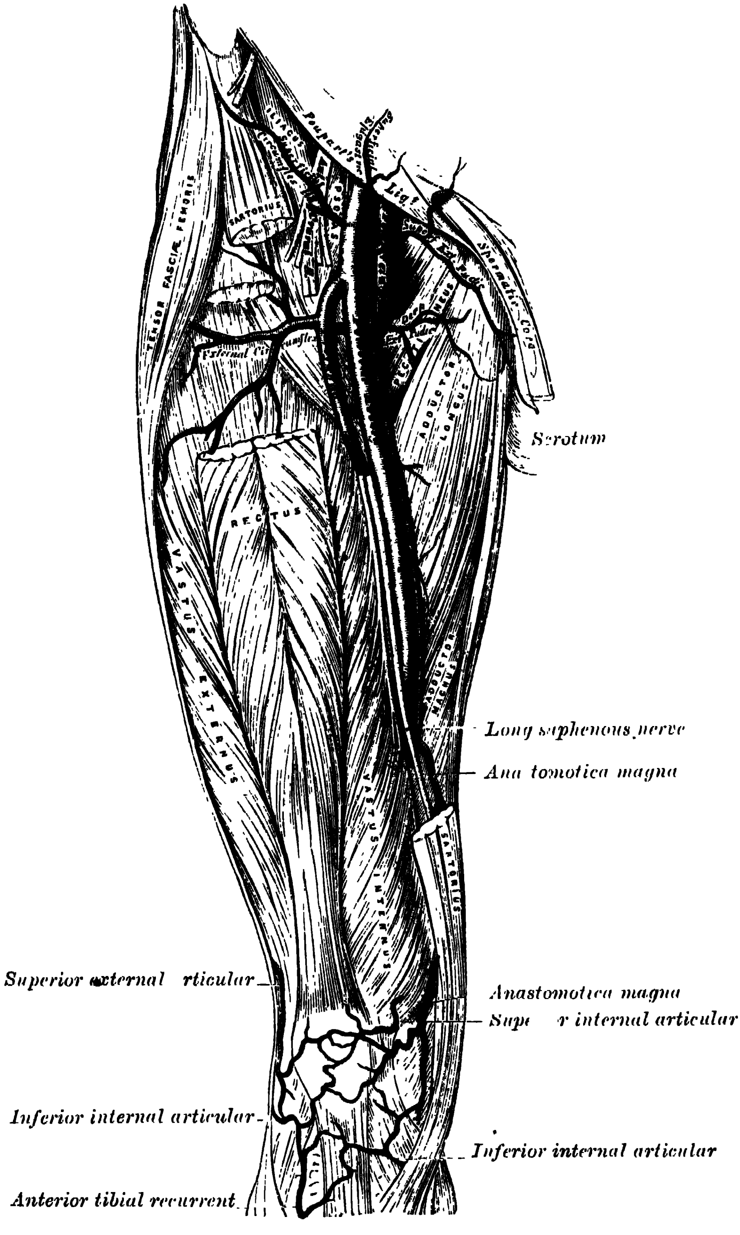
its branches. Besides the vessels and nerves, this space contains some fat and lymphatics.

Hunter's canal is an aponeurotic tunnel in the middle third of the thigh, extending from the apex of Scarpa's triangle to the femoral opening in the Adductor magnus muscle. It is bounded, in front and externally, by the Vastus internus; behind, by the Adductores longus et magnus; and covered in by a strong aponeurosis which extends from the Vastus internus, across the femoral vessels to the Adductores longus et magnus; lying on the aponeurosis is the Sartorius muscle. It contains the femoral artery and vein, the internal or long saphenous nerve, and the nerve to the Vastus internus.

Relations (fig. 617).—In *Scarpa's triangle* the femoral artery is superficial. *In front* of it are the skin and superficial fascia, the superficial inguinal lymphatic

glands, the superficial circumflex iliac vein, the iliac portion of the fascia lata and the anterior part of the femoral sheath. The genital branch of the genito-crural nerve courses for a short distance within the outer compartment of the femoral sheath, and lies at first in front and then on the outer side of the artery. Near the apex of Scarpa's triangle the internal cutaneous nerve crosses the artery from without inwards.

FIG. 618.—The femoral artery.



Behind the artery are the posterior part of the femoral sheath, the pubic portion of the fascia lata, the inner part of the tendon of the Psoas, the Pectineus and the Adductor longus. The artery is separated from the capsule of the hip-joint by the tendon of the Psoas, from the Pectineus by the femoral vein and profunda vessels, and from the Adductor longus by the femoral vein. The nerve to the Pectineus passes inwards behind the artery. On the *outer* side of the artery, but separated

from it by some fibres of the Psoas, is the anterior crural nerve. The femoral vein is on the inner side of the upper part of the artery, but is behind the vessel in the lower part of Scarpa's triangle.

In *Hunter's canal* the femoral artery is more deeply situated, being covered by the integument, the superficial and deep fasciæ, the Sartorius and the fibrous roof of the canal; it is crossed from without inwards by the long saphenous nerve. Behind the artery are the Adductores longus et magnus; in front and to its outer side is the Vastus internus. The femoral vein lies behind the upper part, and on the outer side of the lower part of the artery.

That portion of the femoral artery which extends from Poupart's ligament to the origin of the profunda is sometimes named the *common femoral*.

Peculiarities.—Several cases are recorded in which the femoral artery divided into two trunks below the origin of the profunda, and became reunited near the opening in the Adductor magnus, so as to form a single popliteal artery. One occurred in a patient who was operated upon for popliteal aneurysm. A few cases have been recorded in which the femoral artery was absent, its place being supplied by the sciatic artery which accompanied the great sciatic nerve to the popliteal space. The external iliac in these cases was small, and terminated in the profunda. The femoral vein is occasionally placed along the inner side of the artery, throughout the entire extent of Scarpa's triangle: or it may be split so that a large vein is placed on either side of the artery for a greater or lesser distance.

Surface Marking.—The upper two-thirds of a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle on the inner condyle of the femur, with the thigh abducted and rotated outwards, will indicate the course of the femoral artery.

Applied Anatomy.—*Compression* of the femoral artery, which is constantly requisite in amputations and other operations on the lower limb, and also for the cure of popliteal aneurysm, is most effectually made immediately below Poupart's ligament. In this situation the artery is very superficial, and is merely separated from the ascending ramus of the pubis by the Psoas muscle; so that the surgeon, by means of his thumb or a compressor, may effectually control the circulation through it. The vessel may also be controlled in the middle third of the thigh by placing a pad over the artery, beneath the tourniquet, and directing the pressure from within outwards, so as to press the vessel against the inner side of the shaft of the femur.

The superficial position of the femoral artery in Scarpa's triangle renders it particularly liable to be injured in wounds, stabs, or gunshot injuries in the groin. On account of the close relationship between the artery and vein, the latter vessel is also liable to be wounded in these injuries. In such cases, the artery being compressed as it crosses the ramus of the pubis, the skin wound should be enlarged and the wound in the vessel sought for, and a ligature applied above and below the bleeding point.

The *application of a ligature* to the femoral artery may be required in cases of wound or aneurysm of the popliteal or femoral, or arteries of the leg; and the vessel may be exposed and tied in any part of its course. The great depth of this vessel at its lower part, its close connection with important structures, and the density of its sheath, render the operation in this situation one of greater difficulty than the application of a ligature at its upper part, where it is more superficial.

Ligature of the common femoral artery is not regarded with much favour, on account of the near connection of large branches with it, viz. the deep epigastric and the deep circumflex iliac arising just above Poupart's ligament; on account of the number of small branches which arise from it, in its short course, and on account of the uncertainty of the origin of the profunda femoris, which, if it arise high up, would be too close to the ligature for the formation of a firm coagulum. It would appear, therefore, that the most favourable situation for the application of a ligature to the femoral is at the apex of Scarpa's triangle. In order to reach the artery in this situation, an incision three inches long should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted, and rotated outwards. A large vein is frequently met with, passing in the course of the artery to join the internal saphenous vein: this must be avoided, and the fascia lata having been cautiously divided, and the Sartorius displayed, that muscle must be drawn outwards, in order to expose fully the sheath of the vessels. The finger having been introduced into the wound, and the pulsation of the artery felt, the sheath is opened on the outer side of the vessel to a sufficient extent to allow of the introduction of the aneurysm needle. In this part of the operation the long saphenous nerve and the nerve to the Vastus internus, which are in close relation with the sheath, should be avoided. The aneurysm needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course, and is very closely bound up with it.

To expose the artery in Hunter's canal, an incision between three and four inches in length should be made through the integument, a finger's breadth internal to the line of the artery, the centre of the incision being in the middle of the thigh—i.e. midway between the groin and the knee. The fascia lata having been divided, and the outer

border of the Sartorius exposed, this muscle should be drawn inwards, when the strong fascia which is stretched across from the Adductors to the Vastus internus will be observed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurysm needle between it and the vein, in the direction from without inwards. In this situation the femoral vein lies on the outer side, and the long saphenous nerve in front of the artery.

It has been seen that the femoral artery occasionally divides into two trunks below the origin of the profunda. If, in the operation for tying the femoral, two vessels be met with, the surgeon should alternately compress each, in order to ascertain which is connected with the aneurysmal tumour, or with the bleeding from the wound, and that one only should be tied which is the source of the pulsation or hæmorrhage. If, however, it be necessary to compress both vessels before the circulation is controlled, both should be tied, as it is probable that they become reunited, as in the instances referred to above.

Collateral Circulation.—After ligature of the femoral artery, the main channels for carrying on the circulation are the anastomoses between—(1) the gluteal and sciatic branches of the internal iliac with the internal and external circumflex and superior perforating branches of the profunda femoris; (2) the obturator branch of the internal iliac with the internal circumflex of the profunda; (3) the internal pudic of the internal iliac with the superficial and deep external pudic of the femoral; (4) the deep circumflex iliac of the external iliac with the external circumflex of the profunda and the superficial circumflex iliac of the femoral; and (5) the sciatic and comes nervi ischiadici of the internal iliac with the perforating branches of the profunda.

Branches.—The branches of the femoral artery are:

Superficial epigastric.		Muscular.
Superficial circumflex iliac.	Profunda	External circumflex.
Superficial external pudic.	Profunda	Internal circumflex.
Deep external pudic.	Profunda	Three perforating.
		Anastomotica magna.

The **superficial epigastric** (a. epigastrica superficialis) arises from the front of the femoral artery about half an inch below Poupart's ligament, and, passing through the femoral sheath and the cribriform fascia, turns upwards in front of Poupart's ligament, and ascends between the two layers of the superficial fascia of the abdominal wall nearly as far as the umbilicus. It distributes branches to the superficial inguinal glands, the superficial fascia, and the integument; it anastomoses with branches of the deep epigastric, and with its fellow of the opposite side.

The **superficial circumflex iliac** (a. circumflexa ilium superficialis), the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outwards, parallel with Poupart's ligament, as far as the crest of the ilium; it divides into branches which supply the integument of the groin, the superficial fascia, and the superficial inguinal lymphatic glands, anastomosing with the deep circumflex iliac, and with the gluteal and external circumflex arteries.

The **superficial external pudic** (a. pudenda externa superficialis) arises from the inner side of the femoral artery, close to the preceding vessels, and, after piercing the femoral sheath and cribriform fascia, courses inwards, across the spermatic cord (or round ligament in the female), to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium majus in the female, anastomosing with branches of the internal pudic.

The **deep external pudic** (a. pudenda externa profunda), more deeply seated than the preceding, passes inwards across the Pectineus and Adductor longus muscles; it is covered by the fascia lata, which it pierces at the inner border of the thigh, and is distributed, in the male to the integument of the scrotum and perinæum, in the female to the labium majus; its branches anastomose with those of the superficial perineal artery.

Muscular branches are supplied by the femoral artery to the Sartorius, Vastus internus, and Adductors.

The **profunda** (a. profunda femoris) (fig. 620) is a large vessel arising from the outer and back part of the femoral artery, from one to two inches below Poupart's ligament. At first it lies on the outer side of the femoral artery; it then runs behind it and the femoral vein to the inner side of the femur, and, passing downwards behind the Adductor longus, terminates at the lower third of the thigh in a small branch, which pierces the Adductor magnus, and is distributed on the back of the thigh to the Flexor muscles. The terminal part of the profunda is sometimes named the *fourth perforating artery*.

Relations.—*Behind*, it lies from above downwards upon the Iliacus, Pectineus, Adductor brevis, and Adductor magnus. *In front*, it is separated from the femoral artery by the femoral and profunda veins above, and by the Adductor longus below. On its *outer side*, the origin of the Vastus internus intervenes between it and the femur.

Peculiarities.—This vessel sometimes arises from the inner side, and, more rarely, from the back of the femoral artery; but a more important peculiarity, from a surgical point of view, is that relating to the height at which the vessel arises. In three-fourths of a large number of cases it arose between one and two inches below Poupart's ligament; in a few cases the distance was less than an inch; more rarely, opposite the ligament; and in one case above Poupart's ligament, from the external iliac. Occasionally the distance between the origin of the vessel and Poupart's ligament exceeds two inches.

The profunda gives off the following branches:

External circumflex. Internal circumflex. Three perforating.
Muscular.

The **external circumflex** (a. circumflexa femoris lateralis) supplies the muscles on the front of the thigh. It arises from the outer side of the profunda, passes horizontally outwards, between the divisions of the anterior crural nerve, and behind the Sartorius and Rectus femoris, and divides into ascending, transverse, and descending branches.

The *ascending branch* (ramus ascendens) passes upwards, beneath the Tensor fasciæ femoris muscle, to the outer side of the hip, and anastomoses with the terminal branches of the gluteal and deep circumflex iliac arteries.

The *descending branch* (ramus descendens) runs downwards, behind the Rectus, upon the Vastus externus to which it gives offsets; one long branch descends in the muscle as far as the knee, and anastomoses with the superior external articular branch of the popliteal artery. It is accompanied by the branch of the anterior crural nerve to the Vastus externus.

The *transverse branch* (ramus transversus), the smallest, passes outwards over the Crureus, pierces the Vastus externus, and winds round the femur, just below the great trochanter, anastomosing at the back of the thigh with the internal circumflex, sciatic, and superior perforating arteries.

The **internal circumflex** (a. circumflexa femoris medialis), smaller than the external, arises from the inner and posterior aspect of the profunda, and winds round the inner side of the femur, passing first between the Pectineus and Psoas muscles, and then between the Obturator externus and Adductor brevis. At the upper border of the Adductor brevis, it gives off two branches, one of which passes inwards to be distributed to the Adductor muscles, the Gracilis, and Obturator externus, anastomosing with the obturator artery; the other descends beneath the Adductor brevis, to supply it and the Adductor magnus; while the continuation of the vessel passes backwards and divides into an ascending and a transverse branch. The *ascending branch* (ramus profundus) runs obliquely upwards upon the tendon of the Obturator externus and in front of the Quadratus femoris towards the digital fossa, where it anastomoses with twigs from the gluteal and sciatic arteries. The *transverse branch* (ramus superficialis), larger than the ascending, appears between the Quadratus femoris and upper border of the Adductor magnus, anastomosing with the sciatic, external circumflex, and superior perforating arteries (*crucial anastomosis*). Opposite the hip-joint, the artery gives off an articular vessel, which enters the joint beneath the transverse ligament; and, after supplying the adipose tissue, passes along the round ligament to the head of the femur.

The **perforating arteries** (fig. 613), usually three in number, are so named because they perforate the tendon of the Adductor magnus muscle to reach the back of the thigh. They pass backwards close to the linea aspera of the femur under cover of small tendinous arches in the muscle. The first is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The *first perforating artery* (a. perforans prima) passes backwards between the Pectineus and Adductor brevis (sometimes it perforates the latter); it then pierces the Adductor magnus close to the linea aspera. It gives branches to the Adductor brevis, Adductor magnus, Biceps, and Gluteus maximus muscles, and anastomoses with the sciatic, internal and external circumflex, and middle perforating arteries.

The *second perforating artery* (a. perforans secunda), larger than the first, pierces the tendons of the Adductor brevis and Adductor magnus muscles, and divides into ascending and descending branches, which supply the flexor muscles of the thigh, anastomosing with the first and third perforating. The second artery frequently arises in common with the first. The nutrient artery of the femur (a. nutricia femoris) is usually given off from this branch.

The *third perforating artery* (a. perforans tertia) is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the flexor muscles of the thigh; anastomosing above with the higher perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal. The nutrient artery of the femur may arise from this branch.

The termination of the profunda artery, already described, is sometimes termed the *fourth perforating artery*.

Numerous **muscular branches** arise from the profunda; some of these end in the Adductor muscles, others pierce the Adductor magnus, give branches to the hamstrings, and anastomose with the internal circumflex artery and with upper muscular branches of the popliteal.

The **anastomotica magna** (a. genu suprema) (fig. 618) arises from the femoral artery just before it passes through the tendinous opening in the Adductor magnus muscle, and immediately divides into a superficial and a deep branch.

The *superficial branch* (ramus saphenus) pierces the aponeurotic covering of Hunter's canal, and accompanies the long saphenous nerve to the inner side of the knee. It passes between the Sartorius and Gracilis muscles, and, piercing the fascia lata, is distributed to the integument of the upper and inner part of the leg, anastomosing with the inferior internal articular artery.

The *deep branch* (ramus musculoarticularis) descends in the substance of the Vastus internus, lying in front of the tendon of the Adductor magnus, to the inner side of the knee, where it anastomoses with the superior internal articular artery and anterior recurrent branch of the anterior tibial. A branch from this vessel crosses outwards above the articular surface of the femur, forming an anastomotic arch with the superior external articular artery, and supplying branches to the knee-joint.

The Popliteal Space (fig. 620)

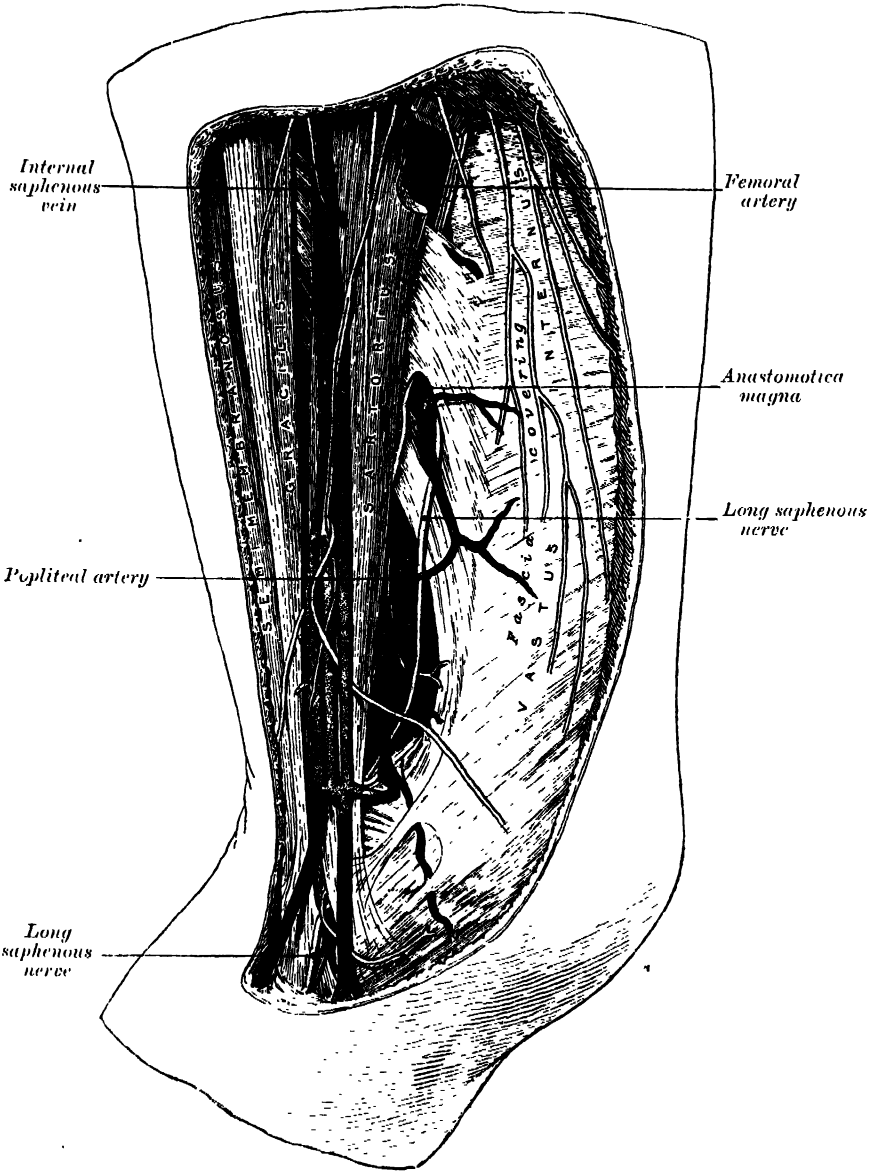
Boundaries.—The **popliteal space,** or **ham,** is a lozenge-shaped space, at the back part of the knee-joint. Above, it is bounded externally by the Biceps and internally by the Semitendinosus and Semimembranosus; below, it is limited by the outer head of the Gastrocnemius and the Plantaris externally and by the inner head of the Gastrocnemius internally. The floor is formed by the lower part of the posterior surface of the shaft of the femur, the posterior ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus muscle; the space is covered in by the fascia lata.

Contents.—The popliteal space contains the popliteal vessels and nerves, together with the termination of the external saphenous vein, the lower part of the small sciatic nerve, the articular branch from the obturator nerve, a few small lymphatic glands, and a considerable quantity of loose adipose tissue. The internal popliteal nerve descends in the middle line of the space, lying under the deep fascia and crossing the vessels from without inwards. The external popliteal nerve descends on the outer side of the upper part of the space, close to the tendon of the Biceps muscle. At the bottom of the space are the popliteal vessels, the vein being superficial to the artery and united to it by dense areolar tissue; the vein is a thick-walled vessel, and lies at first to the outer side of the artery, and then crosses it to gain the inner side below; sometimes it is double, the artery lying between two venæ comites, which are usually connected by short transverse branches. The articular branch from the obturator nerve descends upon the artery to supply the knee. The popliteal lymphatic glands, four or five in number, surround the artery: one usually lies superficial to the vessel; another is situated between it and the bone; and the rest are placed on either side of it. Arising from the artery, and passing off from it at right angles, are its articular branches.

Popliteal Artery (figs. 619, 620)

The **popliteal artery** (a. poplitea) is the continuation of the femoral, and courses through the popliteal space. It extends from the opening in the Adductor magnus, at the junction of the middle and lower thirds of the thigh, downwards and outwards to the intercondyloid notch of the femur, and then

Fig. 619.—Side view of the popliteal artery.
(From a preparation in the Museum of the Royal College of Surgeons of England.)



vertically downwards to the lower border of the Popliteus muscle, where it divides into *anterior* and *posterior tibial arteries*.

Relations.—In *front* from above downwards are the popliteal surface of the femur (which is separated from the artery by some fat), the posterior ligament of the knee joint, and the fascia covering the Popliteus. *Behind*, it is overlapped above by the Semimembranosus, and below it is covered by the Gastrocnemius and Plantaris. In the middle part of its course the artery is separated from the integument and fasciæ by a quantity of fat, and is crossed from without inwards by the

internal popliteal nerve and the popliteal vein, the vein being between the nerve and the artery and closely adherent to the latter. On its *outer* side, above, are the Biceps, the internal popliteal nerve, the popliteal vein, and the external condyle of the femur; below, the Plantaris and the outer head of the Gastrocnemius. On its *inner* side, above, are the Semimembranosus and the internal condyle of the femur; below, the internal popliteal nerve, the popliteal vein, and the inner head of the Gastrocnemius. As already stated, the popliteal lymphatic glands, four or five in number, are grouped around the artery.

Peculiarities in point of division.—Occasionally the popliteal artery divides into its terminal branches opposite the knee-joint. The anterior tibial under these circumstances usually passes in front of the Popliteus muscle.

Unusual branches.—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting, or very small. Occasionally it divides into three branches, the anterior and posterior tibial, and peroneal.

Surface Marking.—The course of the upper part of the popliteal artery is indicated by a line drawn from the outer border of the Semimembranosus muscle at the junction of the middle and lower thirds of the thigh—that is to say, from a point a little internal to the upper angle of the popliteal space—obliquely downwards to the middle of the popliteal space exactly behind the knee-joint. From this point it passes vertically downwards to the level of a line drawn through the lower part of the tubercle of the tibia.

Applied Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee, or by hyper-extension of the knee. It may also be lacerated by fracture of the lower part of the shaft of the femur, or by antero-posterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and in fact has been wounded, in performing Macewen's operation of osteotomy of the lower end of the femur for genu valgum. The popliteal artery is more frequently the seat of aneurysm than any other artery in the body, with the exception of the thoracic aorta. No doubt this is due in a great measure to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles as is the case with most arteries. When the knee is acutely flexed the popliteal artery becomes bent on itself to such an extent as to entirely arrest the circulation through it.

Ligature of the popliteal artery is required in cases of wound of the vessel, but for aneurysm it is preferable to tie the femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of the ham the operation is attended with considerable difficulty, from the great depth of the artery, and from the extreme degree of tension of the lateral boundaries of the space.

In order to expose the upper part of the vessel, the patient should be placed in the supine position, with the knee flexed and the thigh abducted and rotated outwards, so that it rests on its outer surface; an incision three inches in length, beginning at the junction of the middle and lower thirds of the thigh, is to be made parallel to and immediately behind the tendon of the Adductor magnus, and the skin, superficial and deep fasciæ divided. The tendon of the muscle is thus exposed, and is to be drawn forwards, and the hamstring tendons backwards. A quantity of fatty tissue will now be opened up, in which the artery will be felt pulsating. This is to be separated with the point of a director until the artery is exposed. The vein and nerve will not be seen, as they lie to the outer side of the artery. The sheath is to be opened and the aneurysm needle passed from before backwards, keeping its point close to the artery for fear of injuring the vein. The only structure to avoid in the superficial incision is the long saphenous vein.

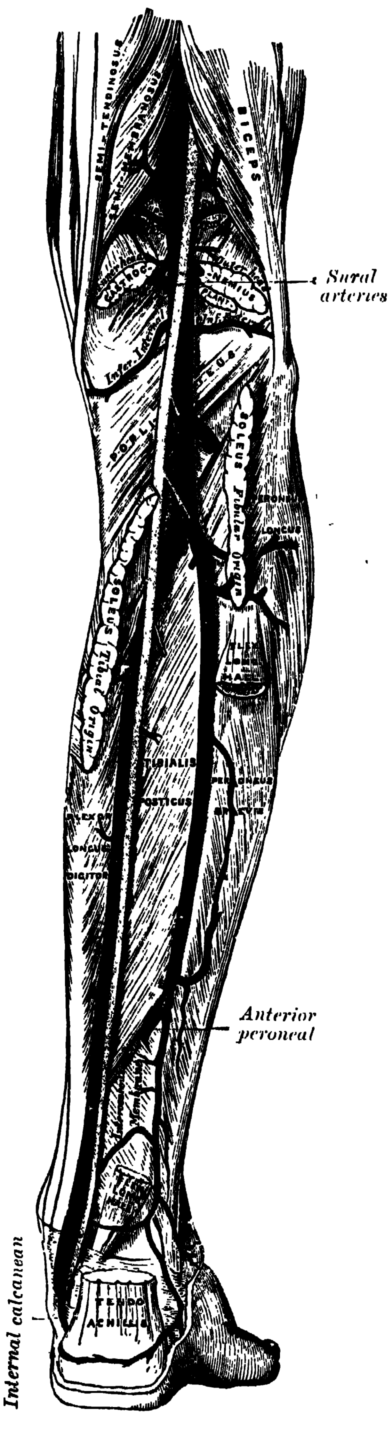
To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the prone position with the limb extended. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the external saphenous vein and nerve. After dividing the deep fascia, and separating some dense cellular tissue, the artery, vein, and nerve will be exposed, between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius, the nerve should be drawn inwards and the vein outwards, and the aneurysm needle passed between the artery and vein from without inwards.

Branches.—The branches of the popliteal artery are:

Muscular { Superior. / Inferior or Sural.	Superior external articular.
	Azygos articular.
Cutaneous.	Inferior internal articular.
Superior internal articular.	Inferior external articular.

The **superior muscular branches**, two or three in number, arise from the upper part of the artery, and are distributed to the lower parts of the Adductor magnus and hamstring muscles, anastomosing with the fourth perforating branch of the profunda.

FIG. 620.—The popliteal, posterior tibial, and peroneal arteries.



The **inferior muscular** or **sural** (aa. surales) are two large branches, which are distributed to the Gastrocnemius, Soleus, and Plantaris. They arise from the popliteal artery opposite the knee-joint.

The **cutaneous branches** arise either from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius muscle, and, piercing the deep fascia, are distributed to the integument of the calf. One branch usually accompanies the short, or external, saphenous vein.

The **superior articular arteries**, two in number, arise one on either side of the popliteal, and wind round the femur immediately above its condyles to the front of the knee-joint. The *superior internal articular* (a. genu superior medialis) runs inwards beneath the inner hamstring muscles, to which it supplies branches, above the inner head of the Gastrocnemius, and passes beneath the tendon of the Adductor magnus. It divides into two branches, one of which supplies the Vastus internus, anastomosing with the anastomotica magna and inferior internal articular; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the superior external articular artery. The superior internal articular artery is frequently of small size, a condition which is associated with an increase in the size of the anastomotica magna. The *superior external articular* (a. genu superior lateralis) passes above the outer condyle, beneath the tendon of the Biceps, and divides into a superficial and a deep branch; the superficial branch supplies the Vastus externus, and anastomoses with the descending branch of the external circumflex and the inferior external articular arteries; the deep branch supplies the lower part of the femur and knee-joint, and forms an anastomotic arch across the front of the bone with the anastomotica magna and the inferior internal articular arteries.

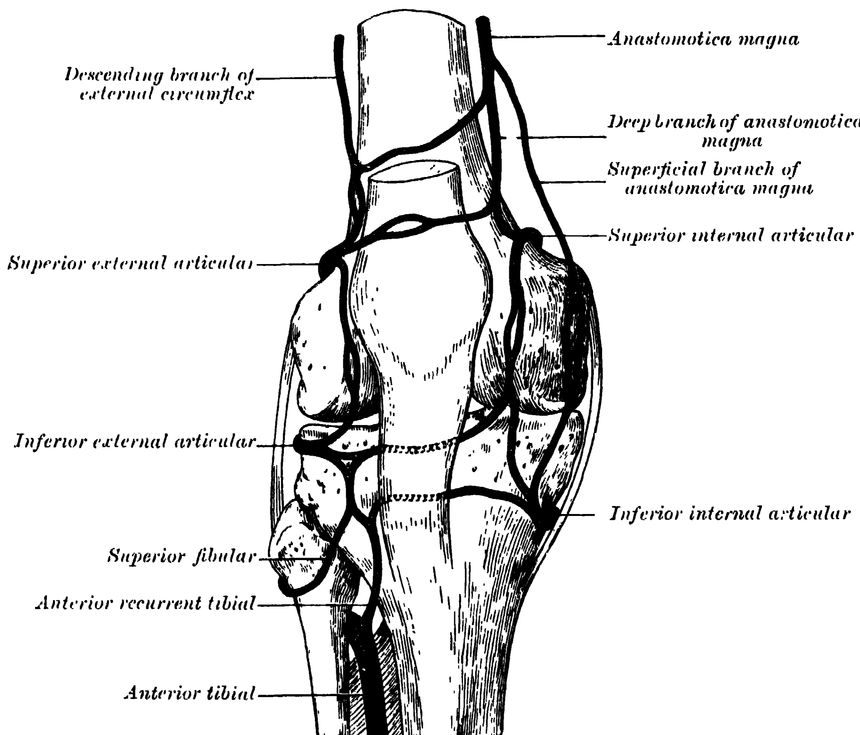
The **azygos articular** (a. genu media) is a small branch, arising opposite the bend of the knee-joint. It pierces the posterior ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

The **inferior articular arteries**, two in number, arise from the popliteal beneath the Gastrocnemius. The *inferior internal articular* (a. genu inferior medialis) first descends along the upper margin of the Popliteus muscle, to which it gives branches;

it then passes below the inner tuberosity of the tibia, beneath the internal lateral ligament, at the anterior border of which it ascends to the front and inner side of the joint, to supply the head of the tibia and the articulation of the knee, anastomosing with the inferior external articular and superior internal articular arteries. The *inferior external articular* (a. genu inferior lateralis) runs outwards above the head of the fibula to the front of the knee-joint, passing in its course beneath the outer head of the Gastrocnemius, the external lateral ligament, and the tendon of the Biceps muscle. It terminates by dividing into branches, which anastomose with the inferior internal articular artery, the superior external articular artery, and the anterior recurrent branch of the anterior tibial.

Circumpatellar anastomosis (fig. 621).—Around and above the patella, and on the contiguous ends of the femur and tibia, is a large network of vessels forming

FIG. 621.—Circumpatellar anastomosis.



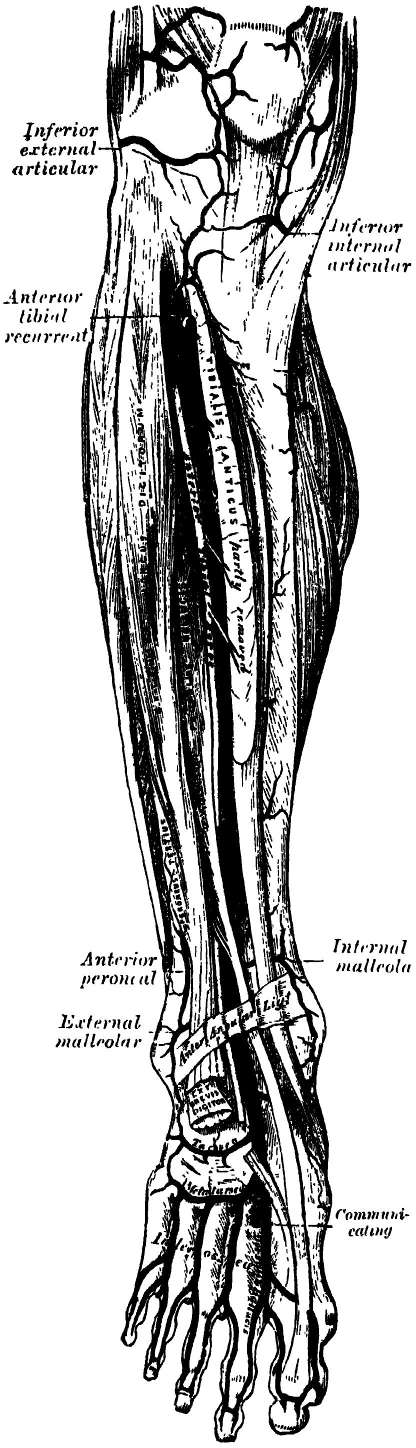
a superficial and a deep plexus. The *superficial plexus* is situated between the fascia and skin round about the patella, and forms three well-defined arches: one, above the upper border of the patella, in the loose connective tissue over the Quadriceps extensor muscle; the other two, below the level of the patella, are situated in the fat behind the ligamentum patellæ. The *deep plexus*, which forms a close network of vessels, lies on the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offsets into the interior of the joint. The arteries from which this plexus is formed are the two internal and the two external articular branches of the popliteal: the anastomotica magna; the descending branch of the external circumflex; and the anterior recurrent branch of the anterior tibial.

ANTERIOR TIBIAL ARTERY (fig. 622)

The **anterior tibial artery** (a. tibialis anterior) commences at the bifurcation of the popliteal, at the lower border of the Popliteus muscle, passes forwards between the two heads of the Tibialis posticus, and through the

large oval aperture above the upper border of the interosseous membrane, to the deep part of the front of the leg: it here lies close to the inner side of the neck of the fibula. It then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; and, at the lower part of the leg, lies on this bone, and then on the anterior ligament of the ankle-joint to the bend of the ankle, where it is more superficial, and becomes the *dorsalis pedis*.

FIG. 622.—Anterior tibial and dorsalis pedis arteries.



Relations.—In the upper two-thirds of its extent, the anterior tibial artery rests upon the interosseous membrane, to which it is connected by delicate fibrous arches thrown across it; in the lower third, upon the front of the tibia, and the anterior ligament of the ankle-joint. In the upper third of its course, it lies between the Tibialis anticus and Extensor longus digitorum; in the middle third between the Tibialis anticus and Extensor proprius hallucis. At the bend of the ankle, it is crossed from without inwards by the tendon of the Extensor proprius hallucis, and lies between it and the innermost tendon of the Extensor longus digitorum. It is covered, in the upper two-thirds of its course, by the muscles which lie on either side of it, and by the deep fascia; in the lower third, by the integument, anterior annular ligament, and fascia.

The anterior tibial artery is accompanied by two veins (venæ comites) which lie one on either side of the artery; the anterior tibial nerve, coursing round the outer side of the neck of the fibula, comes into relation with the outer side of the artery shortly after it has reached the front of the leg; about the middle of the leg it is placed superficial to it; at the lower part of the artery the nerve is generally again on the outer side.

Peculiarities in size.—This vessel may be diminished in size, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial, or by the anterior division of the peroneal artery.

Course.—The artery occasionally deviates in its course towards the fibular side of the leg, regaining its usual position beneath the annular ligament at the front of the ankle. In two instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

Surface Marking.—Draw a line from the inner side of the head of the fibula to a point midway between the two malleoli. This line from a point an inch and a quarter below the head of the fibula will mark the course of the artery.

Applied Anatomy.—The anterior tibial artery is liable to be injured in fractures of the

lower third of the tibia, on account of its close proximity to the bone. The application of a ligature to the vessel is rarely required, except in cases of wound or for traumatic aneurysm. The operation in the upper third of the leg is attended with great difficulty on account of the depth of the vessel from the surface. An incision about four inches in length is made in the line of the artery to about a hand's breadth below the level of the knee-joint. The skin and superficial structures having been divided and the deep fascia exposed, the wound must be carefully dried, its edges retracted, and the white line separating the Tibialis anticus from the Extensor longus digitorum sought for. When this has been clearly defined, the deep fascia is to be divided in this line, and the Tibialis anticus separated from adjacent muscles with the handle of the scalpel or a director until the interosseous membrane is reached. The foot is to be flexed in order to relax the muscles, and upon drawing them apart the artery will be found lying on the interosseous membrane with the nerve on its outer side or on the top of it. The nerve should be drawn outwards, and the venæ comites separated from the artery and the needle passed around it.

To tie the vessel in the lower third of the leg above the ankle-joint, an incision about three inches in length should be made through the integument between the tendons of the Tibialis anticus and Extensor proprius hallucis muscles, the deep fascia being divided to the same extent. The tendon on either side should be retracted, when the vessel, accompanied by the venæ comites, will be seen lying upon the tibia, with the nerve on the outer side.

Branches.—The branches of the anterior tibial artery are:

Posterior recurrent tibial.	Muscular.
Superior fibular.	Internal malleolar.
Anterior recurrent tibial.	External malleolar.

The **posterior recurrent tibial** (a. recurrens tibialis posterior), an inconstant branch, is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends in front of the Popliteus muscle, which it supplies, and anastomoses with the lower articular branches of the popliteal artery, giving an offset to the superior tibio-fibular joint.

The **superior fibular** is sometimes derived from the anterior tibial, sometimes from the posterior tibial. It passes outwards, round the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus.

The **anterior recurrent tibial** (a. recurrens tibialis anterior) arises from the anterior tibial, as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anticus muscle, ramifies on the front and sides of the knee-joint, and assists in the formation of the circumpatellar plexus by anastomosing with the articular branches of the popliteal, and with the anastomotica magna.

The **muscular branches** are numerous; they are distributed to the muscles which lie on either side of the vessel, some piercing the deep fascia to supply the integument, others passing through the interosseous membrane, and anastomosing with branches of the posterior tibial and peroneal arteries.

The **internal malleolar** (a. malleolaris anterior medialis) arises about two inches above the articulation, and passes beneath the tendons of the Extensor proprius hallucis and Tibialis anticus, to the inner side of the ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and internal plantar arteries and with the internal calcanean from the posterior tibial.

The **external malleolar** (a. malleolaris anterior lateralis) passes beneath the tendons of the Extensor longus digitorum and Peroneus tertius, and supplies the outer side of the ankle, anastomosing with the anterior peroneal artery, and with ascending twigs from the tarsal branch of the dorsalis pedis.

Dorsalis Pedis Artery (fig. 622)

The **dorsalis pedis artery** (a. dorsalis pedis), the continuation of the anterior tibial, passes forwards from the bend of the ankle along the tibial side of the dorsum of the foot to the back part of the first intermetatarsal space, where it divides into two branches, the *dorsalis hallucis* and *communicating*.

Relations.—This vessel, in its course forwards, rests upon the anterior ligament of the ankle-joint, the astragalus, navicular, and middle cuneiform bones, and the ligaments connecting them, being covered by the integument, fascia and anterior annular ligament, and crossed near its termination by the innermost tendon of the Extensor brevis digitorum. On its *tibial side* is the tendon of

the Extensor proprius hallucis; on its *fibular side*, the innermost tendon of the Extensor longus digitorum, and the termination of the anterior tibial nerve. It is accompanied by two veins.

Peculiarities in size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or its terminal branches to the toes may be absent, the toes then being supplied by the internal plantar; or its place may be taken altogether by a large anterior peroneal artery.

Position.—This artery frequently curves outwards, lying external to the line between the middle of the ankle and the back part of the first interosseous space.

Surface Marking.—The dorsalis pedis artery is indicated on the surface of the dorsum of the foot by a line drawn from the centre of the space between the two malleoli to the back of the first intermetatarsal space.

Applied Anatomy.—This artery may be tied, by making an incision two inches in length, through the integument, on the fibular side of the tendon of the Extensor proprius hallucis, in the interval between it and the inner border of the short Extensor muscle. The incision should not extend farther forwards than the back part of the first intermetatarsal space, as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the nerve lying upon its outer side.

Branches.—The branches of the dorsalis pedis are:

Tarsal.	Dorsalis hallucis.
Metatarsal—Interosseous.	Communicating.

The **tarsal** (a. tarsea lateralis) arises from the dorsalis pedis, as that vessel crosses the navicular bone; it passes in an arched direction outwards, lying upon the tarsal bones, and covered by the Extensor brevis digitorum; it supplies this muscle and the articulations of the tarsus, and anastomoses with branches from the metatarsal, external malleolar, peroneal, and external plantar arteries.

The **metatarsal** (a. arcuata) arises a little anterior to the preceding; it passes outwards, over the bases of the metatarsal bones, beneath the tendons of the short Extensor, its direction being influenced by its point of origin; and it anastomoses with the tarsal and external plantar arteries. This vessel gives off three *dorsal interosseous arteries* (aa. metatarseæ dorsales), which run forwards upon the outer three Dorsal interossei, and, in the clefts between the toes, divide into two dorsal collateral branches for the adjoining toes. At the back part of each interosseous space these vessels receive the posterior perforating branches from the plantar arch; and at the fore part of each interosseous space they are joined by the anterior perforating branches, from the plantar digital arteries. The outermost interosseous artery gives off a branch which supplies the outer side of the little toe.

The **dorsalis hallucis**, or **first dorsal interosseous artery**, runs forward along the outer border of the first metatarsal bone, and at the cleft between the first and second toes divides into two branches, one of which passes inwards, beneath the tendon of the Extensor proprius hallucis, and is distributed to the inner border of the great toe; the other bifurcates to supply the adjoining sides of the great and second toes.

The **communicating** dips down into the sole of the foot, between the two heads of the First dorsal interosseous muscle, and anastomoses with the termination of the external plantar artery, to complete the plantar arch. It here gives off its plantar digital branch, which is named the *arteria magna hallucis*. This artery passes forwards along the first interosseous space, and, after sending a branch along the inner side of the great toe, bifurcates for the supply of the adjacent sides of the great and second toes.

Posterior Tibial Artery (fig. 620)

The **posterior tibial artery** (a. tibialis posterior) begins at the lower border of the Popliteus muscle, opposite the interval between the tibia and fibula; it extends obliquely downwards, and, as it descends, it approaches the inner side of the leg, lying behind the tibia, and in the lower part of its course is situated midway between the internal malleolus and the tuberosity of the os calcis. Here it divides beneath the origin of the Abductor hallucis into the *internal* and *external plantar* arteries.

Relations.—The posterior tibial artery lies successively upon the Tibialis posticus, the Flexor longus digitorum, the tibia, and the back part of the ankle-joint. It is covered by the deep transverse fascia, which separates it above from the Gastrocnemius and Soleus muscles: at its termination it is covered by the Abductor hallucis muscle. In the lower third of the leg, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the inner border of the tendo Achillis. It is accompanied by two veins, and by the posterior tibial nerve, which lies at first to the inner side of the artery, but soon crosses it, and is, in the greater part of its course, on its outer side.

Behind the inner malleolus, the tendons and blood-vessels are arranged, under cover of the internal annular ligament, in the following order from within outwards: first, the tendons of the Tibialis posticus and Flexor longus digitorum, lying in the same groove, behind the inner malleolus, the former being internal. External to these is the posterior tibial artery, having a vein on either side; and, still more externally, the posterior tibial nerve. About half an inch nearer the heel is the tendon of the Flexor longus hallucis.

Peculiarities in size.—The posterior tibial is not infrequently smaller than usual, or absent, its place being supplied by a large peroneal artery, which passes inwards at the lower end of the tibia, and either joins the small posterior tibial artery, or continues alone to the sole of the foot.

Surface Marking.—The course of the posterior tibial artery is indicated by a line drawn from a point an inch below the centre of the popliteal space to midway between the tip of the internal malleolus and the centre of the convexity of the heel.

Applied Anatomy.—The application of a ligature to the posterior tibial may be required in cases of wound of the sole of the foot, attended with great hæmorrhage, when the vessel should be tied at the inner ankle. In cases of wound of the posterior tibial, it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurysm from wound of the artery low down, the vessel should be tied in the middle of the leg.

To tie the posterior tibial artery at the ankle, a semilunar incision, convex backwards, should be made through the integument, about two inches and a half in length, midway between the heel and inner ankle, or a little nearer the latter. The subcutaneous cellular tissue having been divided, a strong and dense fascia, the internal annular ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the venæ comites on either side. The aneurysm needle should be passed round the vessel from the heel towards the ankle, in order to avoid the posterior tibial nerve, care at the same time being taken not to include the venæ comites.

The vessel may also be tied in the lower third of the leg by making an incision about three inches in length, parallel with the inner margin of the tendo Achillis. The internal saphenous vein being carefully avoided, the two layers of fascia must be divided upon a director, when the artery is exposed along the outer margin of the Flexor longus digitorum, with one of its venæ comites on either side, and the nerve lying external to it.

Ligature of the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its outer side, the knee being partially bent, and the foot extended, so as to relax the muscles of the calf. An incision about four inches in length should then be made through the integument, a finger's breadth behind the inner margin of the tibia, care being taken to avoid the internal saphenous vein. The deep fascia having been divided, the margin of the Gastrocnemius is exposed, and must be drawn aside, and the tibial attachment of the Soleus divided. The artery may now be felt pulsating beneath the deep fascia, about an inch from the margin of the tibia. The fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery and the aneurysm needle passed round the vessel from without inwards, so as to avoid wounding the posterior tibial nerve.

Branches.—The branches of the posterior tibial artery are:

Peroneal.	Muscular.
Nutrient.	Communicating.
Internal calcanean.	

The **peroneal** (a. peronæa) lies, deeply seated, along the back part of the fibular side of the leg. It arises from the posterior tibial, about an inch below

the lower border of the Popliteus muscle, passes obliquely outwards to the fibula, and then descends along the inner side of that bone, contained in a fibrous canal between the Tibialis posticus and the Flexor longus hallucis, or in the substance of the latter muscle. About two inches above the outer malleolus it divides into two terminal branches, the *anterior* and *posterior peroneal*.

Relations.—This vessel lies at first upon the Tibialis posticus, and then, for the greater part of its course, in a fibrous canal between the origins of the Flexor longus hallucis and Tibialis posticus, covered or surrounded by the fibres of the Flexor longus hallucis. It is covered, in the *upper* part of its course, by the Soleus and deep transverse fascia; *below*, by the Flexor longus hallucis.

Peculiarities in origin.—The peroneal artery may arise three inches below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

Its size is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual, a branch from the posterior tibial supplies its place; and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery was entirely wanting.

The anterior peroneal is sometimes enlarged, and takes the place of the dorsal artery of the foot.

The branches of the peroneal are:

Muscular.	Communicating.
Nutrient.	Posterior peroneal.
Anterior peroneal.	External calcanean.

Muscular branches.—The peroneal artery, in its course, gives off branches to the Soleus, Tibialis posticus, Flexor longus hallucis, and Peronei muscles.

The ***nutrient artery*** (a. nutritia fibulæ) supplies the fibula.

The ***anterior peroneal*** (ramus perforans) pierces the interosseous membrane, about two inches above the outer malleolus, to reach the front of the leg, and, passing down beneath the Peroneus tertius to the outer side of the ankle, ramifies on the front and outer side of the tarsus, anastomosing with the external malleolar and tarsal arteries.

The ***communicating*** (ramus communicans) is given off from the peroneal about an inch from its lower end, and passes inwards to join the communicating branch of the posterior tibial.

The ***posterior peroneal*** passes down behind the inferior tibio-fibular articulation to the back of the external malleolus, to terminate in branches which ramify on the outer surface and back of the os calcis, and anastomose with the external malleolar and tarsal arteries.

The ***external calcanean*** (rami calcanei laterales) are the terminal branches of the posterior peroneal artery; they pass to the outer side of the heel, and communicate with the external malleolar and, on the back of the heel, with the internal calcanean arteries.

The **nutrient** (a. nutritia tibiæ) of the tibia arises from the posterior tibial, near its origin, and after supplying a few muscular branches enters the nutrient canal of that bone, which it traverses obliquely from above downwards. This is the largest nutrient artery of bone in the body.

The **muscular branches** of the posterior tibial are distributed to the Soleus and deep muscles along the back of the leg.

The **communicating branch** (ramus communicans) runs transversely across the back of the tibia, about two inches above its lower end, beneath the Flexor longus hallucis, to join a similar branch of the peroneal.

The **internal calcanean** (rami calcanei mediales) are several large arteries which arise from the posterior tibial just before its division; they are distributed to the fat and integument behind the tendo Achillis and about the heel, and to the muscles on the inner side of the sole, anastomosing with the peroneal and internal malleolar and, on the back of the heel, with the external calcanean arteries.

The **internal plantar** (a. plantaris medialis) (figs. 623 and 624), much smaller than the external, passes forwards along the inner side of the foot. It is at first situated above the Abductor hallucis, and then between it and the Flexor brevis digitorum, both of which it supplies. At the base of the first metatarsal bone, where it is much diminished in size, it passes along the inner border of the great toe, anastomosing with its digital branch. Small superficial digital branches

accompany the digital branches of the internal plantar nerve and join the plantar digital arteries of the three inner spaces.

The **external plantar** (a. plantaris lateralis), much larger than the internal, passes obliquely outwards and forwards to the base of the fifth metatarsal bone. It then turns inwards to the interval between the bases of the first and second metatarsal bones, where it anastomoses with the communicating branch from the dorsalis pedis artery, thus completing the *plantar arch*. As this artery passes outwards, it is first placed between the os calcis and Abductor hallucis,

Fig. 623.—The plantar arteries. Superficial view.

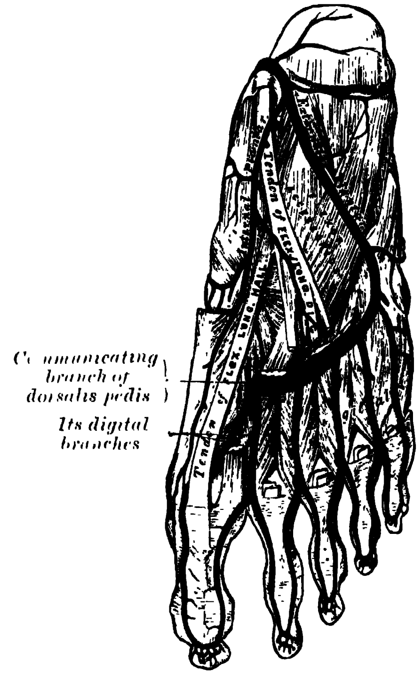


Fig. 624.—The plantar arteries. Deep view.

and then between the Flexor brevis digitorum and Flexor accessorius; as it passes forwards to the base of the little toe, it lies more superficially between the Flexor brevis digitorum and Abductor minimi digiti, covered by the deep fascia and integument. The remaining portion of the vessel is deeply situated; it extends from the base of the metatarsal bone of the little toe to the back part of the first interosseous space, and forms the plantar arch: it is convex forwards, lies below the tarsal ends of the second, third, and fourth metatarsal bones and the corresponding Interosseous muscles, and upon the Adductor obliquus hallucis.

Surface Marking.—The course of the internal plantar artery is represented by a line drawn from the mid-point between the tip of the internal malleolus and the centre of the convexity of the heel to the middle of the under surface of the great toe; the external plantar by a line from the same point to within a finger's breadth of the tuberosity of the fifth metatarsal bone. The plantar arch is indicated by a line drawn from this point i.e. a finger's breadth internal to the tuberosity of the fifth metatarsal bone, transversely across the foot to the back of the first interosseous space.

Applied Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligature it. They must be treated on similar lines to those of wounds of the palmar arches (see page 682). Pressure locally, combined with elevation of the limb, may in some cases be sufficient to arrest the bleeding, but this failing an attempt should be made to find the bleeding point and ligature it. Should this prove unsuccessful, it may be necessary to ligature the superficial femoral, as ligature of the anterior and posterior tibial arteries may not be sufficient to control the hæmorrhage, and it is safer and quicker to tie the femoral under the circumstances.

Branches.—The plantar arch, besides distributing numerous branches to the muscles, integument, and fasciæ in the sole, gives off the following branches:

Posterior perforating. Digital—Anterior perforating.

The **posterior perforating** (rami perforantes) are three small branches, which ascend through the back part of the outer three interosseous spaces, between the heads of the Dorsal interosseous muscles, and anastomose with the interosseous branches from the metatarsal artery.

The **digital branches** (aa. metatarsoæ plantares) are four in number, and supply the outer three toes and half the second toe. The *first* arises from the outer side of the plantar arch, and is distributed to the outer side of the little toe, passing in its course beneath the Abductor and Flexor brevis minimi digiti. The *second, third*, and *fourth* run forwards along the interosseous spaces, and on arriving at the clefts between the toes divide into collateral branches (aa. digitales plantares), which supply the adjacent sides of the outer three toes and the outer side of the second. Near to its point of bifurcation, each digital artery sends upwards, through the fore part of the corresponding interosseous space, a small branch, the *anterior perforating artery*, which anastomoses with the corresponding interosseous branch of the metatarsal artery.

From the description given it will be seen that both sides of the outer three toes, and the outer side of the second toe, are supplied by branches from the plantar arch; both sides of the great toe, and the inner side of the second, are supplied by the arteria magna hallucis.

THE VEINS

The veins convey the blood from the capillaries of the different parts of the body to the heart. They consist of two distinct sets of vessels, the *pulmonary* and *systemic*.

The **Pulmonary Veins** are concerned in the circulation in the lungs. Unlike other vessels of this kind, they contain arterial blood, which they return from the lungs to the left auricle of the heart.

The **Systemic Veins** are concerned in the general circulation; they return the venous blood from the body generally, to the right auricle of the heart.

The **Portal Vein**, an appendage to the systemic venous system, is confined to the abdominal cavity, and returns the venous blood from the spleen and the viscera of digestion to the liver. This vessel ramifies in the substance of the liver and breaks up into a minute network of capillaries. From these capillaries the blood is conveyed by the hepatic veins to the inferior vena cava.

The veins, like the arteries, are found in nearly every tissue of the body. They commence by minute plexuses which receive the blood from the capillaries. The branches which have their commencement in these plexuses unite together into trunks, and these, in their passage towards the heart, constantly increase in size as they receive tributaries, or join other veins. The veins are larger and altogether more numerous than the arteries; hence, the entire capacity of the venous system is much greater than that of the arterial; the capacity of the pulmonary veins, however, only slightly exceeds that of the pulmonary arteries. Since the combined area of the smaller venous branches is greater than that of the main trunks, the venous system may be compared to a cone, the summit of which corresponds to the heart, its base to the periphery of the body. In form, the veins are cylindrical like the arteries; their walls, however, collapse when the vessels are empty, and the uniformity of their surfaces is interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior. They usually retain, however, the same calibre so long as they receive no branches.

The veins communicate very freely with one another, especially in certain regions of the body; and this communication exists between the larger trunks as well as between the smaller branches. Thus, between the sinuses of the cranium, and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral venous system, large and

very frequent anastomoses are found. The same free communication exists between the veins throughout the whole extent of the spinal canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, e.g. the spermatic, uterine, vesical, and prostatic.

Veins have thinner walls than arteries, the difference in thickness being due to the smaller amount of elastic and muscular tissues. The superficial veins usually have thicker coats than the deep veins, and the walls of the veins of the lower limb are thicker than those of the upper.

The minute structure of these vessels has been described in the section on Histology (pages 59 and 60).

The systemic veins are subdivided into three sets, viz. superficial and deep veins, and venous sinuses.

The **Superficial** or **Cutaneous Veins** are found between the layers of the superficial fascia, immediately beneath the integument; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

The **Deep Veins** accompany the arteries, and are usually enclosed in the same sheaths with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called *venæ comites*. The larger arteries—such as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and spinal canal, the hepatic veins in the liver, and the larger veins returning blood from the bones.

Venous Sinuses are channels which, in their structure and mode of distribution, differ altogether from the veins. They are found only in the interior of the skull, and consist of canals formed by a separation of the two layers of the dura mater; the outer coat consists of fibrous tissue, the inner of an endothelial layer continuous with the lining membrane of the veins.

THE PULMONARY VEINS

The **pulmonary veins** (venæ pulmonales) return the arterialised blood from the lungs to the left auricle of the heart. They are four in number, two for each lung, and are destitute of valves. They commence in a capillary network upon the walls of the air-sacs, where they are continuous with the capillary ramifications of the pulmonary artery, and, joining together, form one vessel for each lobule. These vessels, uniting successively, form a single trunk for each lobe, three for the right, and two for the left lung. The vein from the middle lobe of the right lung generally unites with that from the upper lobe, so that ultimately two trunks from each lung are formed; they perforate the pericardium and open separately into the upper and back part of the left auricle. Occasionally the three veins on the right side remain separate. Not infrequently, the two left pulmonary veins terminate by a common opening.

Within the lung, the branches of the pulmonary artery are in front, the veins behind, and the bronchi between the two.

At the root of the lung, the upper pulmonary vein lies in front of and a little below the pulmonary artery; the lower is situated below the other structures in the lung root, and on a plane posterior to the upper vein. Behind the pulmonary artery is the bronchus.

Within the pericardium, their anterior surfaces are invested by the serous layer of this membrane.

The right pulmonary veins pass behind the right auricle and superior vena cava; the left in front of the thoracic aorta.

***Applied Anatomy.*—Thrombosis of larger or smaller branches of the pulmonary veins is common in inflamed areas of the lung, or as a consequence of pressure from tumours, but it does not give rise to any special symptoms.**

THE SYSTEMIC VEINS

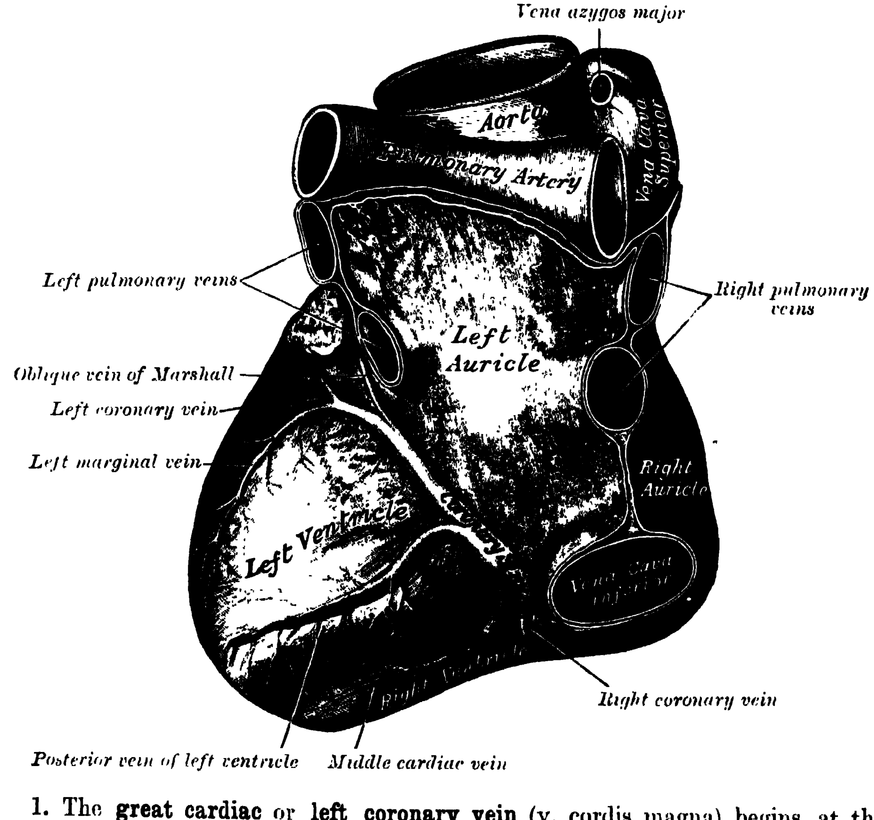
The **systemic veins** may be arranged into three groups: 1. The cardiac veins. 2. The veins of the head and neck, upper extremity, and thorax, which terminate in the superior vena cava. 3. The veins of the lower extremity, abdomen, and pelvis, which terminate in the inferior vena cava.

CARDIAC VEINS

The **coronary sinus** (sinus coronarius) is a wide venous channel about an inch in length which receives the majority of the veins draining the blood from the substance of the heart. It is situated in the posterior part of the auriculo-ventricular groove, and is covered by muscular fibres from the left auricle. It terminates in the right auricle between the opening of the inferior vena cava and the auriculo-ventricular aperture, its orifice being guarded by a semilunar valve, the *valve of Thebesius.*

Its tributaries are the great, small, and middle cardiac veins, the posterior vein of the left ventricle, and the oblique vein of Marshall, all of which, except the last, are provided with valves at their orifices.

FIG. 625.—Base and postero-inferior surface of heart.



1. The **great cardiac** or **left coronary vein** (v. cordis magna) begins at the apex of the heart and ascends along the anterior interventricular groove to the base of the ventricles. It then curves to the left in the auriculo-ventricular groove to the back of the heart, and opens into the left extremity of the coronary sinus. It receives tributaries from the left auricle and from both ventricles: one of these, the *left marginal vein*, is of considerable size, and ascends along the left margin of the heart.

2. The **small cardiac** or **right coronary vein** (v. cordis parva) runs in the groove between the right auricle and ventricle, and opens into the right extremity

of the coronary sinus. It receives blood from the back of the right auricle and ventricle; its largest tributary, the *right marginal vein*, ascends along the right margin of the heart and joins it in the auriculo-ventricular groove.

3. The **middle cardiac vein** (v. cordis media) commences at the apex of the heart, ascends in the posterior interventricular groove, and ends in the coronary sinus near its right extremity.

4. The **posterior vein of the left ventricle** (v. posterior ventriculi sinistri) ascends on the back of the left ventricle to the coronary sinus, but may end in the great cardiac vein.

5. The **oblique vein of Marshall** (v. obliqua atrii sinistri) is a small vessel which descends obliquely on the back of the left auricle and ends in the coronary sinus near its right extremity; it is continuous above with the *vestigial fold of Marshall*, and the two structures form the remnant of the left Cuverian duct.

The following cardiac veins do not terminate in the coronary sinus: (1) the **anterior cardiac veins** (vv. cordis anteriores), comprising three or four small vessels which collect blood from the front of the right ventricle and open into the right auricle. The right marginal vein frequently opens into the right auricle, and is therefore sometimes regarded as belonging to this group. (2) The **veins of Thebesius** (vv. cordis minimæ), consisting of a number of minute veins which arise in the muscular wall of the heart; the majority open into the auricles, but a few terminate in the ventricles.

VEINS OF THE HEAD AND NECK

The veins of the head and neck may be subdivided into three groups: 1. The veins of the exterior of the head and face. 2. The veins of the neck. 3. The veins of the diploë and the interior of the cranium.

Veins of the Exterior of the Head and Face (fig. 626)

The veins of the exterior of the head and face are:

Frontal.	Superficial temporal.
Supra-orbital.	Internal maxillary.
Angular.	Temporo-maxillary.
Facial.	Posterior auricular.

Occipital.

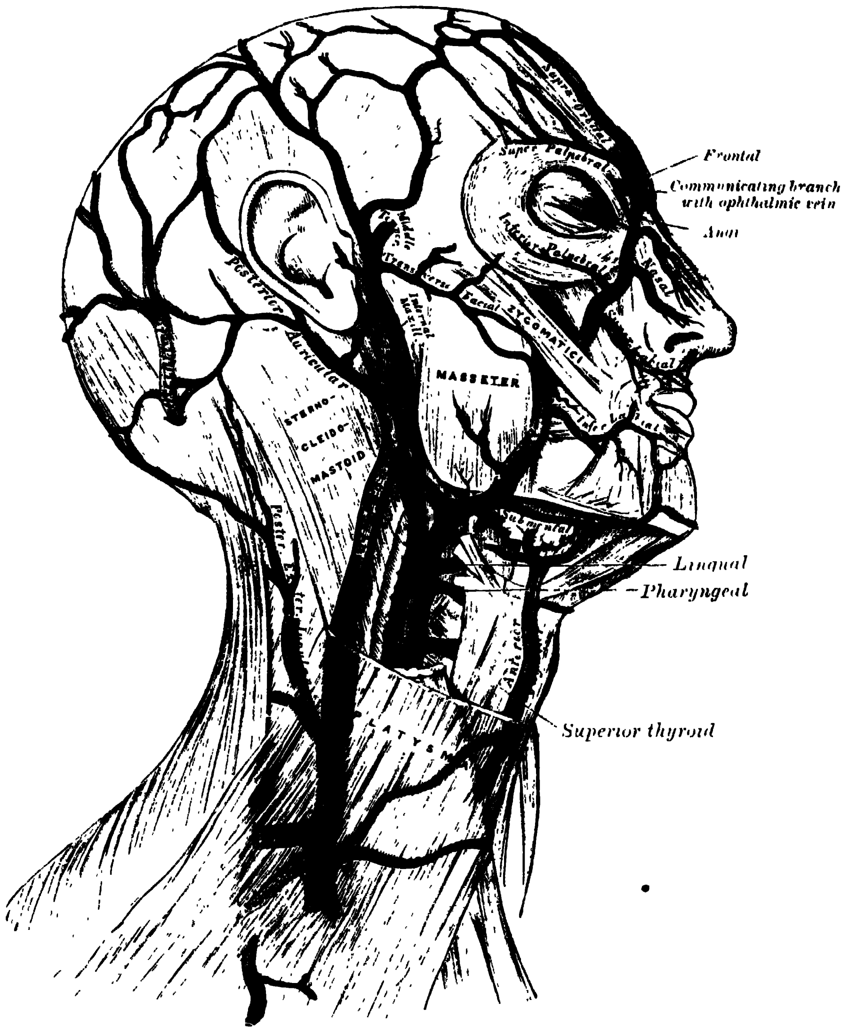
The **frontal vein** (v. frontalis) commences on the anterior part of the skull in a venous plexus which communicates with the anterior tributaries of the temporal vein. The veins converge to form a single trunk, which runs downwards near the middle line of the forehead parallel with the vein of the opposite side. The two veins are joined, at the root of the nose, by a transverse branch, called the *nasal arch*, which receives some small veins from the dorsum of the nose. Occasionally the frontal veins join to form a single trunk, which bifurcates at the root of the nose into the two angular veins. At the root of the nose the veins diverge, and, each at the inner angle of the orbit, joins the *supra-orbital vein*, to form the *angular vein*.

The **supra-orbital vein** (v. supraorbitalis) commences on the forehead, communicating with the anterior temporal vein, and runs downwards and inwards, superficial to the Occipito-frontalis muscle; it receives tributaries from the neighbouring structures, and joins the frontal vein at the inner angle of the orbit to form the *angular vein*. Previous to its junction with the frontal vein, it sends through the supra-orbital notch into the orbit a branch which communicates with the ophthalmic vein. As this vessel passes through the notch, it receives a diploic vein from the diploë of the frontal bone, through a foramen at the bottom of the notch.

The **angular vein** (v. angularis), formed by the junction of the frontal and supra-orbital veins, runs obliquely downwards and outwards, on the side of the root of the nose, to the level of the lower margin of the orbit, where it becomes the facial vein. It receives the veins of the ala nasi on its inner side, and the superior palpebral veins on its outer side; it communicates with the ophthalmic vein, thus establishing an important anastomosis between the facial vein and the cavernous sinus.

The **facial vein** (v. facialis anterior) commences at the side of the root of the nose, being a direct continuation of the angular vein. It lies behind the facial artery and follows a less tortuous course. It runs obliquely downwards and outwards, beneath the Zygomaticus major and minor muscles, descends along the anterior border of the Masseter, crosses over the body of the lower jaw, with the facial artery, and passes obliquely outwards and backwards, beneath the Platysma and cervical fascia superficial to the submaxillary gland. It unites with the anterior division of the temporo-maxillary vein to form a large trunk, the *common facial vein* (v. facialis communis), which enters the internal jugular vein.

FIG. 626.—Veins of the head and neck.



From near its termination a communicating branch often runs down the anterior border of the Sterno-mastoid to join the lower part of the anterior jugular vein.

Tributaries.—The facial vein receives, near the angle of the mouth, a communicating tributary of considerable size, the *deep facial vein*, from the pterygoid plexus. It is also joined by the inferior palpebral, the superior and inferior labial, the buccal and the masseteric veins. Below the jaw it receives the submental; the inferior palatine which returns the blood from the plexus around the tonsil and soft palate; the submaxillary which commences in the submaxillary gland; and, generally, the ranine vein.

Applied Anatomy.—There are some points about the facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement by the angular and supra-orbital veins which communicate with the ophthalmic vein, a tributary of the cavernous sinus, but also by the deep facial vein, which communicates through the pterygoid plexus with the cavernous sinus by branches which pass through the foramen ovale and foramen lacerum medium (see page 730). These facts have an important bearing upon the surgery of some diseases of the face; for on account of its patency the facial vein favours septic absorption, and therefore any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the facial vein, and detached portions of the clot may give rise to purulent foci in other parts of the body. On account of its communications with the cerebral sinuses, these thrombi are apt to extend upwards into them, and so induce a fatal issue; this has been known to follow facial carbuncle.

The **superficial temporal vein** (v. temporalis superficialis) commences on the side and vertex of the skull in a plexus which communicates with the frontal and supra-orbital veins in front, the corresponding vein of the opposite side, and the posterior auricular and occipital veins behind. From this network anterior and posterior branches arise, and unite above the zygoma to form the trunk of the vein, which is joined in this situation by a large vein, the *middle temporal* (v. temporalis media), from the substance of the Temporal muscle. It then crosses the posterior root of the zygoma, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the temporo-maxillary vein.

Tributaries.—The temporal vein receives in its course some parotid veins, articular veins from the temporo-mandibular joint, anterior auricular veins from the external ear, and a vein of large size, the *transverse facial* (v. transversa faciei), from the side of the face. The middle temporal vein, previous to its junction with the temporal vein, receives the *orbital vein*, which is formed by some external palpebral branches, and passes backwards between the layers of the temporal fascia.

The **pterygoid plexus** (plexus pterygoideus) is of considerable size, and is situated between the Temporal and External pterygoid, and partly between the two Pterygoid muscles. It receives tributaries corresponding with the branches of the internal maxillary artery. Thus it receives the middle meningeal, the deep temporal, the pterygoid, masseteric buccal, alveolar, some palatine veins, and the inferior dental, and a branch which communicates with the ophthalmic vein through the spheno-maxillary fissure. This plexus communicates very freely with the facial vein; it also communicates with the cavernous sinus, by branches through the foramen Vesalii, foramen ovale, and foramen lacerum medium, at the base of the skull.

The **internal maxillary vein** (v. maxillaris interna) is a short trunk which accompanies the first part of the internal maxillary artery. It is formed by a confluence of the veins of the pterygoid plexus, and passes backwards between the internal lateral ligament and the neck of the mandible, and unites with the temporal vein to form the temporo-maxillary vein.

The **temporo-maxillary vein** (v. facialis posterior), formed by the union of the temporal and internal maxillary veins, descends in the substance of the parotid gland, superficial to the external carotid artery but beneath the facial nerve, between the ramus of the mandible and the Sterno-mastoid muscle. It divides into two branches, an anterior, which passes inwards to join the facial vein, and a posterior, which is joined by the posterior auricular vein and becomes the external jugular.

The **posterior auricular vein** (v. auricularis posterior) commences upon the side of the head, in a plexus which communicates with the tributaries of the temporal and occipital veins. It descends behind the external ear, and joins the posterior division of the temporo-maxillary vein to form the external jugular. It receives the stylo-mastoid vein, and some tributaries from the back part of the external ear.

The **occipital vein** (v. occipitalis) commences in a plexus at the back part of the vertex of the skull. From the plexus emerges a single vessel, which pierces the cranial attachment of the Trapezius and, dipping into the sub-occipital triangle, joins the deep cervical vein. Occasionally it follows the course of the

occipital artery instead and terminates in the internal jugular; in other instances, it joins the posterior auricular and passes into the external jugular. As it passes across the mastoid portion of the temporal bone, it receives the mastoid vein, and thus establishes a communication with the lateral sinus.

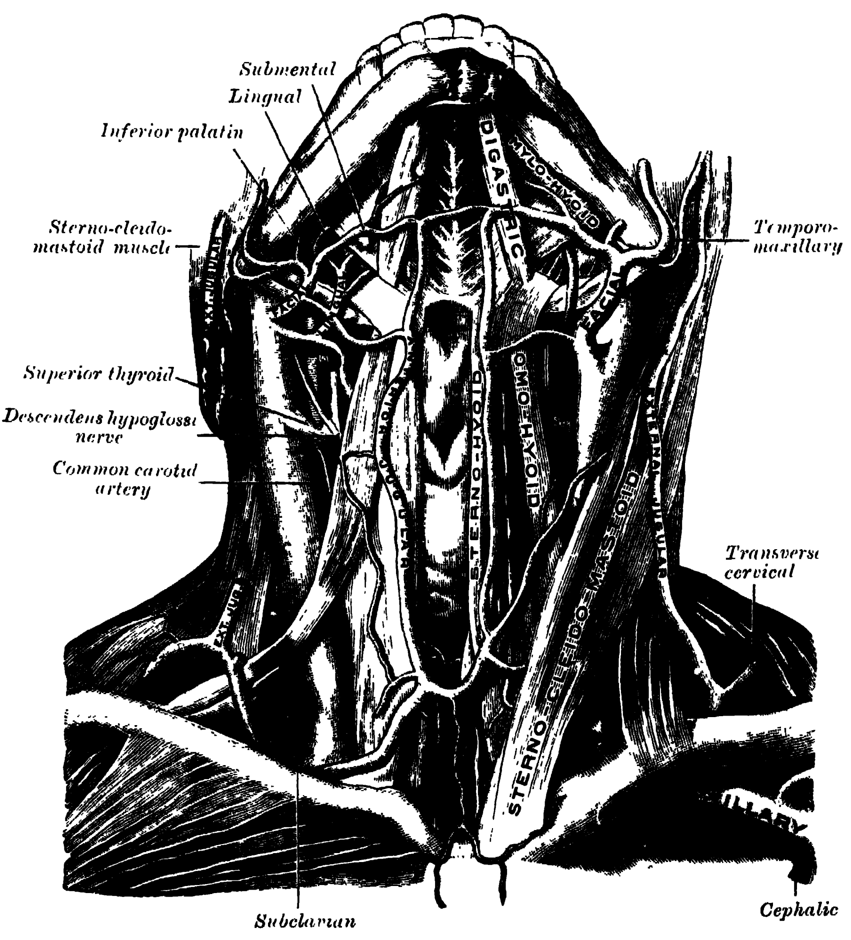
Veins of the Neck (fig. 627)

The veins of the neck, which return the blood from the head and face, are:

External jugular. Anterior jugular.
Posterior external jugular. Internal jugular.
Vertebral.

The **external jugular vein** (v. jugularis externa) receives the greater part of the blood from the exterior of the cranium and deep parts of the face, being formed by the junction of the posterior division of the temporo-maxillary with the posterior auricular vein. It commences in the substance of the parotid gland, on a level with the angle of the mandible, and runs perpendicularly

Fig. 627.—The veins of the neck, viewed from in front. (Spalteholz.)



down the neck, in the direction of a line drawn from the angle of the mandible to the middle of the clavicle. In its course it crosses the Sterno-mastoid muscle, and in the subclavian triangle perforates the deep fascia, and terminates in the subclavian vein, on the outer side or in front of the Scalenus anticus muscle. It is separated from the Sterno-mastoid by the investing layer of the deep cervical fascia, and is covered by the Platysma, the superficial fascia,

and the integument; it crosses the superficial cervical nerve, and its upper half runs parallel with the great auricular nerve. The external jugular vein varies in size, bearing an inverse proportion to the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper pair in most cases about an inch and a half above the clavicle. The portion of vein between the two sets of valves is often dilated, and is termed the *sinus*. These valves do not prevent the regurgitation of the blood, or the passage of injection from below upwards.

Applied Anatomy.—Venesection used formerly to be performed on the external jugular vein, but is now probably never resorted to. The anatomical point to be remembered in performing this operation is to cut across the fibres of the Platysma in opening the vein, so that by their contraction they will expose the orifice in the vein and so allow the flow of blood.

Tributaries.—This vein receives the occipital occasionally, the posterior external jugular, and, near its termination, the transverse cervical, suprascapular, and anterior jugular veins; in the substance of the parotid, a large branch of communication from the internal jugular joins it.

The **posterior external jugular vein** commences in the occipital region and returns the blood from the integument and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius muscles. It runs down the back part of the neck, and opens into the external jugular just below the middle of its course.

The **anterior jugular vein** (v. jugularis anterior) commences near the hyoid bone from the confluence of several superficial veins from the submaxillary region. It descends between the median line and the anterior border of the Sterno-mastoid, and, at the lower part of the neck, passes beneath that muscle to open into the termination of the external jugular, or, in some instances, into the subclavian vein (figs. 626, 627). It varies considerably in size, bearing usually an inverse proportion to the external jugular; most frequently there are two anterior jugulars, a right and left; but sometimes only one. Its tributaries are some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum, the two anterior jugular veins communicate by a transverse trunk, which receives tributaries from the inferior thyroid veins; each also communicates with the internal jugular. There are no valves in this vein.

The **internal jugular vein** (v. jugularis interna) collects the blood from the interior of the cranium, from the superficial parts of the face, and from the neck. It is directly continuous with the lateral sinus, and commences in the posterior compartment of the jugular foramen, at the base of the skull (fig. 636). At its origin it is somewhat dilated, and this dilatation is called the *sinus*, or *bulb* (bulbus venæ jugularis superior). It runs down the side of the neck in a vertical direction, lying at first on the outer side of the internal carotid artery, and then on the outer side of the common carotid, and at the root of the neck unites with the subclavian vein to form the innominate vein. At its commencement it lies upon the Rectus capitis lateralis, behind the internal carotid artery and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glosso-pharyngeal and hypoglossal nerves passing forwards between them; the pneumogastric descends between and behind them in the same sheath, and the spinal accessory runs obliquely outwards, behind or in front of the vein. At the root of the neck the right internal jugular vein is placed at a little distance from the common carotid artery, and crosses the first part of the subclavian artery, while the left internal jugular vein usually overlaps the common carotid artery. The left vein is usually smaller than the right, and each contains a pair of valves, which are placed about an inch above the termination of the vessel.

Tributaries.—The vein receives in its course the inferior petrosal sinus, the common facial, lingual, pharyngeal, superior and middle thyroid veins, and sometimes the occipital. At its point of junction with the common facial vein it becomes greatly increased in size.

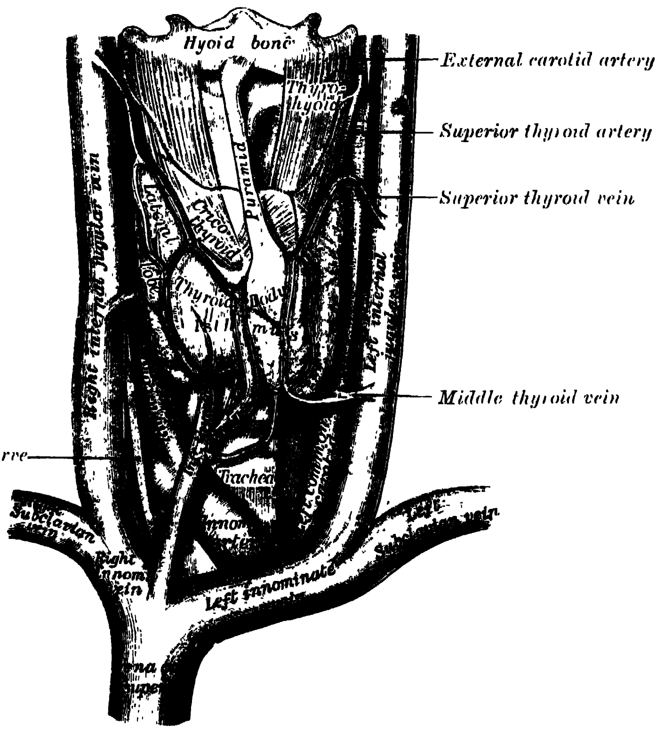
The **inferior petrosal sinus** (sinus petrosus inferior) leaves the skull through the anterior compartment of the jugular foramen, and joins the vein near its commencement.

The **lingual veins** (vv. linguales) commence on the dorsum, sides, and under surface of the tongue, and, passing backwards along the course of the lingual artery and its branches, terminate in the internal jugular. The *ranine vein*, a branch of considerable size, commencing below the tip of the tongue, may join the lingual; generally, however, it passes backwards on the Hyo-glossus muscle in company with the hypoglossal nerve, and joins the facial.

The **pharyngeal veins** (vv. pharyngeæ) begin in the *pharyngeal plexus* on the wall of the pharynx, and, after receiving meningeal tributaries, and the Vidian and spheno-palatine veins, terminate in the internal jugular. They occasionally open into the facial, lingual, or superior thyroid vein.

The **superior thyroid vein** (v. thyreoidea superior) (fig. 628) begins in the substance and on the surface of the thyroid gland, by tributaries corresponding with the branches of the superior thyroid artery, and terminates in the upper part of the internal jugular vein. It receives the superior laryngeal and crico-thyroid veins.

FIG. 628.—The veins of the thyroid body.



The **middle thyroid vein** (v. thyreoidea media) (fig. 628) collects the blood from the lower part of the lateral lobe of the thyroid gland, and after being joined by some veins from the larynx and trachea, terminates in the lower part of the internal jugular vein.

The **facial** and **occipital veins** have been described above.

Applied Anatomy.—The internal jugular vein requires ligature in cases of septic thrombosis of the lateral sinus from suppuration in the middle ear, in order to prevent septic emboli being carried into the general circulation. This operation has been performed recently in many cases, with the most satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and setting up septic thrombosis of the lateral sinus extending to the internal jugular vein. Such cases are always extremely grave, for there is a danger of a portion of the septic clot being detached and causing septic embolism in the thoracic viscera. If the condition be suspected, the diseased bone should be removed at once from the mastoid process. The sinus is then investigated, and if it be found thrombosed,

the surgeon should proceed to ligature the internal jugular vein, by an incision along the anterior border of the sterno-mastoid, the centre of which is on a level with the greater cornu of the hyoid bone. The vein should be ligatured in two places and divided between. After the vessel has been secured and divided, the lateral sinus is to be thoroughly cleared out, and by removing the ligature from the upper end of the divided vein, all septic clots removed by syringing from the sinus through the vein. If hæmorrhage occur from the distal end of the sinus, it can be arrested by careful plugging with antiseptic gauze.

The internal jugular vein is also surgically important, because it is surrounded by a large number of the deep chain of cervical lymphatic glands; and when these are enlarged in tuberculous or malignant disease, they are apt to become adherent to the vessel, rendering their removal difficult and often dangerous. The proper course to pursue in these cases is to ligature the vessel above and below the glandular mass, and resect the included portion together with the glands.

Cardiac pulsation is often demonstrable in the internal jugular vein at the root of the neck. There are no valves in the innominate veins or superior vena cava; in consequence, the systole of the right auricle causes a wave to pass up these vessels, and when the conditions are favourable this wave appears as a somewhat feeble flicker over the internal jugular vein at the root of the neck, quite distinct from, and just preceding, the more forcible impulse transmitted from the underlying common carotid artery and due to the ventricular systole. This auricular systolic venous impulse is much increased in conditions in which the right auricle is abnormally distended with blood or is hypertrophied, as is often the case in disease of the mitral valves. In Stokes-Adams' disease (p. 611) it is this pulsation which gives evidence of the fact that the auricles are beating faster—often two or three times faster—than the ventricles.

The **vertebral vein** (*v. vertebralis*) is formed in the suboccipital triangle, from numerous small tributaries which spring from the intraspinal venous plexuses and issue from the spinal canal above the posterior arch of the atlas. They unite with small veins from the deep muscles at the upper and back part of the neck, and form a vessel which passes outwards and enters the foramen in the transverse process of the atlas, and descends, forming a dense plexus around the vertebral artery, in the canal formed by the foramina in the transverse processes of the cervical vertebræ. This plexus unites at the lower part of the neck into a single trunk, which emerges from the foramen in the transverse process of the sixth cervical vertebra, and terminates at the root of the neck in the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves. On the right side, it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein receives in its course a vein from the inside of the skull through the posterior condyloid foramen; muscular veins, from the muscles in the prevertebral region; posterior-spinal veins, from the back part of the cervical portion of the vertebral column; intra-spinal veins, from the interior of the spinal canal; the anterior and posterior vertebral veins; and close to its termination it is sometimes joined by the first intercostal vein.

The **anterior vertebral vein** commences in a plexus around the transverse processes of the upper cervical vertebræ, descends in company with the ascending cervical artery between the Scalenus anticus and Rectus capitis anticus major muscles, and opens into the vertebral vein just before its termination.

The **posterior vertebral** or **deep cervical vein** (*v. cervicalis profunda*) accompanies the profunda cervicis artery, lying between the Complexus and Semispinalis colli. It commences in the suboccipital region by communicating branches from the occipital vein and tributaries from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebræ, and terminates in the lower end of the vertebral vein.

Veins of the Diploë (fig. 629)

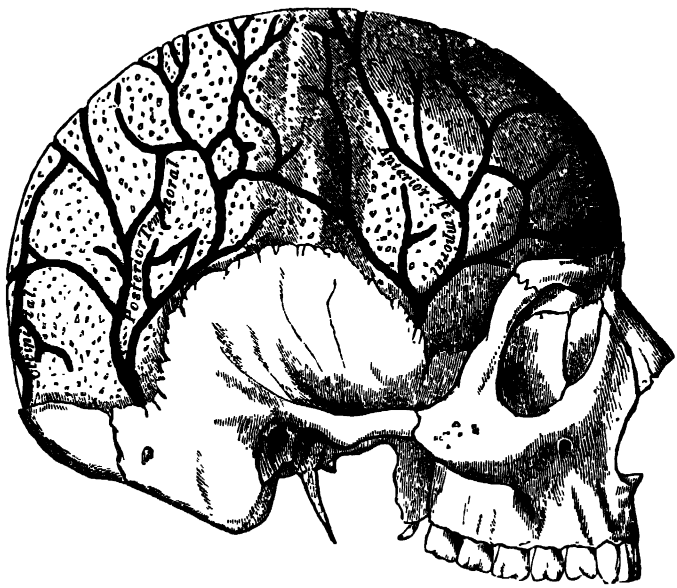
The **diploic veins** (*venæ diploicæ*) occupy channels in the cancellous tissue of the cranial bones.

They are large and exhibit at irregular intervals pouch-like dilatations; their walls are thin, and formed of endothelium resting upon a layer of elastic tissue.

In adult life, so long as the cranial bones are distinct and separable, these veins are confined to the particular bones; but in old age, when the sutures are united, they communicate with each other, and increase in size. They

communicate, in the interior of the cranium, with the meningeal veins and the sinuses of the dura mater; and, on the exterior of the skull, with the veins of the pericranium. They consist of (1) the *frontal* (v. diploica frontalis), which opens into the supra-orbital vein by an aperture in the supra-orbital notch; (2) the *anterior temporal* (v. diploica temporalis anterior), which is confined chiefly to the frontal bone, and opens into one of the deep temporal

FIG. 629.—Veins of the diploë as displayed by the removal of the outer table of the skull.



veins, through an aperture in the great wing of the sphenoid; (3) the *posterior temporal* (v. diploica temporalis posterior), which is situated in the parietal bone, and terminates in the lateral sinus, through an aperture at the postero-inferior angle of the parietal bone or through the mastoid foramen; and (4) the *occipital* (v. diploica occipitalis), the largest of the four, which is confined to the occipital bone, and opens either externally into the occipital vein, or internally into the lateral sinus or torcular Herophili.

VEINS OF THE BRAIN

The veins of the brain (venæ cerebri) possess no valves, and their walls, owing to the absence of muscular tissue, are extremely thin. They pierce the arachnoid membrane, and the inner or meningeal layer of the dura mater, and open into the cranial venous sinuses. They may be divided into two sets, cerebral and cerebellar.

The **cerebral veins** consist of (*a*) the superficial veins which are placed on the surface of the brain, and (*b*) the deep veins which occupy its interior.

The **superficial cerebral veins** ramify upon the surface of the cerebrum, being lodged in the sulci between the convolutions, a few running across the convolutions. They receive tributaries from the cerebral cortex, and are divisible into two sets, superior and inferior.

The **superior cerebral veins** (vv. cerebri superiores), eight to twelve in number on either side, return the blood from the convolutions on the superior surface of the hemisphere; they pass forwards and inwards towards the great longitudinal fissure, where they receive the veins from the median surface of the hemisphere; near their terminations they become invested with tubular sheaths of the arachnoid membrane, and open into the superior longitudinal sinus, in the opposite direction to the course of the current of the blood in the sinus.

The **inferior cerebral veins** (vv. cerebri inferiores) ramify on the lower part of the outer, and on the under, surfaces of the cerebral hemisphere. One of large size, the *middle cerebral*, or *superficial Sylvian vein* (vena cerebri media), commences on

the surface of the temporal lobe, and, running along the fissure of Sylvius, opens into the cavernous sinus. Another large vein, the *great anastomotic vein of Trolard*, connects the superior longitudinal and cavernous sinuses, by becoming continuous above with one of the superior cerebral veins, and below by joining the middle cerebral vein. A third, the *posterior anastomotic vein of Labbé*, connects the middle cerebral vein with the lateral sinus by coursing over the temporal lobe. A fourth, the *basilar vein* (v. basalis [Rosenthali]), is formed at the anterior perforated spot by the union of (*a*) a small *anterior cerebral vein* which accompanies the anterior cerebral artery, (*b*) the *deep Sylvian vein* which receives tributaries from the island of Reil and neighbouring convolutions, and runs in the lower part of the Sylvian fissure, and (*c*) the *inferior striate veins* which leave the corpus striatum through the anterior perforated space. The basilar vein passes backwards round the crus cerebri, and ends in the vein of Galen; it receives tributaries from the interpeduncular space, the descending horn of the lateral ventricle, the uncinate gyrus, and the mid-brain. Small inferior cerebral veins from the under surface of the frontal lobe end in the cavernous sinus; others from the temporal lobe terminate in the superior petrosal and lateral sinuses.

The **deep cerebral veins** (vv. cerebri internæ) are collected into two large trunks, named the *veins of Galen*. Each of these is formed by the union of two veins, the *vena corporis striati* and the *choroid vein* (v. choroidea). They run backwards, parallel with one another, between the layers of the velum interpositum, and beneath the splenium of the corpus callosum, where they unite to form a short trunk, the *vena magna Galeni* (v. cerebri magna), which ends in the anterior extremity of the straight sinus. Just before their union each receives the corresponding basilar vein.

The *vena corporis striati* commences in the groove between the corpus striatum and thalamus, receives numerous veins from both of these parts, and unites behind the anterior pillar of the fornix with the choroid vein, to form one of the venæ Galeni. The *choroid vein* runs along the whole length of the outer border of the choroid plexus, and receives veins from the hippocampus major, the fornix and the corpus callosum.

The **cerebellar veins** are placed on the surface of the cerebellum, and are disposed in two sets, superior and inferior. The *superior cerebellar veins* (vv. cerebelli superiores) pass partly forwards and inwards, across the superior vermis, to terminate in the straight sinus and venæ Galeni, partly outwards to the lateral and superior petrosal sinuses. The *inferior cerebellar veins* (vv. cerebelli inferiores), of large size, terminate in the lateral, superior petrosal, and occipital sinuses.

Sinuses of the Dura Mater

The sinuses of the dura mater (sinus duræ matris) are venous channels which drain the blood from the brain; they are situated between the two layers of the dura mater and lined by endothelium continuous with that which lines the veins. They are fourteen in number, of which six are single and situated in the middle line; the other eight are paired, four being placed on either side of the middle line. They may be divided into two groups: (1) a postero-superior group situated at the upper and back part of the skull, and (2) an antero-inferior group at the base of the skull.

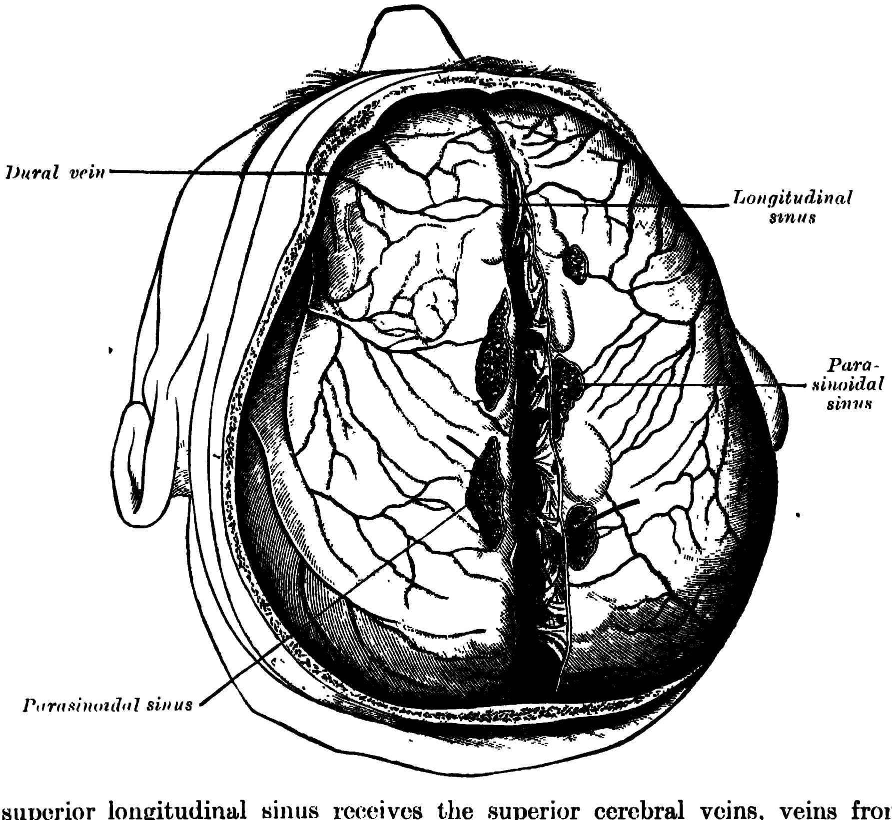
The postero-superior group comprises the

Superior longitudinal sinus.	Straight sinus.
Inferior longitudinal sinus.	Two lateral sinuses.
Occipital sinus.	

The **superior longitudinal sinus** (sinus sagittalis superior) (fig. 630) occupies the attached margin of the falx cerebri. Commencing at the foramen cæcum, through which it communicates by a small branch with the veins of the nasal fossæ, it runs from before backwards, grooving the inner surface of the frontal, the adjacent margins of the two parietals, and the superior division of the crucial ridge of the occipital; near the internal occipital protuberance it deviates to one or other side (usually the right), and is continued as the corresponding lateral sinus. The sinus is triangular in section; it is narrow in front, and gradually increases in size as it passes backwards. Its inner surface

presents the openings of the superior cerebral veins, which run, for the most part, from behind forwards, and open chiefly at the back part of the sinus, their orifices being concealed by fibrous folds; numerous fibrous bands (*chordæ Willisii*) extend transversely across the inferior angle of the sinus; and, lastly, small openings communicate with *venous lacunæ* in the dura mater, into which small white bodies, the *glandulæ Pacchionii*, project. The

FIG. 630.—Superior longitudinal sinus laid open after removal of the skull-cap. The chordæ Willisii are clearly seen. The parasinoidal sinuses are also well shown; from two of them probes are passed into the superior longitudinal sinus. (Poirier and Charpy.)



superior longitudinal sinus receives the superior cerebral veins, veins from the diploë and dura mater, and, at the posterior extremity of the sagittal suture, veins from the pericranium, which pass through the parietal foramina.

Applied Anatomy.—The numerous communications which take place between this sinus and the veins of the nose, scalp and diploë, cause it to be frequently the seat of infective thrombosis from suppurative processes in these parts.

The **inferior longitudinal sinus** (sinus sagittalis inferior) (fig. 631) is contained in the posterior half or two-thirds of the free margin of the falx cerebri. It is of a cylindrical form, increases in size as it passes backwards, and terminates in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the mesial surface of the hemispheres.

The **straight sinus** (sinus rectus) (figs. 631, 632) is situated at the line of junction of the falx cerebri with the tentorium cerebelli. It is triangular in section, increases in size as it proceeds backwards, and runs obliquely downwards and backwards from the termination of the inferior longitudinal sinus to the lateral sinus of the opposite side to that into which the superior longitudinal sinus is prolonged. Its terminal part communicates by a cross branch with the torcular Herophili. Besides the inferior longitudinal sinus, it receives the vena magna Galeni and the superior cerebellar veins. A few transverse bands cross its interior.

The **lateral sinuses** (figs. 631, 632) are of large size, and commence at the internal occipital protuberance; one, generally the right, being the direct

FIG. 631.—Sagittal section of the skull, showing the sinuses of the dura mater.

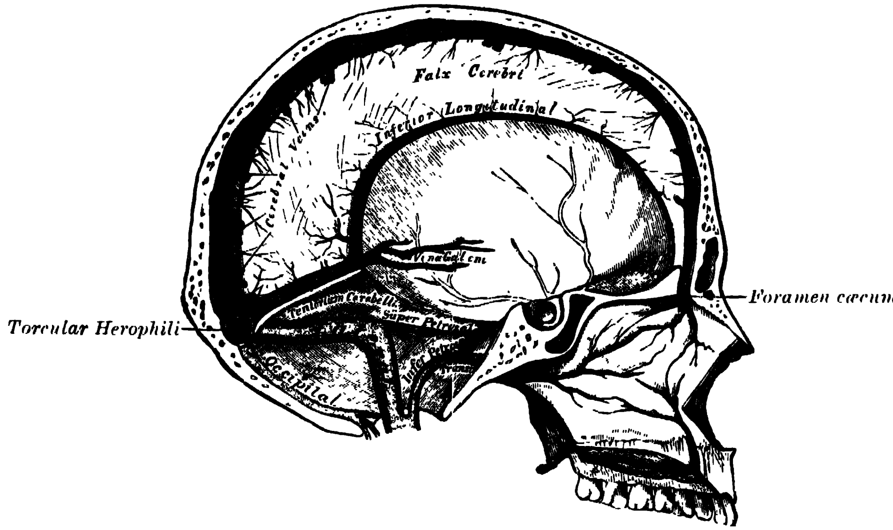


FIG. 632.—Tentorium cerebelli from above.

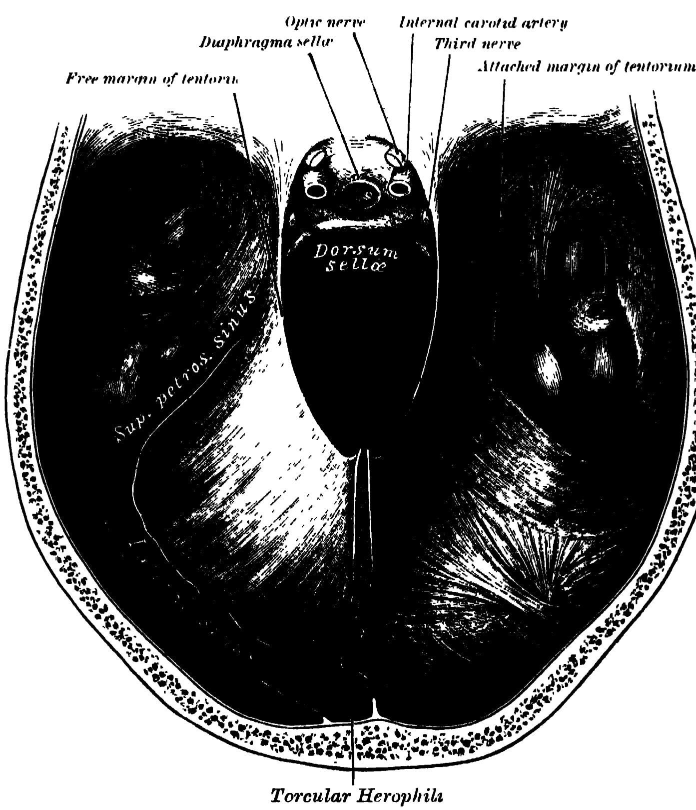


continuation of the superior longitudinal sinus, the other of the straight sinus. Each lateral sinus (sinus transversus) passes outwards and forwards, describing a slight curve with its convexity upwards, to the base of the petrous portion

of the temporal bone, and is situated, in this part of its course, in the attached margin of the tentorium cerebelli; it then leaves the tentorium and curves downwards and inwards to reach the jugular foramen, where it terminates in the internal jugular vein. In its course it rests upon the inner surface of the occipital, the postero-inferior angle of the parietal, the mastoid portion of the temporal, and on the occipital, again, just before its termination. The portion of the sinus which occupies the groove on the mastoid part of the temporal is known as the *sigmoid sinus*. The lateral sinuses are frequently of unequal size, that formed by the superior longitudinal sinus being the larger; they increase in size as they proceed from behind forwards. The horizontal portion is of a prismatic form, the curved portion semicylindrical. The inner surfaces are smooth, and not crossed by the fibrous bands found in the other sinuses. They receive the blood from the superior petrosal sinuses at the base of the petrous portion of the temporal bone; they communicate with the veins of the pericranium by means of the mastoid and condyloid emissary veins; and they receive some of the inferior cerebral and inferior cerebellar veins, and some veins from the diploë. The *petro-squamous sinus*, when present, runs backwards along the junction of the petrous and squamous portions of the temporal, and opens into the lateral sinus.

The **occipital sinus** (sinus occipitalis) (fig. 631) is the smallest of the cranial sinuses. It is generally single, but occasionally there are two. It is situated in the attached margin of the falx cerebelli. It commences around the margin of the foramen magnum by several small veins, one of which joins the termination of the lateral sinus; it communicates with the posterior spinal veins, and terminates in the torcular Herophili.

The *torcular Herophili*, or *confluence of the sinuses* (confluens sinuum) is the term applied to the dilated extremity of the superior longitudinal sinus. It is of irregular form, and is lodged on one side (generally the right) of the internal occipital protuberance. From it the lateral sinus of the side to which it is deflected is derived. It receives also the blood from the occipital sinus, and is connected across the middle line with the commencement of the lateral sinus of the opposite side.

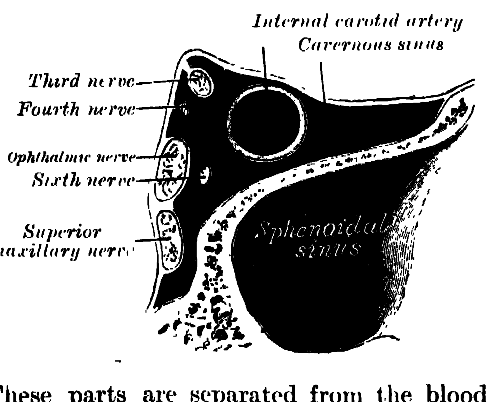
The antero-inferior group of sinuses comprises the

Two cavernous sinuses.	Two superior petrosal sinuses.
Circular sinus.	Two inferior petrosal sinuses.

Basilar sinus.

The **cavernous sinuses** are so named because they present a reticulated structure, due to their being traversed by numerous interlacing filaments. They are of irregular form, larger behind than in front, and are placed one on either side of the body of the sphenoid, extending from the sphenoidal fissure to the apex of the petrous portion of the temporal bone. Each cavernous sinus (sinus cavernosus) receives anteriorly the superior ophthalmic vein through the sphenoidal fissure, and opens behind into the petrosal sinuses. On the inner wall of each sinus is the internal carotid artery, accompanied by filaments of the carotid plexus and by the sixth nerve; and on the outer wall, the third and fourth nerves, and the ophthalmic and superior maxillary divisions of the fifth nerve (fig. 635). These parts are separated from the blood flowing along the sinus by the lining membrane, which is continuous with the inner coat of the veins. The cavernous sinus receives some of the cerebral veins, and also the small *spheno-parietal sinus* (sinus sphenoparietalis), which extends inwards on the

FIG. 633.—Oblique section through the cavernous sinus.



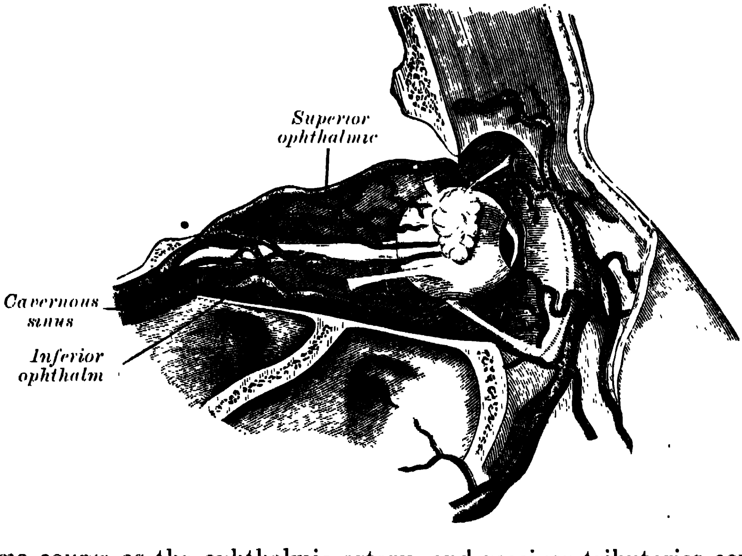
under aspect of the lesser wing of the sphenoid. It communicates with the lateral sinus by means of the superior petrosal sinus; with the internal jugular vein through the inferior petrosal sinus and through a plexus of veins on the internal carotid artery; with the pterygoid venous plexus through the foramen Vesalii or foramen ovale, and with the angular vein through the ophthalmic vein. The two sinuses also communicate with each other by means of the circular sinus.

Applied Anatomy.—An arterio-venous communication may be established between the cavernous sinus and the internal carotid artery, giving rise to a pulsating tumour in the orbit. These communications may be the result of injury, such as a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation, or they may occur from the rupture of an aneurysm or a diseased condition of the internal carotid artery. The symptoms are sudden noise and pain in the head, followed by exophthalmos, swelling and congestion of the lids and conjunctivæ, and development of a pulsating tumour at the margin of the orbit, with thrill and the characteristic bruit; accompanying these symptoms there may be impairment of sight, paralysis of the iris and orbital muscles, and pain of varying intensity. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the circular sinus; or the arterial blood may find its way through the emissary veins (see page 743) into the pterygoid plexus, and thence into the veins of the face. Pulsating tumours of the orbit may also be due to traumatic aneurysm of one of the orbital arteries, and symptoms resembling those of pulsating tumour may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurysm of the internal carotid artery. Ligature of the internal or common carotid artery has been performed in these cases with some degree of success.

Of recent years more attention has been paid to thrombosis of the cavernous sinus than formerly, and it is now well established that caries in the upper parts of the nasal fossæ and suppuration in certain of the accessory sinuses of the nose, are frequently responsible for septic thrombosis of the cavernous sinuses, in exactly the same way as lateral sinus thrombosis is due to septic disease in the mastoid process. Many deaths from meningitis, hitherto unaccounted for, are in reality due to the spread of an infection from an ethmoidal or sphenoidal air cell to the cavernous sinus, and thence to the meninges. It is obvious, therefore, that no case of chronic nasal suppuration should be left untreated.

The **ophthalmic veins** (fig. 634) are two in number, superior and inferior. The *superior ophthalmic vein* (v. ophthalmica superior) connects the angular vein at the inner angle of the orbit with the cavernous sinus; it pursues the

FIG. 634.—Veins of orbit. (Poirier and Charpy.)



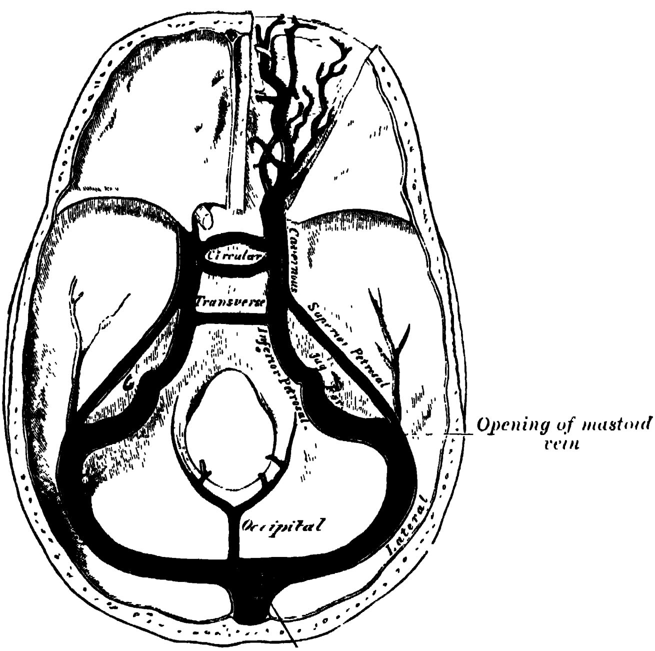
same course as the ophthalmic artery, and receives tributaries corresponding to the branches derived from that vessel. Forming a short single trunk, it passes through the inner extremity of the sphenoidal fissure, and terminates in the cavernous sinus.

The *inferior opthalmic vein* (v. ophthalmica inferior) receives the veins from the floor of the orbit, and either passes out of the orbit through the spheno-maxillary fissure to join the pterygoid plexus of veins; or else, passing backwards through the sphenoidal fissure, it enters the cavernous sinus, either by a separate opening, or more frequently in common with the superior ophthalmic vein.

The **circular sinus** (sinus circularis) (fig. 635) is formed by two transverse vessels, the *anterior* and *posterior intercavernous sinuses,* which connect together the two cavernous sinuses: one passes in front of and the other behind the pituitary body, and thus they form with the cavernous sinuses a venous circle around that body. The anterior one is usually the larger of the two, and one or other is occasionally absent.

The **superior petrosal sinus** (sinus petrosus superior) is situated along the superior border of the petrous portion of the temporal bone, in the attached margin of the tentorium. It is small and narrow, and connects the cavernous and lateral sinuses, opening into the latter as it curves downwards on the inner surface of the mastoid part of the temporal bone. It receives

FIG. 635.—The sinuses at the base of the skull.



some cerebellar and inferior cerebral veins, and veins from the tympanic cavity.

The **inferior petrosal sinus** (sinus petrosus inferior) is situated in the groove formed by the junction of the posterior border of the petrous portion of the temporal with the basilar process of the occipital. It begins in the cavernous sinus, and, passing through the anterior compartment of the jugular foramen, ends in the commencement of the internal jugular vein. The inferior petrosal sinus receives the veins from the internal ear (vv. auditivæ internæ) and also veins from the medulla, pons, and under surface of the cerebellum.

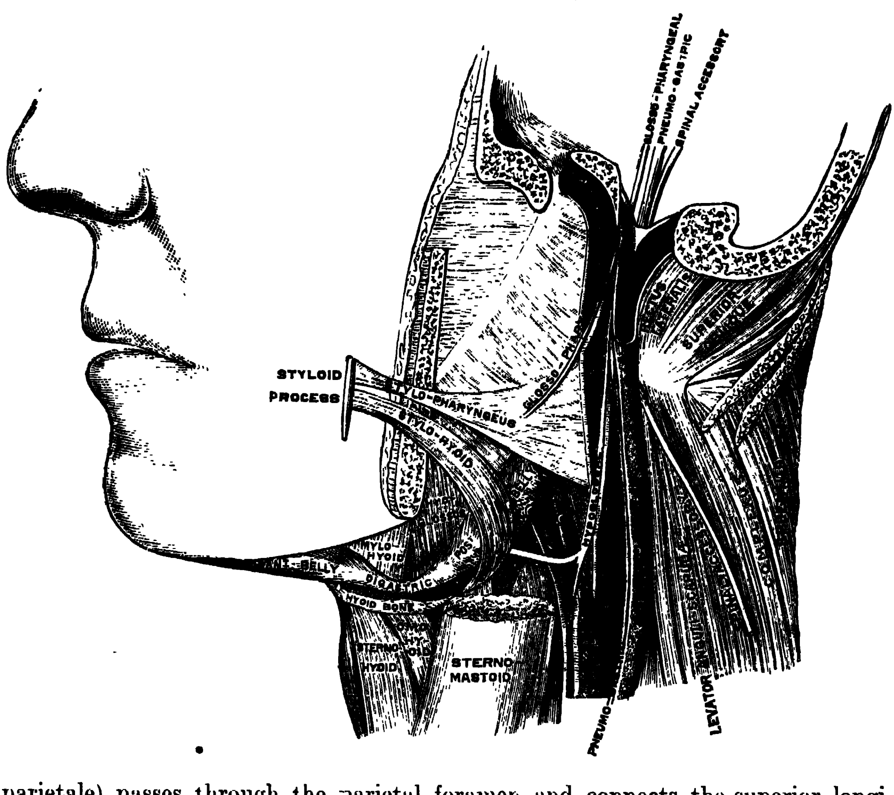
The exact relation of the parts to one another in the jugular foramen is as follows (fig. 636): the inferior petrosal sinus is in front, with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downwards and backwards; the lateral sinus is situated at the back part of the foramen with a meningeal branch of the occipital artery, and between the two are the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. These three sets of

structures are divided from each other by two processes of fibrous tissue. The junction of the inferior petrosal sinus with the internal jugular vein takes place superficial to the nerves, so that these latter lie a little internal to the venous channels in the foramen.

The **basilar sinus** (plexus basilaris) consists of several interlacing veins between the layers of the dura mater over the basilar process of the occipital bone, which serve to connect the two inferior petrosal sinuses. They communicate with the anterior spinal veins.

Emissary veins.—The emissary veins are vessels which pass through apertures in the cranial wall and establish communications between the sinuses inside the skull and the veins external to it. Some of these are always present, others only occasionally so. They vary much in size in different individuals. The principal emissary veins are the following. 1. A vein (emissarium mastoideum), almost always present, runs through the mastoid foramen and unites the lateral sinus with the posterior auricular or with the occipital vein. 2. A vein (emissarium

FIG. 636.—Relation of structures in jugular foramen.



parietale) passes through the parietal foramen and connects the superior longitudinal sinus with the veins of the scalp. 3. A plexus of minute veins (rete canalis hypoglossi) traverses the anterior condyloid foramen and joins the lateral sinus with the vertebral vein and deep veins of the neck. 4. An inconstant vein (emissarium condyloideum) passes through the posterior condyloid foramen and connects the lateral sinus with the deep veins of the neck. 5. A plexus of veins (rete foraminis ovalis) unites the cavernous sinus with the pterygoid and pharyngeal plexuses through the foramen ovale. 6. Two or three small veins run through the foramen lacerum medium and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 7. There is sometimes a small vein passing through the foramen of Vesalius connecting the same parts. 8. A plexus of veins (plexus venosus caroticus internus) traverses the carotid canal and unites the cavernous sinus with the internal jugular vein. 9. A vein is transmitted through the foramen cæcum and connects the superior longitudinal sinus with the veins of the mucous membrane of the nose.

Applied Anatomy.—These emissary veins together with the other communications between the intra- and extra-cranial circulation are of great importance in surgery. Inflammatory processes commencing on the outside of the skull may travel inwards through them, and lead to osteo-phlebitis of the diploë and inflammation of the membranes of the brain. To this in former days was to be attributed one of the principal dangers of wounds of the scalp.

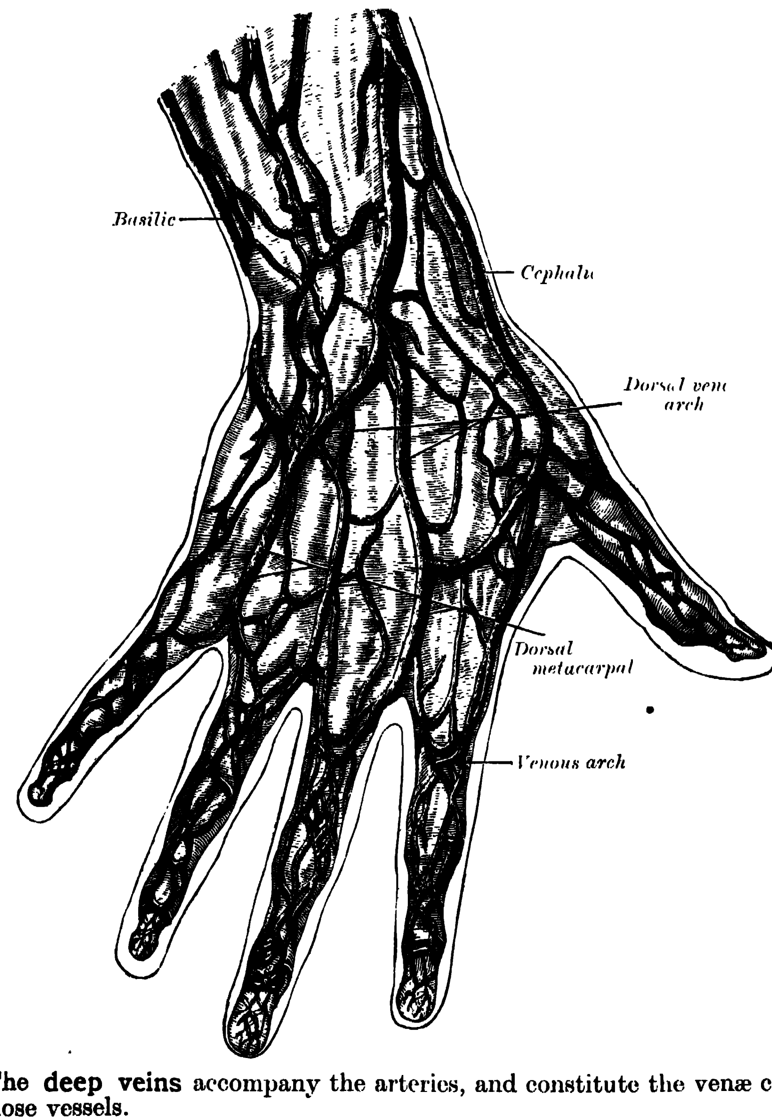
By means of these emissary veins blood may be abstracted almost directly from the intracranial circulation—e.g. leeches applied behind the ear drain blood almost directly from the lateral sinus, through the mastoid vein. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being partly derived from the superior longitudinal sinus by means of the vein passing through the foramen cæcum.

VEINS OF THE UPPER EXTREMITY AND THORAX

The veins of the upper extremity are divided into two sets, *superficial* and *deep*.

The **superficial veins** are placed immediately beneath the integument between the two layers of superficial fascia.

FIG. 637.—The veins on the dorsum of the hand. (Bourgery.)



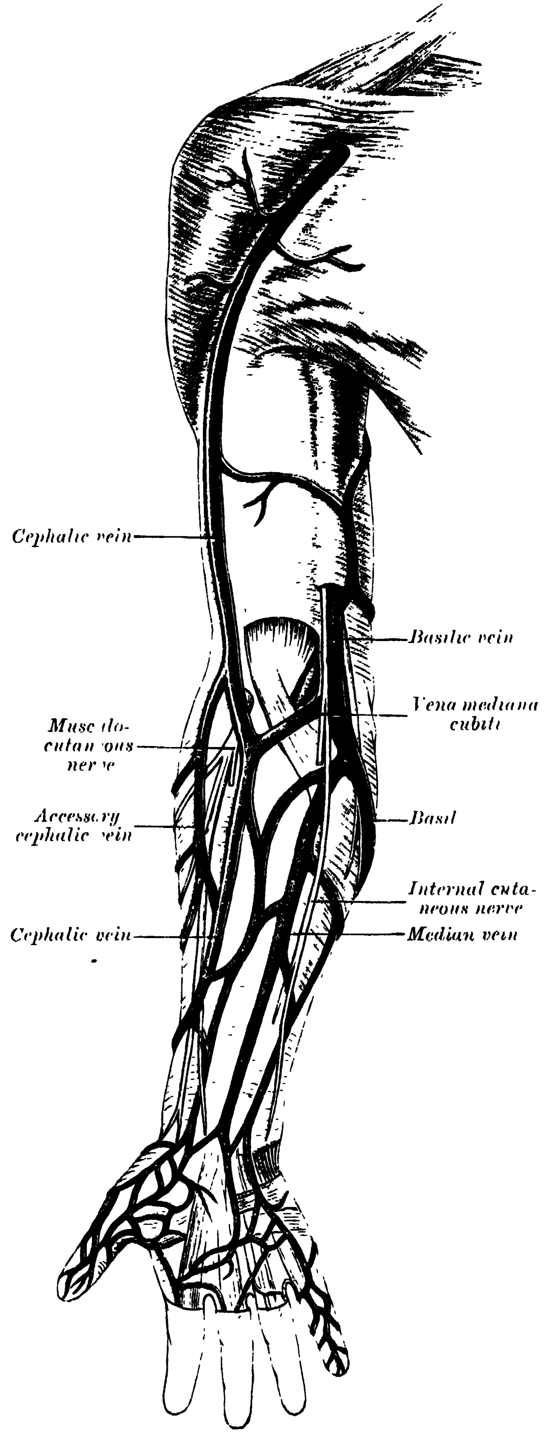
The **deep veins** accompany the arteries, and constitute the venæ comites of those vessels.

Both sets of vessels are provided with valves, which are more numerous in the deep than in the superficial.

The superficial veins of the upper extremity are. the

Digital.
Metacarpal.
Cephalic.
Basilic.
Median.

FIG. 638.—The superficial veins of the upper extremity.



Digital veins.—The dorsal digital veins pass along the sides of the fingers and are joined to one another by oblique communicating branches. Those from the adjacent sides of the index, middle, ring, and little fingers unite to form three dorsal metacarpal veins (vv. metacarpeæ dorsales), which terminate in a dorsal venous arch (fig. 637) opposite the middle of the metacarpus. The arch is convex distally; its radial extremity is joined by the dorsal digital vein from the radial side of the index finger and by the dorsal digital veins of the thumb, and is prolonged upwards as the cephalic vein. The ulnar extremity of the arch receives the dorsal digital vein of the ulnar side of the little finger and is continued upwards as the basilic vein. A communicating branch frequently connects the dorsal venous arch with the cephalic vein, about the middle of the forearm.

The palmar digital veins (vv. digitales volares) on each finger are connected to one another and to the dorsal digital veins by oblique vessels (vv. intercapitulares). They drain into a venous plexus which is situated over the thenar and hypothenar eminences and across the front of the wrist.

The **cephalic vein** (v. cephalica) (fig. 638) begins in the radial end of the dorsal venous arch and winds upwards round the radial border of the forearm,

receiving tributaries from both surfaces. Below the front of the elbow it gives off the *vena mediana cubiti*, which passes across to join the basilic. It then ascends in front of the elbow in the groove between the Brachio-radialis and the Biceps. It crosses superficial to the musculo-cutaneous nerve and ascends in the groove along the outer border of the Biceps. In the upper third of the arm it passes between the Pectoralis major and the Deltoid, where it is accompanied by the descending or humeral branch of the acromio-thoracic artery. It pierces the costo-coracoid membrane and, crossing the axillary artery, ends in the axillary vein just below the clavicle.

The *accessory cephalic vein* (v. cephalica accessoria) arises either from a small tributary plexus on the back of the forearm or from the ulnar side of the dorsal venous arch; it joins the cephalic below the elbow. In some cases the accessory cephalic springs from the cephalic above the wrist and joins it again higher up. A large oblique branch frequently connects the basilic and cephalic veins on the back of the forearm.

The **basilic vein** (v. basilica) (fig. 638) begins in the ulnar end of the dorsal venous arch. It runs up the posterior surface of the ulnar side of the forearm and inclines forward to the anterior surface below the elbow, where it is joined by the vena mediana cubiti. It ascends obliquely in the groove between the Biceps and Pronator teres across the brachial artery, from which it is separated by the bicipital fascia; filaments of the internal cutaneous nerve pass both in front of and behind this portion of the vein. It then runs upwards along the inner side of the Biceps, perforates the deep fascia a little below the middle of the arm and, ascending on the inner side of the brachial artery to the lower border of the Teres major, is continued onwards as the axillary vein.

The **median vein** (v. mediana antibrachii) drains the plexus on the palmar surface of the hand. It ascends on the ulnar side of the front of the forearm and ends in the basilic vein or in the vena mediana cubiti; in a small proportion of cases it divides into two branches, one of which joins the basilic, the other the cephalic, below the elbow.*

Applied Anatomy.—Venesection is generally performed at the bend of the elbow, and as a matter of practice the largest vein in this situation is commonly selected. This is usually the vena mediana cubiti (median basilic), and there are anatomical advantages and disadvantages in selecting this vein. The advantages are, that in addition to its being the largest vessel and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the bicipital fascia on which it rests. The disadvantages are, that it is in close relationship with the brachial artery, separated only by the bicipital fascia; and formerly, when venesection was frequently practised, arterio-venous aneurysm was no uncommon result of this practice.

Intravenous infusion of normal saline solution is very frequently required in modern surgery for all conditions of severe shock and after profuse hæmorrhages, the older method of transfusion of blood having quite sunk into oblivion. The patient's arm is surrounded by a tight bandage so as to impede the venous return, and a small incision is made over the largest vein visible in front of the elbow; a double ligature is now passed around the vein, and the lower one is tied; the vein is then opened and a canula connected with a funnel by tubing and filled with hot saline solution is inserted. The bandage is next removed from the arm, and two, three, or more pints of fluid are allowed to flow into the vein; when a sufficient quantity has gone in, the upper ligature round the vein is tied and a stitch put in the skin wound.

The **deep veins of the upper extremity** follow the course of the arteries, forming their venæ comites. They are generally arranged in pairs, and are situated one on either side of the corresponding artery, and connected at intervals by short transverse branches.

Two digital veins accompany each artery along the sides of the fingers: these, uniting at the bases of the fingers, pass along the interosseous spaces in the palm, and terminate in the two venæ comites which accompany the superficial palmar arch. Branches from these vessels on the radial side of the hand accompany the superficialis volæ, and on the ulnar side terminate in the deep ulnar veins. The deep ulnar veins, as they pass in front of the wrist, communicate with the interosseous and superficial veins, and, at the

* Consult an article by Berry and Newton, *Anatomischer Anzeiger*, Band xxxiii., December 1908.

elbow, unite with the deep radial veins to form the venæ comites of the brachial artery.

The **interosseous veins** accompany the anterior and posterior interosseous arteries. The anterior interosseous veins commence in front of the wrist, where they communicate with the deep radial and ulnar veins; at the upper part of the forearm they receive the posterior interosseous veins, and terminate in the venæ comites of the ulnar artery.

The **deep palmar veins** accompany the deep palmar arch, being formed by tributaries which follow the ramifications of that vessel. They communicate with the deep ulnar veins at the inner side of the hand, and on the outer side terminate in the venæ comites of the radial artery. At the wrist, they receive a dorsal and a palmar tributary from the thumb, and unite with the venæ comites of the radial artery.

The **brachial veins** (vv. brachiales) are placed one on either side of the brachial artery, receiving tributaries corresponding with the branches given off from that vessel; near the lower margin of the Subscapularis, they join the axillary vein; the inner of the two frequently joins the basilic vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins.

The **axillary vein** (v. axillaris) is of large size, and is the continuation upwards of the basilic vein. It commences at the lower border of the Teres major, increases in size as it ascends, by receiving tributaries corresponding with the branches of the axillary artery, and terminates immediately beneath the clavicle at the outer border of the first rib, where it becomes the subclavian vein. This vessel is covered in front by the Pectoral muscles and costo-coracoid membrane, and lies on the thoracic side of the axillary artery, which it partially overlaps. Near the lower margin of the Subscapularis it receives the venæ comites of the brachial artery, and, near its termination, the cephalic vein. It is provided with a pair of valves opposite the lower border of the Subscapularis muscle; valves are also found at the terminations of the cephalic and subscapular veins.

Applied Anatomy.—Since the axillary vein is superficial to and larger than the axillary artery, which it overlaps, it is more liable to be wounded than the artery in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to it. When it is wounded, there is always a danger of air being drawn into its interior, and death resulting. To avoid wounding the axillary vein in the extirpation of glands from the axilla, it is always advisable to expose the vein as soon as possible; no sharp cutting instruments should be used after the axillary cavity has been freely exposed; and care should be taken to use no undue force in isolating the glands (see page 773). Should the vein be so imbedded in a malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done after the vessel has been ligatured above and below.

The **subclavian vein** (v. subclavia), the continuation of the axillary, extends from the outer border of the first rib to the inner end of the clavicle, where it unites with the internal jugular to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius muscle; behind and above, with the subclavian artery, from which it is separated internally by the Scalenus anticus muscle and phrenic nerve. Below, it rests in a depression on the first rib and upon the pleura. It is usually provided with a pair of valves, which are situated about an inch from its termination.

The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and in one or two instances has been seen passing with this vessel behind the Scalenus anticus.

Tributaries.—This vein receives the external jugular vein, sometimes the anterior jugular vein, and occasionally a small branch from the cephalic. At its angle of junction with the internal jugular, the left subclavian vein receives the thoracic duct; while the right subclavian vein receives the right lymphatic duct.

The **innominate or brachio-cephalic veins** (vv. anonymæ dextra et sinistra) (fig. 639) are two large trunks, placed one on either side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side.

The **right innominate vein** is a short vessel, an inch in length, which commences at the inner end of the clavicle, and, passing almost vertically downwards, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the superior vena cava. It lies superficial and external to the innominate artery; on its right side is the phrenic nerve, and the pleura is here interposed between it and the apex of the lung. This vein, at the angle of junction of the internal jugular with the subclavian, receives the right vertebral vein; and, lower down, the right internal mammary, right inferior thyroid, and sometimes the right superior intercostal veins.

The **left innominate vein,** about two and a half inches in length, and larger than the right, passes from left to right across the upper part and front of the chest, at the same time inclining downwards, to unite with its fellow of the opposite side, and form the *superior vena cava*. It is in relation, in front, with the manubrium sterni, from which it is separated by the Sterno-hyoid and Sterno-thyroid muscles, the thymus gland or its remains, and some loose areolar tissue. Behind it are the three large arteries arising from the arch of the aorta, together with the vagus and phrenic nerves. This vessel is joined by the left vertebral, left internal mammary, left inferior thyroid, and the left superior intercostal veins, and occasionally some thymic and pericardiac veins. There are no valves in the innominate veins.

Peculiarities.—Sometimes the innominate veins open separately into the right auricle; in such cases the right vein takes the ordinary course of the superior vena cava: but the left vein—*left superior vena cava,* as it is termed—after communicating by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, receives the cardiac veins, and terminates in the back of the right auricle. This occasional condition in the adult is due to the persistence of the early fœtal condition, and is the normal state of things in birds and some mammalia.

The **internal mammary veins** (vv. mammariæ internæ), two to each internal mammary artery, follow the course of that vessel, and receive tributaries corresponding to its branches. The two veins unite into a single trunk, which terminates in the corresponding innominate vein. The *superior phrenic vein* (i.e. the vein accompanying the arteria comes nervi phrenici) usually opens into the internal mammary vein.

The **inferior thyroid veins** (vv. thyreoideæ inferiores), two, frequently three or four, in number, arise in the venous plexus on the thyroid body, communicating with the middle and superior thyroid veins. They form a plexus in front of the trachea, behind the Sterno-thyroid muscles. From this plexus, a left vein descends and joins the left innominate trunk, and a right vein passes obliquely downwards and outwards across the innominate artery to open into the right innominate vein, just at its junction with the superior vena cava. These veins receive œsophageal, tracheal, and inferior laryngeal veins, and are provided with valves at their termination in the innominate veins.

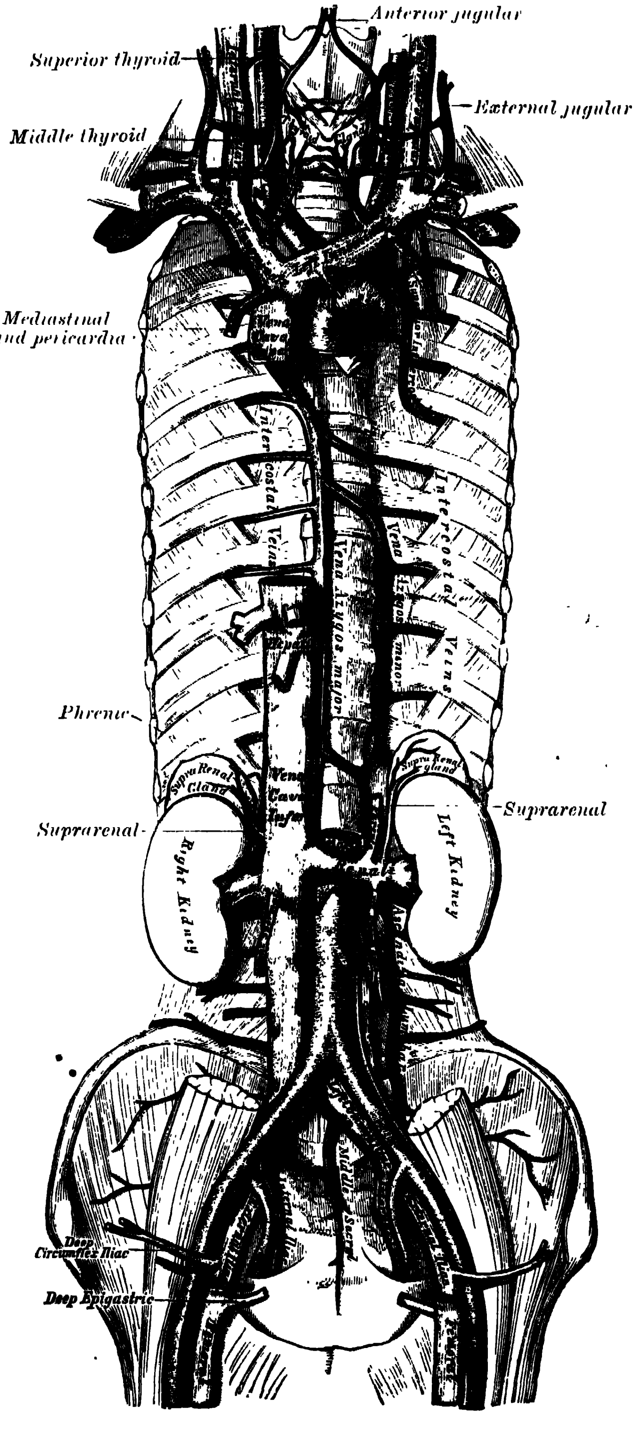
The **superior intercostal veins** (right and left) drain the blood from two or three of the intercostal spaces below the first. The *right* vein (v. intercostalis suprema dextra) passes downwards and inwards and opens into the vena azygos major; the *left* (v. intercostalis suprema sinistra) runs across the arch of the aorta and opens into the left innominate vein. It usually receives the left bronchial and left superior phrenic vein, and communicates below with the vena azygos minor superior. The vein from the first intercostal space opens directly into the corresponding vertebral or innominate vein.

The **vena cava superior** receives the blood which is conveyed to the heart from the whole of the upper half of the body. It is a short trunk, varying from two inches and a half to three inches in length, formed by the junction of the two innominate veins. It commences immediately below the cartilage of the first rib close to the sternum on the right side, and, descending vertically, enters the pericardium about an inch and a half above the heart, and terminates in the upper part of the right auricle opposite the upper border of the third right costal cartilage. In its course it describes a slight curve, the convexity of which is to the right side.

Relations.—*In front,* it is in relation with the pericardium and the process of cervical fascia which is continuous with that sac; these separate it from the

thymus gland, and from the second and third costal cartilages; *behind*, with the root of the right lung. On its *right side*, it is in relation with the phrenic nerve

FIG. 639.—The venæ cavæ and azygos veins, with their formative branches.



and right pleura; on its *left side*, with the commencement of the innominate artery and the ascending part of the aorta, the latter overlapping it. Just before it

enters the pericardium, it receives the vena azygos major and several small veins from the pericardium and parts in the mediastinum. The portion contained within the pericardium is covered, in front and laterally, by the serous layer of that membrane. The superior vena cava has no valves.

The **azygos veins** (fig. 639) are three in number; they collect the blood from the majority of the intercostal spaces, and connect the superior and inferior venæ cavæ.

The **vena azygos major** (v. azygos) commences opposite the first or second lumbar vertebra, by a branch, the *ascending lumbar vein* (v. lumbalis ascendens) connecting the right lumbar veins; sometimes by a branch from the right renal vein, or from the inferior vena cava. It enters the thorax through the aortic opening in the Diaphragm, and passes along the right side of the vertebral column to the fourth thoracic vertebra, where it arches forward over the root of the right lung, and terminates in the superior vena cava, just before that vessel enters the pericardium. While passing through the aortic opening, it lies with the thoracic duct on the right side of the aorta; and in the thorax it lies upon the intercostal arteries, on the right side of the aorta and thoracic duct, and is partly covered by pleura.

Tributaries.—It receives the subcostal vein and the lower ten intercostal veins of the right side, the upper two or three of these latter opening first of all into the right superior intercostal vein. It receives the azygos minor veins, several œsophageal, mediastinal, and pericardial veins; near its termination, the right bronchial vein; and generally the right superior intercostal vein. A few imperfect valves are found in this vein; but its tributaries are provided with complete valves.

The intercostal veins on the left side, below the three upper intercostal spaces, usually form two trunks, named vena azygos minor inferior and vena azygos minor superior.

The **vena azygos minor inferior** (v. hemiazygos) commences in the lumbar region, by a branch (*ascending lumbar*) connecting the lumbar veins or by a branch from the left renal. It enters the thorax, through the left crus of the Diaphragm, and, ascending on the left side of the vertebral column, as high as the ninth thoracic vertebra, passes across the column, behind the aorta, œsophagus, and thoracic duct, to terminate in the vena azygos major. It receives the lower four or five intercostal veins and the subcostal vein of the left side, and some œsophageal and mediastinal veins.

The **vena azygos minor superior** (v. hemiazygos accessoria) varies inversely in size with the left superior intercostal. It receives veins from the intercostal spaces between the left superior intercostal vein and highest tributary of the left lower azygos. They are usually three or four in number, and join to form a trunk which either crosses the body of the eighth thoracic vertebra to join the vena azygos major or ends in the vena azygos minor superior. When this vein is small, or altogether wanting, the left superior intercostal vein will extend as low as the fifth or sixth intercostal space. It sometimes receives the left bronchial vein.

Applied Anatomy.—In obstruction of the inferior vena cava, the azygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior venæ cavæ, and communicating with the common iliac veins by the ascending lumbar veins and with many of the tributaries of the inferior vena cava.

Thrombosis of the superior vena cava is oftenest due to pressure exerted on the vessel by an aneurysm or a tumour; it may also occur by propagation of clotting from a tributary peripheral vein. If occlusion of the vessel take place slowly, a collateral venous circulation may be established; the patient will have some œdema with dilatation and congestion of the veins about the head and neck, and may also suffer from attacks of dyspnœa and recurrent pleural effusion. In most cases, however, the blockage of the superior cava takes place rapidly, and is rapidly fatal.

The **bronchial veins** (vv. bronchiales) return the blood from the larger bronchi, and from the structures at the roots of the lungs; that of the right side opens into the vena azygos major, near its termination; that of the left side, into the left superior intercostal vein or vena azygos minor superior. A considerable quantity of the blood which is carried to the lungs through the bronchial arteries is returned to the left side of the heart through the pulmonary veins.

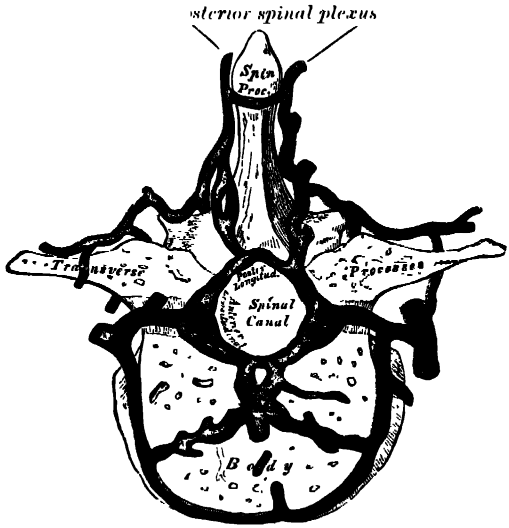
THE SPINAL VEINS (figs. 640, 641)

The spinal veins may be arranged into four groups, viz.:
1. The extra-spinal veins.
2. The intra-spinal veins, between the vertebræ and the dura mater.
3. The veins of the bodies of the vertebræ.
4. The veins of the spinal cord.

1. The **extra-spinal veins** form an anterior and a posterior spinal plexus.

The *anterior spinal plexus* (plexus venosi vertebrales anteriores) is situated on the front of the bodies of the vertebræ, and is best marked in the cervical region. It consists of relatively small vessels, which anastomose with the intraspinal veins and the veins from the bodies of the vertebræ, and open into the deep cervical, intercostal, lumbar, and lateral sacral veins in the respective regions of the vertebral column.

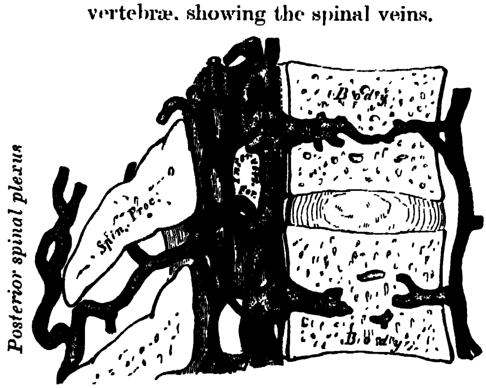
FIG. 640.—Transverse section of a thoracic vertebra, showing the spinal veins.



The *posterior spinal plexus* (plexus venosi vertebrales posteriores) receives tributaries from the integument of the back and from the muscles in the vertebral grooves. It forms a complicated network, which surrounds the spinous processes, the laminæ, and the transverse and articular processes of all the vertebræ. It communicates with the intra-spinal veins by branches which perforate the ligamenta subflava and others which pass through the intervertebral foramina. It terminates by joining the vertebral veins in the neck, the intercostal veins in the thorax, and the lumbar and sacral veins in the loins and pelvis.

2. The **intra-spinal veins** (vv. spinales internæ) are situated between the dura mater and the vertebræ. They consist of two longitudinal plexuses, one of which runs along the posterior surfaces of the bodies of the vertebræ (*anterior longitudinal spinal veins*); the other (*posterior longitudinal spinal veins*) is placed on the inner or anterior surfaces of the laminæ of the vertebræ.

FIG. 641.—Vertical section of two thoracic vertebræ, showing the spinal veins.



The *anterior longitudinal spinal veins* consist of two large, tortuous veins, which extend from the foramen magnum to the base of the coccyx, being placed one on either side of the posterior surface of the bodies of the vertebræ, along the margin of the posterior common ligament. They communicate through the foramen magnum with the basilar and occipital sinuses, and give off branches which unite above the atlas to form the commencement of the vertebral vein. They also communicate with one another opposite each vertebra by a transverse trunk, which passes beneath the posterior common ligament; these transverse branches receive the *venæ basivertebrales* from the interior of the vertebral bodies. The anterior longitudinal spinal veins are least developed in the cervical and sacral

regions. They are not of uniform size throughout, being alternately enlarged and constricted. At the intervertebral foramina they communicate with the posterior spinal plexus, and with the vertebral veins in the neck, with the intercostal veins in the thoracic region, and with the lumbar and sacral veins in the corresponding regions.

The *posterior longitudinal spinal veins*, smaller than the anterior, are situated one on either side, between the inner surfaces of the laminæ and the dura mater. They communicate (like the anterior), opposite the vertebræ, by transverse trunks; and with the anterior longitudinal veins, by lateral transverse branches, which pass from behind forwards. They join with the posterior spinal plexus by branches which perforate the ligamenta subflava, and communicate through the intervertebral foramina with the vertebral, intercostal, lumbar, and sacral veins.

3. The **veins of the bodies of the vertebræ** (vv. basivertebrales) emerge from the foramina on the posterior surfaces of the vertebral bodies. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. They communicate through small openings on the front and sides of the bodies of the vertebræ with the anterior spinal plexus, and converge to the principal canal which is sometimes double towards its posterior part, and open into the transverse branches which unite the anterior longitudinal veins. They become greatly enlarged in advanced age.

4. The **veins of the spinal cord** are situated in the pia mater and form a minute, tortuous, venous plexus covering the entire surface of the cord. They emerge chiefly from the median furrows of the cord and are largest in the lumbar region. In this plexus there are: (1) two median longitudinal veins, one in front of the anterior fissure, and the other behind the posterior fissure of the cord; and (2) four lateral longitudinal veins which run behind the nerve-roots. Near the base of the skull they unite, and form two or three small trunks, which communicate with the vertebral veins, and then terminate in the inferior cerebellar veins, or in the inferior petrosal sinuses. Each of the spinal nerves is accompanied by a branch as far as the intervertebral foramen; here this branch joins the other veins from the spinal canal.

There are no valves in the spinal veins.

VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS

The veins of the lower extremity are subdivided, like those of the upper, into two sets, superficial and deep: the superficial veins are placed beneath the integument, between the two layers of superficial fascia; the deep veins accompany the arteries, and form the venæ comites of those vessels. Both sets of veins are provided with valves, which are more numerous in the deep than in the superficial set. Valves are also more numerous in the veins of the lower than in those of the upper limb.

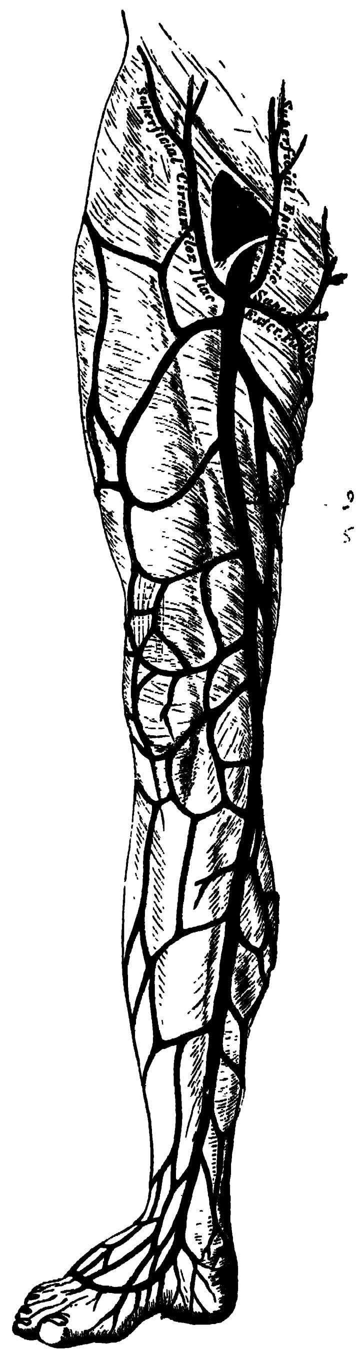
The **superficial veins of the lower extremity** are the *internal* or *long saphenous*, and the *external* or *short saphenous*.

On the dorsum of the foot is a venous arch (arcus venosus dorsalis pedis), situated in the superficial fascia over the anterior extremities of the metatarsal bones. Its convexity is directed forwards, and receives the veins from the upper surfaces of the toes; at its concavity it is joined by numerous small veins, which form a plexus on the dorsum of the foot. The arch terminates internally in the long saphenous, externally in the short saphenous vein.

The **internal or long saphenous vein** (v. saphena magna) (fig. 642) commences at the inner side of the venous arch on the dorsum of the foot; it ascends in front of the inner malleolus, and along the inner side of the leg, behind the inner margin of the tibia, in relation with the internal saphenous nerve. At the knee, it passes behind the inner condyle of the femur, ascends along the inside of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament. It receives in its course cutaneous tributaries from the leg and thigh, and at the saphenous opening (fig. 643) the superficial epigastric, superficial circumflex iliac, and superficial external pudic veins. The veins from the inner and back part of the thigh frequently unite to form a large vessel (v. saphena accessoria) which enters the main trunk near the saphenous opening; and

sometimes those on the outer side of the thigh join to form another large vessel; so that occasionally three large veins are seen converging from different parts of the thigh towards the saphenous opening. The internal saphenous vein communicates in the foot with the internal plantar vein; in the leg, with the posterior tibial veins, by branches which perforate the tibial origin of the Soleus muscle, and also with the anterior tibial veins; at the knee, with the articular veins; in the thigh, with the femoral vein by one or more branches. The valves in this vein vary from ten to twenty in number; they are more numerous in the thigh than in the leg.

FIG. 642.—The internal or long saphenous vein and its tributaries.



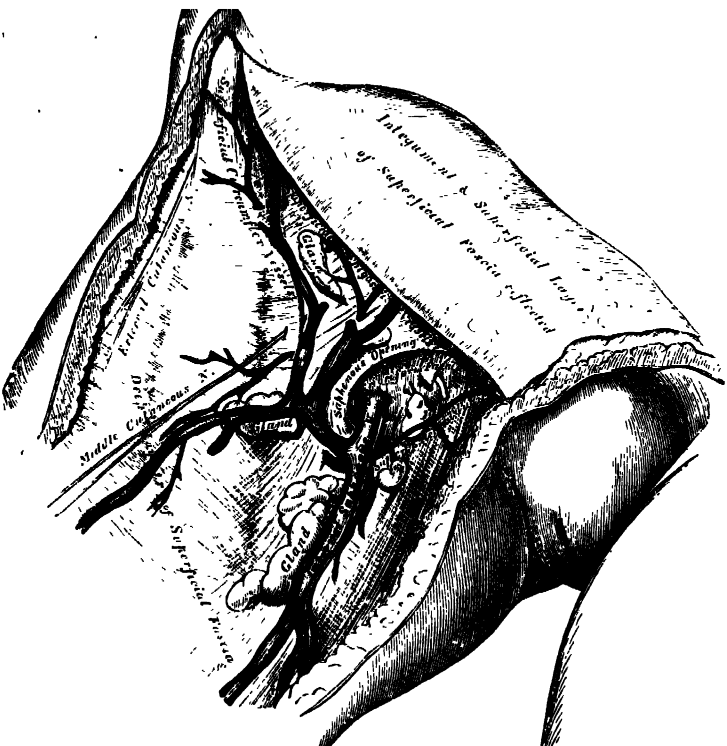
The **external or short saphenous vein** (v. saphena parva) (fig. 644) commences at the outer side of the venous arch on the dorsum of the foot; it ascends behind the outer malleolus, and along the outer border of the tendo Achillis, across which it passes to reach the middle line of the posterior aspect of the leg. Running directly upwards, it perforates the deep fascia in the lower part of the popliteal space, and terminates in the popliteal vein, between the heads of the Gastrocnemius muscle. It receives numerous large tributaries from the back part of the leg, and communicates with the deep veins on the dorsum of the foot, and behind the outer malleolus. Before it perforates the deep fascia, it gives off a communicating branch, which passes upwards and inwards to join the internal saphenous vein. The external saphenous vein contains from nine to twelve valves, one of which is always found near its termination in the popliteal vein. The external saphenous nerve lies close beside this vein.

Applied Anatomy.—A varicose condition of the saphenous veins is more frequently met with than in the other veins of the body, except perhaps the spermatic and hæmorrhoidal veins. The main cause of this is the high blood-pressure, determined chiefly by the erect position, and the length of the column of blood, which has to be propelled in an uphill direction. In normal vessels there is only just sufficient force to perform this task; and in those cases where there is diminished resistance of the walls of the veins, these vessels are liable to dilate and a varicose condition is set up. This diminished resistance may be due to heredity, the vein-walls being congenitally weak, or it may follow inflammatory conditions of the vessels. Increased blood pressure in the veins, caused by any obstacle to the return of the venous blood, such as the pressure of a tumour, or the gravid uterus, or tight gartering, may also produce varix. In the normal condition of the veins, the valves in their interior break up the column of blood into a number of smaller columns, and so to a considerable

extent mitigate the ill effects of the erect position; but when the dilatation of the veins has reached a certain limit, the valves become incapable of supporting the overlying column of blood, and the pressure is increased, tending to emphasise also the varicose condition. Both the saphenous veins in the leg are accompanied by nerves, the internal saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact.

Operations for the relief of varicose veins are frequently required, portions of the veins being removed after having been ligatured above and below. It is important to note

Fig. 643.—The internal saphenous vein and its tributaries at the saphenous opening.



whether the main varicose area drains into the internal or the external saphenous vein—the former condition being much the more common—and to control the venous return by removing a small portion of the main trunk just before it opens into the deep vein by passing through the deep fascia; thus in most cases a piece should be removed from the internal saphenous just before it passes through the saphenous opening, and in addition the affected veins should be excised just above and just below the level of the knee-joint. In other cases the external saphenous will have to be dealt with immediately below the point where it pierces the fascial roof of the popliteal space.

The **deep veins of the lower extremity** accompany the arteries and their branches, and are called the *venæ comites* of those vessels.

The **external** and **internal plantar veins** unite to form the **posterior tibial veins** (vv. tibiales posteriores), which accompany the posterior tibial artery, and are joined by the *peroneal veins* (vv. peronææ).

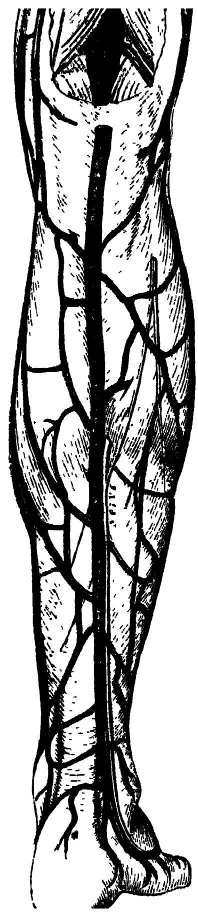
The **anterior tibial veins** (vv. tibiales anteriores) are the upward continuations of the venæ comites of the dorsalis pedis artery. They leave the front of the leg by passing between the tibia and fibula, over the interosseous membrane, and form, by their junction with the posterior tibial, the *popliteal* vein.

The valves in the deep veins are very numerous.

The **popliteal vein** (v. poplitea) is formed by the junction of the venæ comites of the anterior and posterior tibial arteries at the lower border of the Popliteus muscle; it ascends through the popliteal space to the tendinous aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is placed internal to the artery; between the heads of the Gastrocnemius it is superficial to that vessel; but above the knee-joint, it is close to its outer side. It receives tributaries corresponding to the branches of the popliteal artery, and it also receives the external saphenous vein. The valves in this vein are usually four in number.

The **femoral vein** (v. femoralis) accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies external to the artery; higher up, it is behind it; and at Poupart's ligament, it lies to its inner side, and on the same plane. It receives numerous muscular tributaries, and about an inch and a half below Poupart's ligament it is joined by the profunda femoris: near its termination it is joined by the internal saphenous vein. The valves in the femoral vein are three in number.

FIG. 644.—External or short saphenous vein.



The *profunda femoris vein* (v. profunda femoris) receives tributaries corresponding to the perforating branches of the profunda artery, and through these establishes communications with the popliteal vein below and the sciatic vein above. It also receives the internal and external circumflex veins.

The **external iliac vein** (v. iliaca externa) (fig. 645) commences at the termination of the femoral, beneath Poupart's ligament, and, passing upwards along the brim of the pelvis, terminates opposite the sacro-iliac articulation, by uniting with the internal iliac to form the common iliac vein. On the right side, it lies at first along the inner side of the external iliac artery; but, as it passes upwards, gradually inclines behind it. On the left side, it lies altogether on the inner side of the artery. It receives, immediately above Poupart's ligament, the deep epigastric and deep circumflex iliac veins, and a small pubic vein corresponding to the pubic branch of the obturator artery. It frequently contains one, sometimes two, valves.

Tributaries.—The external iliac vein receives the deep epigastric, deep circumflex iliac, and pubic veins.

The **deep epigastric vein** (v. epigastrica inferior) is formed by the union of the venæ comites of the deep epigastric artery, which communicate above with the superior epigastric vein; it joins the external iliac about half an inch above Poupart's ligament.

The **deep circumflex iliac vein** (v. circumflexa ilium profunda) is formed by the union of the venæ comites of the deep circumflex iliac artery, and joins the external iliac vein about three-quarters of an inch above Poupart's ligament.

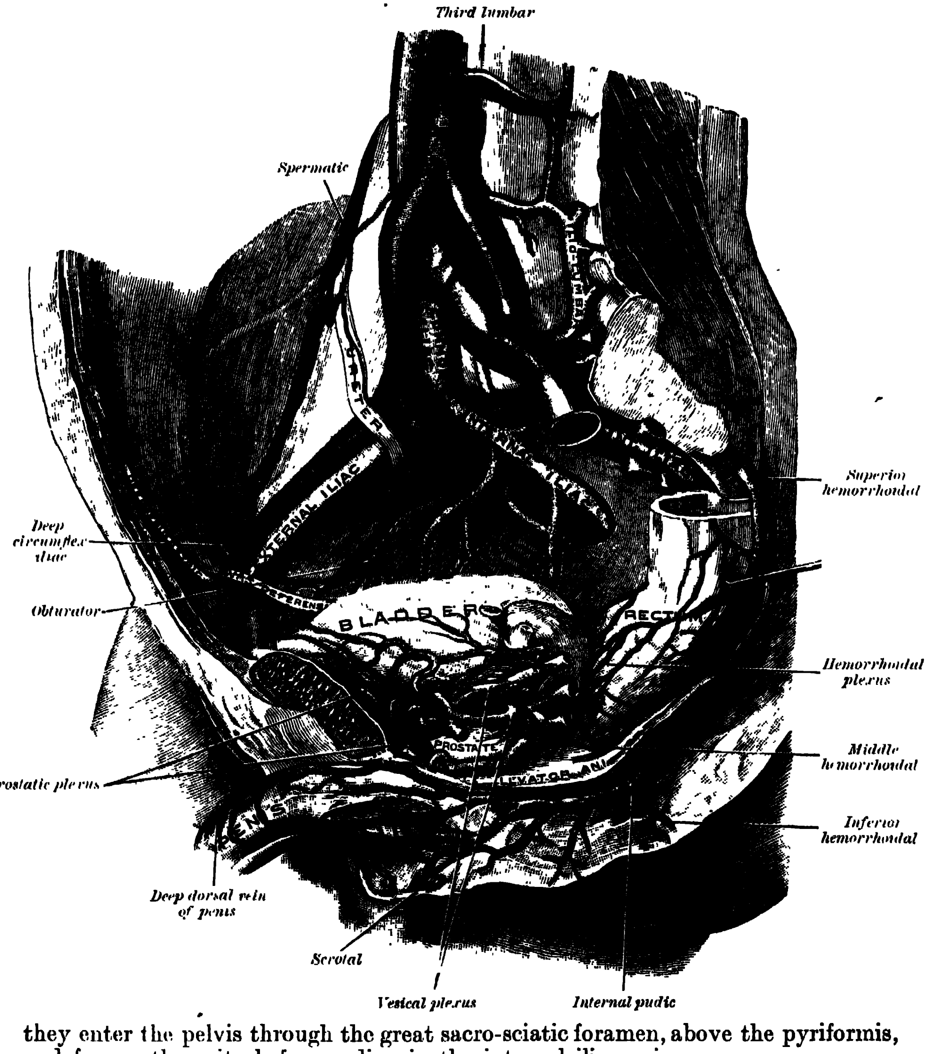
The *pubic vein* communicates with the obturator vein in the thyroid foramen, and ascends on the back of the pubis to the external iliac vein.

The **internal iliac vein** (v. hypogastrica) (fig. 645) commences near the upper part of the great sacro-sciatic foramen, passes upwards behind and slightly to the inner side of the internal iliac artery and, at the brim of the pelvis, joins with the external iliac to form the common iliac vein.

Tributaries.—With the exception of the fœtal umbilical vein which passes upwards and backwards from the umbilicus to the liver, and the ilio-lumbar vein which usually joins the common iliac vein, the tributaries of the internal iliac vein correspond with the branches of the internal iliac artery. It receives (*a*) the gluteal, sciatic, internal pudic, and obturator veins, which have their origins outside the pelvis; (*b*) the lateral sacral veins, which lie in front of the sacrum; and (*c*) the middle hæmorrhoidal, vesical, uterine, and vaginal veins, which originate in venous plexuses connected with the pelvic viscera.

1. The **gluteal veins** (vv. glutææ superiores) or venæ comites of the gluteal artery, receive tributaries from the buttock corresponding with the branches of the artery;

FIG. 645.—The veins of the right half of the male pelvis. (Spalteholz.)



they enter the pelvis through the great sacro-sciatic foramen, above the pyriformis, and frequently unite before ending in the internal iliac vein.

2. The **sciatic veins** (vv. glutææ inferiores) or venæ comites of the sciatic artery begin on the upper part of the back of the thigh, where they anastomose with the internal circumflex and first perforating veins. They enter the pelvis through the lower part of the sacro-sciatic foramen and join to form a single stem which opens into the lower part of the internal iliac vein.

3. The **internal pudic veins** (vv. pudendæ internæ) are the venæ comites of the internal pudic artery. They commence in the veins which issue from the corpus

cavernosum, accompany the internal pudic artery, and unite to form a single vessel, which ends in the internal iliac vein. They receive the veins from the bulb of the urethra, and the superficial perineal and inferior hæmorrhoidal veins (vv. hæmorrhoidales inferiores). The deep dorsal vein of the penis communicates with the internal pudic veins, but ends mainly in the vesico-prostatic venous plexus.

4. The **obturator vein** (v. obturatoria) begins in the upper portion of the adductor region of the thigh and enters the pelvis through the anterior part of the obturator foramen. It runs backwards and upwards on the lateral wall of the pelvis below the obturator artery, and then passes between the ureter and the internal iliac artery, to end in the internal iliac vein.

5. The **lateral sacral veins** (vv. sacrales laterales) accompany the lateral sacral arteries on the anterior surface of the sacrum and terminate in the internal iliac vein.

6. The **middle hæmorrhoidal vein** (v. hæmorrhoidalis media) takes origin in the hæmorrhoidal plexus and receives tributaries from the bladder, prostate gland, and seminal vesicle: it runs outwards on the pelvic surface of the Levator ani to end in the internal iliac vein.

The **hæmorrhoidal plexus** surrounds the rectum, and communicates in front with the vesico-prostatic plexus in the male, and the utero-vaginal plexus in the female. It consists of two parts, an *internal* in the submucosa, and an *external* outside the muscular coat. Below, the internal plexus presents a series of dilated pouches which are arranged in a circle around the tube immediately above the anal orifice and are connected by transverse branches. The lower part of the external plexus is drained by the inferior hæmorrhoidal veins into the internal pudic; its middle part by the middle hæmorrhoidal vein which joins the internal iliac; and its upper part by the superior hæmorrhoidal vein which forms the commencement of the inferior mesenteric vein, a tributary of the portal vein. A free communication between the portal and systemic venous systems is established through the hæmorrhoidal plexus.

The **vesico-prostatic plexus** surrounds the prostate gland and the neck of the bladder, and lies partly in the fascial sheath of the prostate and partly between the sheath and the capsule of the gland. In front it receives the deep dorsal vein of the penis; behind, it communicates with the hæmorrhoidal and vesical plexuses, and derives tributaries from the vasa deferentia and vesiculæ seminales. It is drained into the internal iliac veins by one or more vessels on either side. The corresponding plexus in the female is named the *vesico-vaginal.*

The **vesical plexus** lies on the muscular coat of the bladder, and is best marked towards the base and sides of the viscus; it drains into the vesico-prostatic plexus.

Applied Anatomy.—The veins of the hæmorrhoidal plexus are apt to become dilated and varicose, and form piles. This is due to several anatomical reasons: the vessels are contained in very loose, lax connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood pressure; the condition is favoured by gravitation, being influenced by the erect posture, either sitting or standing, and by the fact that the superior hæmorrhoidal and portal veins have no valves; the veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defæcation; they are affected by every form of portal obstruction.

The prostatic plexus of veins is apt to become congested in many inflammatory conditions in the neighbourhood, such as acute gonorrhœal prostatitis. It is owing to the free communication which exists between this and the middle hæmorrhoidal plexus that great relief can be given by free saline purgation.

Hæmorrhage may be very free from the prostatic plexus after operations on that gland, but can usually be checked by hot fluid irrigation. Septic thrombosis sometimes occurs after operations, and infected emboli may find their way into the general circulation.

The **dorsal veins of the penis** are two in number, a superficial and a deep. The *superficial* vein drains the prepuce and skin of the penis, and, running backwards in the subcutaneous tissue, inclines to the right or left, and opens into the corresponding superficial external pudic vein, a tributary of the internal or long saphenous vein. The *deep* vein receives the blood from the glans penis and corpora cavernosa:

it courses backwards in the middle line between the dorsal arteries, underneath the deep fascia, and near the root of the penis passes between the two parts of the suspensory ligament and then through an aperture between the subpubic ligament and the triangular ligament of the urethra, and divides into two branches, which enter the prostatic plexus. The deep vein also communicates below the symphysis pubis with the internal pudic vein.

The **uterine plexuses** lie along the sides and superior angles of the uterus between the two layers of the broad ligament, and communicate with the ovarian and vaginal plexuses. They are drained by a pair of uterine veins on either side: these arise from the lower part of the plexuses, opposite the os uteri externum, and open into the corresponding internal iliac vein.

The **vaginal plexuses** are placed at the sides of the vagina; they communicate with the uterine, vesical, and hæmorrhoidal plexuses, and are drained by the vaginal veins, one on either side, into the internal iliac veins.

The **common iliac veins** are formed by the union of the external and internal iliac veins in front of the sacro-iliac articulation; passing obliquely upwards towards the right side, they terminate upon the fifth lumbar vertebra, by uniting with each other at an acute angle to form the inferior vena cava. The *right common iliac* (v. iliaca communis dextra) is shorter than the left, nearly vertical in its direction, and ascends behind and then to the outer side of its corresponding artery. The *left common iliac* (v. iliaca communis sinistra), longer than the right and more oblique in its course, is at first situated on the inner side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the ilio-lumbar, and sometimes the lateral sacral veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The **middle sacral veins** accompany the corresponding artery along the front of the sacrum, and join to form a single vein (v. sacralis media), which terminates in the left common iliac vein; sometimes in the angle of junction of the two iliac veins.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form the vena cava. In these cases, the two common iliacs are connected by a small communicating branch at the spot where they are usually united.*

The **vena cava inferior** (fig. 639) returns to the heart the blood from all the parts below the Diaphragm. It is formed by the junction of the two common iliacs, on the right side of the fifth lumbar vertebra. It passes upwards along the front of the vertebral column, on the right side of the aorta, and, having reached the liver, is contained in a groove on its posterior surface. It then perforates the Diaphragm between the mesial and right portions of its central tendon; it subsequently inclines forwards and inwards for about an inch, and, piercing the fibrous pericardium, passes behind the serous pericardium to open into the lower and back part of the right auricle. In front of its auricular orifice is a semilunar valve, termed the *valve of Eustachius*: this is rudimentary in the adult, but is of large size and exercises an important function in the fœtus.

Relations.—The *abdominal portion* of the inferior vena cava is in relation *in front*, from below upwards, with the mesentery, right spermatic artery, transverse portion of the duodenum, the pancreas, portal vein, and the posterior surface of the liver, which partly and occasionally completely surrounds it; *behind*, with the vertebral column, the right Psoas muscle, the right crus of the Diaphragm, the right renal and lumbar arteries, right semilunar ganglion, and the inner part of the right suprarenal body; on the *right side*, with the right kidney and ureter; on the *left side*, with the aorta.

The *thoracic portion* is only about an inch in length, and is situated partly inside and partly outside the pericardial sac. The *extra-pericardial part* is separated from the right pleura and lung by a fibrous band, named the *right phrenico-pericardiac ligament* of Teutleben. This ligament, often feebly marked, is attached

* See two cases which have been described by Walsham in the *St. Bartholomew's Hospital Reports*, vols. xvi. and xvii.

below to the margin of the vena-caval opening in the Diaphragm, and above to the pericardium in front of and behind the root of the right lung. The *intra-pericardiac part* is very short, and is covered antero-laterally by the serous layer of the pericardium.

Peculiarities.—In position.—This vessel is sometimes placed on the left side of the aorta, as high as the left renal vein, after receiving which it crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, as far upwards as its termination in the heart: in such cases, the abdominal and thoracic viscera, together with the great vessels, are all transposed.

Point of termination.—Occasionally the inferior vena cava joins the right azygos vein, which is then of large size. In such cases, the superior vena cava receives the whole of the blood from the body before transmitting it to the right auricle, except the blood from the hepatic veins, which passes directly into the right auricle.

Applied Anatomy.—Thrombosis of the inferior vena cava is due to much the same causes as that of the superior (see page 750). It usually causes œdema of the legs and back, without ascites; if the renal veins are involved, blood and albumin will often appear in the urine. An extensive collateral venous circulation is soon established by enlargement either of the superficial or of the deep veins, or of both. In the first case the epigastric, the circumflex iliac, the long thoracic, the internal mammary, the intercostals, the external pudic, and the lumbo-vertebral anastomotic veins of Braune effect the communication with the superior cava; in the second, the deep anastomosis is made by the azygos and hemiazygos and the lumbar veins.*

Tributaries.—It receives in its course the following veins:

Lumbar.	Renal.	Inferior phrenic.
Right spermatic, or ovarian.	Suprarenal.	Hepatic.

The **lumbar veins** (vv. lumbales), four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins, and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the vertebral column, they receive veins from the spinal plexuses, and then pass forwards, round the sides of the bodies of the vertebræ, beneath the Psoas magnus, and terminate in the back part of the inferior cava. The left lumbar veins are longer than the right, and pass behind the aorta. The lumbar veins are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebræ, and is called the *ascending lumbar*. It forms the most frequent origin of the corresponding vena azygos, and serves to connect the common iliac, ilio-lumbar, lumbar, and azygos veins of its own side of the body.

The **spermatic veins** (vv. spermaticæ) emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus, called the *spermatic plexus* (plexus pampiniformis), which constitutes the greater mass of the cord: the vessels composing this plexus are very numerous, and ascend along the cord, in front of the vas deferens. Below the external abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal abdominal ring, coalesce to form two veins, which ascend on the Psoas muscle, behind the peritoneum, lying one on either side of the spermatic artery. These unite to form a single vein, which opens on the right side into the inferior vena cava, at an acute angle; on the left side into the left renal vein, at a right angle. The spermatic veins are provided with valves.† The left spermatic vein passes behind the iliac colon, and is thus exposed to pressure from the contents of that part of the bowel.

Applied Anatomy.—The spermatic veins are very frequently varicose, constituting the condition known as *varicocele*. Though it is quite possible that the originating cause of this affection may be a congenital weakness of the walls of the veins of the pampiniform plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose: viz. the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position;

* G. Blumer, in Osler and McCrae's *System of Medicine*, London, 1908, vol. iv.

† Rivington has pointed out that valves are usually found at the orifices of both the right and left spermatic veins. When no valves exist at the opening of the left spermatic vein into the left renal vein, valves are generally present in the left renal vein within a quarter of an inch from the orifice of the spermatic vein.—*Journal of Anatomy and Physiology*, vol. vii. p. 163.

their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall. Varicocele almost invariably occurs on the left side, and this has been accounted for by the facts that the left spermatic vein joins the left renal at a right angle; that it is overlaid by the iliac colon, and that when this portion of the gut is full of fæcal matter, in cases of constipation, its weight impedes the return of the venous blood; and that the left spermatic veins are somewhat longer than the right.

The operation for the removal of a varicocele consists in making a small incision just over the external abdominal ring and passing an aneurysm needle round the mass of veins, taking care that the vas deferens is not included. The veins are isolated from the vas and ligatured above and below, as high and as low as possible, and the intermediate portion cut away; the divided ends are fixed together with a suture, and the skin wound closed.

The **ovarian veins** (vv. ovaricæ) correspond with the spermatic in the male; they form a plexus in the broad ligament near the ovary and Fallopian tube, and communicate with the uterine plexus. They terminate in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. Like the uterine veins, they become much enlarged during pregnancy.

The **renal veins** (vv. renales) are of large size, and placed in front of the renal arteries. The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic, the left inferior phrenic, and, generally, the left suprarenal veins. It opens into the vena cava at a slightly higher level than the right.

The **suprarenal veins** (vv. suprarenales) are two in number: the right terminates in the vena cava; the left, in the left renal or phrenic vein.

The **inferior phrenic veins** (vv. phrenicæ inferiores) follow the course of the phrenic arteries; the right ends in the inferior vena cava, the left in the left renal vein.

The **hepatic veins** (vv. hepaticæ) commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery, and consist of two groups, upper and lower. The *upper group* is usually made up of three large veins, which converge towards the posterior surface of the liver, and open into the inferior vena cava, while that vessel is situated in the groove on the back part of the liver. The veins of the *lower group* vary in number, and are of small size; they come from the right and Spigelian lobes. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

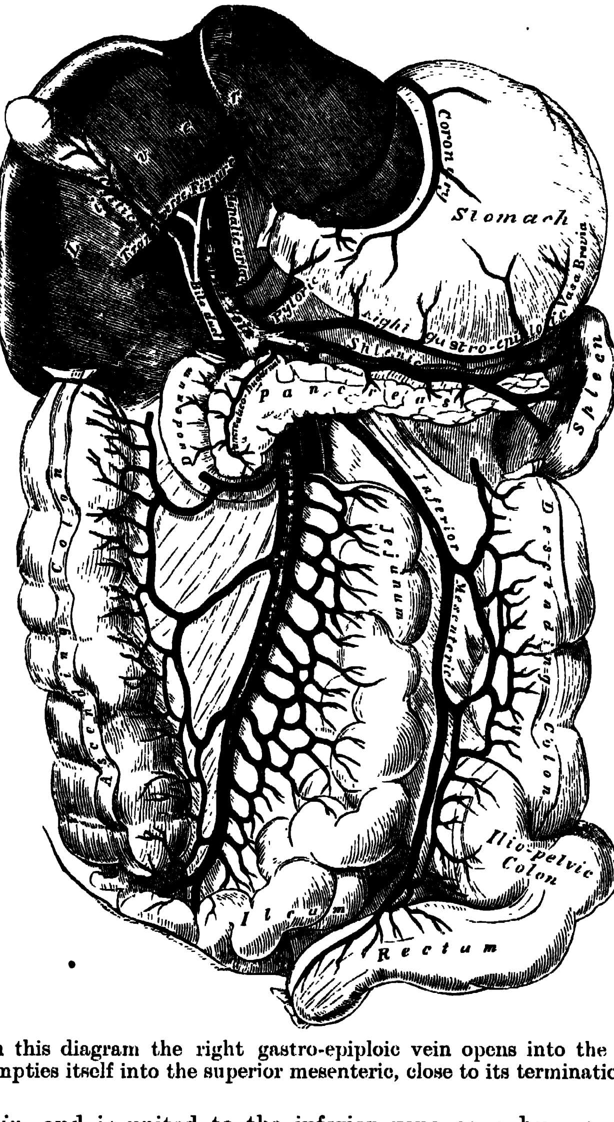
Portal System of Veins (fig. 646)

The portal system includes all the veins which drain the blood from the abdominal part of the alimentary canal (with the exception of the lower part of the rectum) and from the spleen, pancreas, and gall bladder. From these viscera the blood is conveyed to the liver by the *portal vein*. In the substance of the liver the portal vein ramifies like an artery and terminates in the *portal capillaries*, from which the blood is conveyed to the inferior vena cava by the hepatic veins. From this it will be seen that the blood of the portal system passes through two sets of capillary vessels, viz. (*a*) the capillaries of the alimentary canal, spleen, pancreas, and gall bladder; and (*b*) the portal capillaries in the substance of the liver. The portal vein and its tributaries are destitute of valves.

The **portal vein** (vena portæ) is about three inches in length, and is formed at the level of the second lumbar vertebra by the junction of the superior mesenteric and splenic veins, the union of these veins taking place in front of the inferior vena cava and behind the neck of the pancreas. It passes upwards behind the first part of the duodenum and then ascends in the right border of the small omentum to the right extremity of the transverse fissure of the liver, where it divides into a right and a left branch, which accompany the corresponding branches of the hepatic artery into the substance of the liver. In the small omentum it is placed behind and between the common bile duct and the hepatic artery, the former lying to the right of the latter. It is surrounded by the hepatic plexus of nerves, and is accompanied by numerous lymphatic vessels and some lymphatic glands. The *right branch* of the portal vein enters

the right lobe of the liver, but before doing so generally receives the cystic vein. The *left branch*, longer but of smaller calibre than the right, crosses the longitudinal fissure, gives branches to the caudate and Spigelian lobes, and then enters the left lobe of the liver. As it crosses the longitudinal fissure it is joined in front by a fibrous cord, the *ligamentum teres* of the liver or *obliterated*

FIG. 646.—Portal vein and its tributaries.



NOTE.—In this diagram the right gastro-epiploic vein opens into the splenic vein; generally it empties itself into the superior mesenteric, close to its termination.

umbilical vein, and is united to the inferior vena cava by a second fibrous cord, the *ligamentum venosum* or *obliterated ductus venosus*.

The tributaries of the portal vein are:

Splenic.	Pyloric.
Superior mesenteric.	Cystic.
Coronary.	Parumbilical.

The **splenic vein** (v. lienalis) commences by five or six large branches which return the blood from the spleen. These unite to form a single vessel, which passes from left to right, grooving the upper and back part of the

pancreas, below the splenic artery, and terminates behind the neck of the pancreas by uniting at a right angle with the superior mesenteric to form the portal vein. The splenic vein is of large size, but is not tortuous like the artery.

Tributaries.—The splenic vein receives the short gastric veins, the left gastro-epiploic vein, the pancreatic veins, and the inferior mesenteric veins.

(*a*) The **short gastric veins** (vv. gastricæ breves), some four or five in number, drain the fundus and left part of the greater curvature of the stomach, and pass between the two layers of the gastro-splenic omentum to terminate in the splenic vein or in one of its large tributaries.

(*b*) The **left gastro-epiploic vein** (v. gastroepiploica sinistra) receives branches from the anterior and posterior surfaces of the stomach and from the great omentum; it runs from right to left along the greater curvature of the stomach and ends in the commencement of the splenic vein.

(*c*) The **pancreatic veins** (vv. pancreaticæ) consist of several small vessels which drain the body and tail of the pancreas, and open into the trunk of the splenic vein.

(*d*) The **inferior mesenteric vein** (v. mesenterica inferior) returns blood from the rectum, and the pelvic, iliac, and descending parts of the colon. It begins in the rectum as the *superior hæmorrhoidal vein* (v. hæmorrhoidalis superior), which has its origin in the hæmorrhoidal plexus, and through this plexus communicates with the middle and inferior hæmorrhoidal veins. The superior hæmorrhoidal vein leaves the pelvis and crosses the iliac vessels in company with the superior hæmorrhoidal artery, and is continued upwards as the inferior mesenteric vein. This vein lies to the left of the inferior mesenteric artery, and ascends behind the peritoneum and in front of the left Psoas; it then passes behind the body of the pancreas and opens into the splenic vein; sometimes it terminates in the angle of union of the splenic and superior mesenteric veins.

Tributaries.—The inferior mesenteric vein receives the *sigmoid veins* (vv. sigmoideæ) from the ilio-pelvic colon and the *left colic vein* (v. colica sinistra) from the descending colon and splenic flexure.

The **superior mesenteric vein** (v. mesenterica superior) returns the blood from the small intestine, and from the cæcum and the ascending and transverse portions of the colon. It begins in the right iliac fossa by the union of the veins which drain the terminal part of the ilium, the cæcum and vermiform appendix, and ascends between the two layers of the mesentery on the right side of the superior mesenteric artery. In its upward course it passes in front of the right ureter, the inferior vena cava, the third part of the duodenum, and the lower portion of the head of the pancreas. Behind the neck of the pancreas it unites with the splenic vein to form the portal vein.

Tributaries.—Besides the tributaries which correspond with the branches of the superior mesenteric artery: viz. the *veins of the small intestine* (vv. intestinales), the *ileo-colic* (v. ileocolica), the *right colic* (vv. colicæ dextræ) and the *middle colic* (v. colica media), the superior mesenteric vein is joined by the right gastro-epiploic and pancreatico-duodenal veins.

The *right gastro-epiploic vein* (v. gastroepiploica dextra), receives branches from the great omentum and from the lower parts of the anterior and posterior surfaces of the stomach; it runs from left to right along the greater curvature of the stomach, between the two layers of the great omentum.

The *pancreatico-duodenal veins* (vv. pancreaticoduodenales) accompany their corresponding arteries; the lower of the two frequently joins the right gastro-epiploic vein.

The **coronary vein** (v. coronaria ventriculi) derives tributaries from both surfaces of the stomach; it runs from right to left along the lesser curvature of the stomach, between the two layers of the gastro-hepatic omentum, to the œsophageal opening of the stomach, where it receives some œsophageal veins. It then turns backwards and passes from left to right behind the lesser sac of the peritoneum and ends in the portal vein.

The **pyloric vein** (v. pylorica) is of small size, and runs from left to right along the pyloric portion of the lesser curvature of the stomach, between the two layers of the gastro-hepatic omentum, to terminate in the portal vein.

The **cystic vein** (v. cystica) drains the blood from the gall bladder, and, ascending alongside the cystic duct, usually terminates in the right branch of the portal vein.

Parumbilical veins (vv. parumbilicales).—In the course of the ligamentum teres of the liver, and of the urachus, small veins (parumbilical) are found, which establish an anastomosis between the veins of the anterior abdominal wall and the portal and iliac veins. The best marked of these small veins is one which commences at the umbilicus and runs backwards and upwards in, or on the surface of, the ligamentum teres between the layers of the falciform ligament to terminate in the left portal vein.

Applied Anatomy.—Obstruction to the portal vein may produce ascites, and this may arise from many causes: as (1) the pressure of a tumour on the portal vein, such as cancer or hydatid cyst in the liver, enlarged lymphatic glands in the lesser omentum, or cancer of the head of the pancreas; (2) from cirrhosis of the liver, when the radicles of the portal vein are pressed upon by the contracting fibrous tissue in the portal canals; (3) from valvular disease of the heart, and back pressure on the hepatic veins, and so on the whole of the circulation through the liver. In this condition the prognosis as regards life and freedom from ascites may be much improved by the establishment of a good collateral venous circulation to relieve the portal obstruction in the liver. This is effected by communications between (*a*) the gastric veins, and the œsophageal veins emptying themselves into the vena azygos minor, which often project as a varicose bunch into the stomach; (*b*) the veins of the colon and duodenum, and the left renal vein; (*c*) the accessory portal system of Sappey, branches of which pass in the round and falciform ligaments (particularly the latter) to unite with the epigastric and internal mammary veins, and through the diaphragmatic veins with the azygos; a single large vein, shown to be a parumbilical vein, may pass from the hilus of the liver by the round ligament to the umbilicus, producing there a bunch of prominent varicose veins known as the *Caput Medusæ*; (*d*) the veins of Retzius, which connect the intestinal veins with the inferior vena cava and its retroperitoneal branches; (*e*) the inferior mesenteric veins, and the hæmorrhoidal veins that open into the internal iliacs; (*f*) very rarely the ductus venosus remains patent, affording a direct connection between the portal vein and the inferior vena cava.

An operation for the relief of portal obstruction on these lines has been advocated by Rutherford Morison and by Talma. It consists in curetting the opposed surfaces of the liver and diaphragm and stitching them together, so as to secure vascular inflammatory adhesions between the two. The great omentum may with advantage be interposed between them, so as to increase the amount of the adhesions, and the spleen has been similarly scraped and sutured to or into the abdominal wall. The operation should not be deferred until the patient is moribund.

Thrombosis of the portal vein, or pylethrombosis, is a very serious event, and is oftenest due to pathological processes causing compression of the vessel or injury to its wall, such as tumours or inflammation about the pylorus, head of the pancreas, or appendix, or to gall-stones or cirrhosis of the liver. If the thrombus is infected with bacteria, as is often the case when it is due to appendicitis, septic or suppurative pylophlebitis results; this condition is known also as *portal pyæmia*. Fragments of the infected clot break off and are carried away to lodge in the smaller veins in the liver, with the development of multiple abscesses in its substance and a rapidly fatal result. When the thrombus is sterile, the chief signs produced are enlargement of the spleen, recurrent ascites, and the establishment of a collateral venous circulation, the case clinically resembling one of atrophic cirrhosis of the liver.

The symptoms of thrombosis of the mesenteric veins are very much the same as those of embolism of the mesenteric arteries (see p. 694).

THE LYMPHATIC SYSTEM

The lymphatic system includes the lymphatic vessels and lymphatic glands. The lymphatic vessels of the small intestine receive the special designation of *lacteals* or *chyliferous vessels*; they differ in no respect from the lymphatic vessels generally, excepting that during the process of digestion they contain a milk-white fluid, the *chyle*.

The lymphatic vessels are exceedingly delicate, and their coats are so transparent that the fluid they contain is readily seen through them. They retain a nearly uniform size, being interrupted at intervals by constrictions, which give them a knotted or beaded appearance. These constrictions are due to the presence of valves in their interior. Lymphatic vessels have been found in nearly every texture and organ of the body which contains

blood-vessels. Such non-vascular structures as cartilage, the nails, cuticle, and hair have none, but with these exceptions it is probable that eventually all parts will be found to be permeated by these vessels.

The lymphatic vessels are arranged into a superficial and a deep set. On the surface of the body the *superficial* lymphatic vessels are placed immediately beneath the integument, accompanying the superficial veins; they join the deep lymphatic vessels in certain situations by perforating the deep fascia. In the interior of the body they lie in the submucous areolar tissue, throughout the whole length of the gastro-pulmonary and genito-urinary tracts; and in the subserous tissue of the thoracic and abdominal walls. The method of their origin has been described along with the details of their minute anatomy. Here it will be sufficient to say that a plexiform network of minute lymphatic vessels may be found interspersed among the proper elements and blood-vessels of the several tissues; the vessels composing the network, as well as the meshes between them, are much larger than those of the capillary plexus. From these networks small vessels emerge, which pass, either to a neighbouring gland, or to join some larger lymphatic trunk. The *deep* lymphatic vessels, fewer in number, and larger than the superficial, accompany the deep blood-vessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatic vessels of any part or organ exceed the veins in number, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect, the continuous trunks retaining the same diameter.

The **lymphatic glands** are small, solid, glandular bodies, situated in the course of the lymphatic vessels. In size they vary from a hemp-seed to an almond, and their colour, on section, is of a pinkish-grey tint, excepting in the bronchial glands, which in the adult are mottled with black. Each gland is invested by a fibrous capsule, from which prolongations dip into its substance, forming partitions. Before entering a gland a lymphatic or lacteal vessel divides into several small branches, which are named *afferent vessels*. As they enter, their external coat becomes continuous with the capsule of the gland, and the vessels much thinned and consisting only of their internal or endothelial coats pass into the gland, and open into the lymph sinuses. From these sinuses fine branches proceed to form a plexus, the vessels of which unite to form a single *efferent vessel*; this, on emerging from the hilus of the gland, is again invested with an external coat.

Applied Anatomy.—The lymphatic channels and glands draining any infected area of the body are very liable to become infected, with the production of acute or chronic lymphangitis and lymphadenitis. In acute cases the paths of the superficial lymphatics are often marked out on the skin by the appearance over them of the four cardinal signs of inflammation—pain, redness, heat, and swelling—while the glands swell and may suppurate. Chronic inflammation leads to growth and fibrosis of the lymphatics and the connective tissue round them; obstruction to the passage of the lymph results, as the fibrous tissue contracts and causes stenosis or obliteration of the lymphatic channels, and hard œdema of the involved skin and subcutaneous tissues follows (*pachydermia lymphangiectatica*). Chronic lymphangitis, together with the blocking of numerous lymphatic vessels by the escaped ova of the minute parasitic worm *Microfilaria nocturna*, is the cause of elephantiasis, a condition common in the tropics and subtropics, and characterised by enormous enlargement and thickening of the integuments of some part of the body, most frequently of the leg. Tubercular and syphilitic enlargements of the lymphatics and glands are both very commonly met with. Primary tumours of the lymphatics are lymphangioma and endothelioma; the so-called 'congenital cystic hygroma' of the neck, arm, trunk, or thigh, is a cystic lymphangioma. Primary tumours of the lymphatic glands may be innocent (lymphadenoma, myxoma, chondroma) or malignant (lymphosarcoma); cancer is never met with as a primary affection, but is extremely common secondarily to cancer of some other part of the body.

The appearance of secondary malignant deposits or of secondary infection in parts of the body that seem not to be directly associated by any lymphatic connection with the seat of the primary growth or infection has often been observed, and explained as due to 'retrograde transport' of cancer cells or bacteria by a reversed flow of lymph. Weleminsky,* however, believes that the explanation is to be found in the fact that when the infected glands have grown to a certain size they no longer permit the normal flow of lymph through them, and that under these circumstances very delicate lymphatic

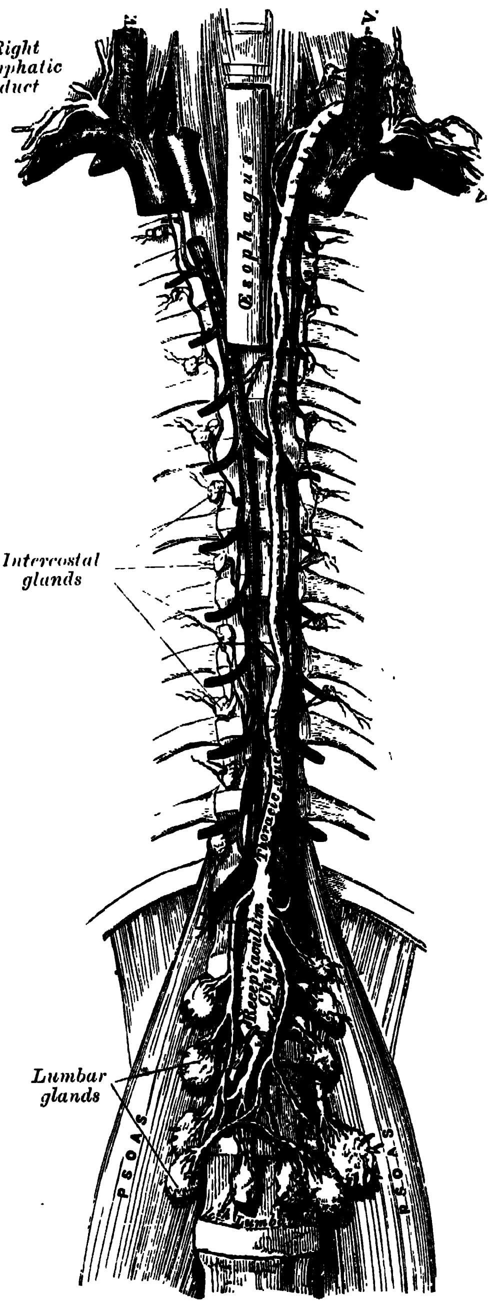
* *Berliner klin. Woch.*, 1905, No. 24, p. 743.

connections, whose existence normally remains unsuspected, develop to a surprising extent between groups of lymphatic glands that at first sight appear to be unconnected with one another.

Thoracic Duct

The **thoracic duct** (ductus thoracicus) (fig. 647) conveys the great mass of the lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body, excepting those of the right side of the head, neck, and thorax, and right upper extremity, the right lung, right side of the heart, and the convex surface of the liver. In the adult it varies in length from fifteen to eighteen inches, and extends from the second lumbar vertebra to the root of the neck. It commences in the abdomen by a triangular dilatation, the *receptaculum chyli*, which is situated on the front of the body of the second lumbar vertebra, to the right side of and behind the aorta, by the side of the right crus of the Diaphragm. It enters the thorax through the aortic opening of the Diaphragm, and is then placed in the posterior mediastinum between the aorta and vena azygos major. Here it lies in front of the vertebral column, from which it is separated by the right intercostal arteries, and by the azygos minor veins as they cross the middle line to open into the vena azygos major. Opposite the fifth thoracic vertebra, it inclines towards the left side, enters the superior mediastinum, and ascends behind the arch of the aorta, on the left side of the œsophagus, and behind the first portion of the left subclavian artery, to the upper orifice of the thorax. Opposite the seventh cervical vertebra, it turns outwards in front of the vertebral vein and artery, behind the left common carotid artery and vagus nerve, and then curves downwards over the subclavian artery, and in front of the Scalenus anticus muscle and the phrenic nerve, so as to form an arch; it terminates in the angle of junction of the left subclavian vein with the left internal jugular vein. The thoracic duct, at its commencement, is about equal in diameter to a goose-quill,

Fig. 647.—The thoracic and right lymphatic ducts.



but it diminishes considerably in calibre in the middle of the thorax, and is again dilated just before its termination. It is generally flexuous and constricted at intervals so as to present a varicose appearance. Not infrequently it divides in the middle of its course into two branches of unequal size, which soon reunite, or into several branches which form a plexiform interlacement. It occasionally divides at its upper part into two branches, right and left; the left terminates in the usual manner, while the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has several valves: at its termination it is provided with a pair of valves, the free borders of which are turned towards the vein, so as to prevent the passage of venous blood into the duct.

The **receptaculum chyli** (cisterna chyli) (fig. 648) receives the two lumbar lymphatic trunks, right and left, and the intestinal lymphatic trunk. The *lumbar lymphatic trunks* (trunci lumbales) are formed by the union of the efferent vessels from the lateral aortic lymphatic glands. They receive the lymph from the lower limbs, from the walls and viscera of the pelvis, from the kidneys and suprarenal bodies, and the deep lymphatics of the

greater part of the abdominal wall. The *intestinal lymphatic trunk* (truncus intestinalis) receives the lymph from the stomach and small intestine, from the pancreas and spleen, and from the lower and front part of the liver.

Tributaries.—Opening into the commencement of the thoracic duct, on either side, is a descending trunk from the posterior intercostal glands of the lower six or seven intercostal spaces. In the thorax the duct is joined, on either side, by a trunk which drains the upper lumbar glands and pierces the crus of the Diaphragm. It also receives the efferents from the posterior mediastinal glands and from the posterior intercostal glands of the upper six left spaces. In the neck it is joined by the *left jugular* and *left subclavian* trunks, and sometimes by the left *broncho-mediastinal* trunk; the last-named, however, usually opens independently into the junction of the left subclavian and internal jugular veins.

Structure.—The thoracic duct is composed of three coats, which differ in some respects from those of the other lymphatic vessels. The *internal coat* consists of a single layer of flattened, lanceolate endothelial cells, with serrated borders; a subendothelial layer similar to that found in the arteries; and an elastic fibrous coat, the fibres of which run in a longitudinal direction. The *middle coat* consists of a longitudinal layer of white connective tissue with elastic fibres, external to which are several laminæ of muscular tissue, the fibres of which are for the most part disposed transversely, but some are oblique or longitudinal, and intermixed with elastic fibres. The *external coat*

is composed of areolar tissue, with elastic fibres and isolated fasciculi of muscular fibres.

The **right lymphatic duct** (ductus lymphaticus dexter) (fig. 649), about half an inch in length, courses along the inner border of the Scalenus anticus at the root of the neck and terminates in the right subclavian vein, at its angle

a. Jugular trunk. *b*. Subclavian trunk. *c*. Broncho-mediastinal trunk. *d*. Right lymphatic trunk. *e*. Gland of internal mammary chain. *f*. Gland of deep cervical chain.

of junction with the right internal jugular vein. Its orifice is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

Tributaries.—It receives the lymph from the right side of the head and neck through the *right jugular trunk*; from the right upper extremity through the *right subclavian trunk*; from the right side of the thorax, the right lung, and right side of the heart, and from part of the convex surface of the liver, through the *right broncho-mediastinal trunk*. These three collecting trunks frequently open separately in the angle of union of the two veins.

Applied Anatomy.—Blockage of the thoracic duct by mature specimens of the minute parasitic worm *Microfilaria nocturna* gives rise to stasis of the chyle, and to its passage in various abnormal directions on its course past the obstruction. The neighbouring abdominal, renal, and pelvic lymphatics become enlarged, varicose, and tortuous, and chyle may make its way into the urine (chyluria), the tunica vaginalis (chylocele), the abdominal cavity (chylous ascites), or the pleural cavity (chylous pleural effusion), in consequence of rupture of some of these distended lymphatic vessels.

The thoracic duct may be secondarily infected in intestinal or pulmonary tuberculosis, and may contain either miliary tubercles, caseating tuberculous masses, or even tuberculous ulcers. It is often the seat of secondary carcinomatous deposits in cases of cancer of some abdominal viscus, becoming infiltrated throughout until it becomes a stiff moniliform rod as thick as a pencil, with multiple stenoses and dilatations of its lumen; in such cases the left supraclavicular glands often become infected and enlarged, while the lungs remain entirely free from secondary growths.

LYMPHATICS OF THE HEAD, FACE, AND NECK

The **lymphatic glands of the head** (fig. 650) are arranged in the following groups:

Occipital.	Facial.
Posterior auricular.	Internal maxillary.
Parotid.	Lingual.
Retro-pharyngeal.	

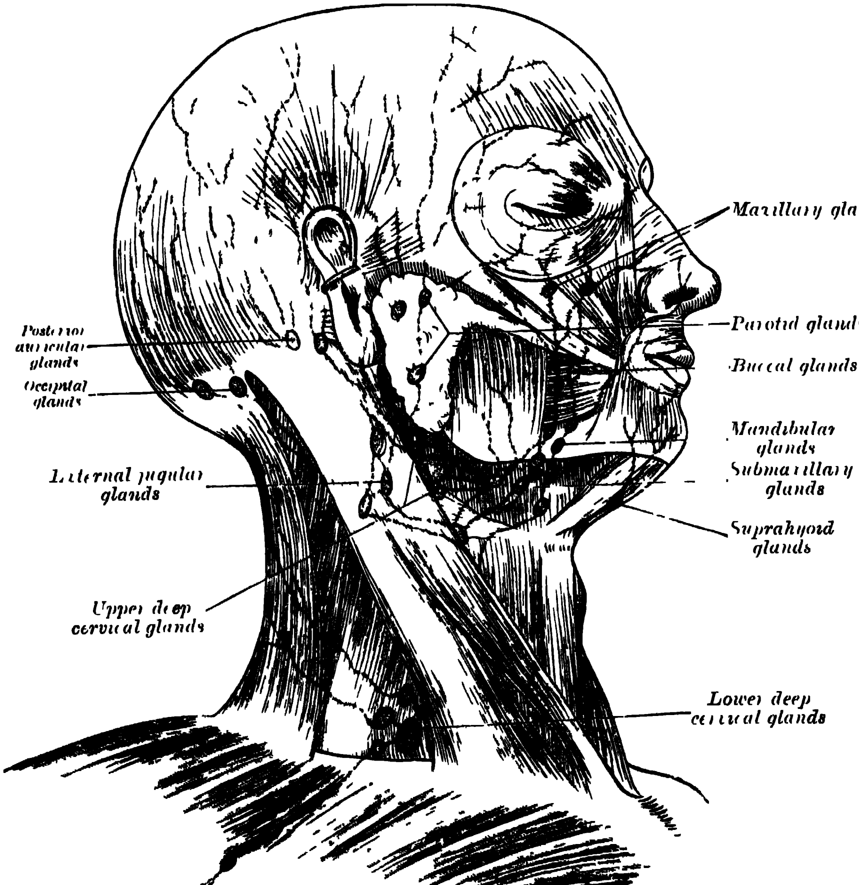
The **occipital glands** (lymphoglandulæ occipitales), one to three in number, are placed on the back of the head close to the margin of the Trapezius and resting on the insertion of the Complexus. Their afferent vessels drain the occipital region of the scalp, while their efferents pass to the upper glands of the deep cervical group.

The **posterior auricular** or **mastoid glands** (lymphoglandulæ auriculares posteriores), usually two in number, are situated on the mastoid insertion of the Sterno-mastoid. Their afferent vessels drain the posterior part of the

temporo-parietal region, the upper part of the internal surface of the pinna, and the back of the external auditory meatus; their efferents pass to the upper glands of the deep cervical group.

The **parotid glands** (lymphoglandulæ parotideæ) form three groups in relation with the parotid salivary gland, viz. a superficial group, situated over the gland but under the parotid fascia (lymphoglandulæ auriculares anteriores), a deeper group imbedded in the substance of the gland, and a group of subparotid glands lying on the lateral wall of the pharynx. Occasionally small glands are found in the subcutaneous tissue over the parotid gland. The afferent vessels of the lymphatic glands under the fascia, and of those in the substance of the gland, drain the root of the nose, the eyelids, the fronto-temporal region,

FIG. 650.—Superficial lymphatic glands and vessels of head and neck.



the outer surface of the pinna, the external auditory meatus and the tympanum, possibly also the posterior parts of the palate and of the floor of the nose. The efferents of these glands pass to the upper glands of the deep cervical group. The afferents of the subparotid glands drain the naso-pharynx and posterior part of the nasal fossa; their efferents pass to the upper deep cervical glands.

The **facial glands** (lymphoglandulæ faciales) comprise three groups: (*a*) *maxillary*, scattered over the infra-orbital region from the groove between the nose and cheek to the zygoma; (*b*) *buccal*, one or more placed on the Buccinator opposite the angle of the mouth; (*c*) *mandibular*, on the outer surface of the mandible, in front of the Masseter and in contact with the facial vessels. Their afferent vessels drain the eyelids, the conjunctiva, and the

integument and mucous membrane of the nose and cheek; their efferents pass to the submaxillary glands.

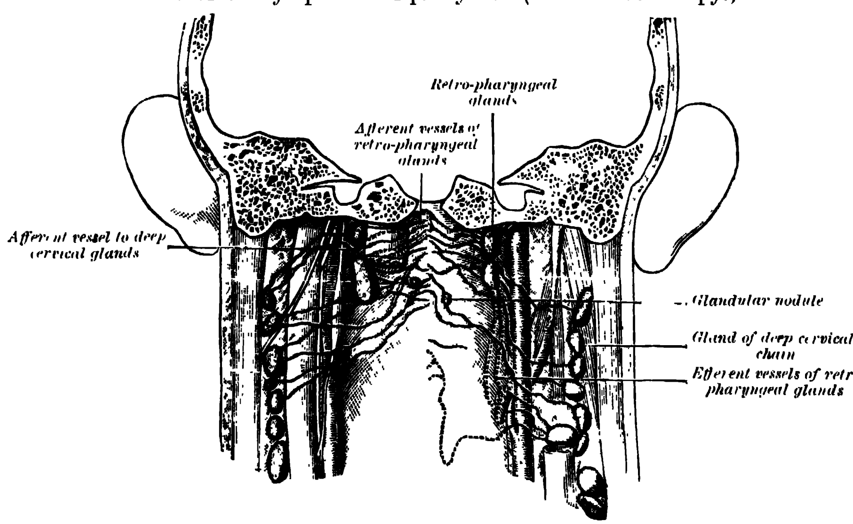
The internal maxillary glands (lymphoglandulæ faciales profundæ) are deeply placed beneath the ramus of the mandible, on the outer surface of the External pterygoid, in relation to the internal maxillary artery. Their afferent vessels drain the temporal and zygomatic fossæ and the naso-pharynx; their efferents pass to the upper glands of the deep cervical group.

The **lingual glands** (lymphoglandulæ linguales) are two or three small nodules lying on the Hyo-glossus, and under the Genio-hyoglossus. They form merely glandular sub-stations in the course of the lymphatic vessels of the tongue.

The **retro-pharyngeal glands** (fig. 651) lie in the bucco-pharyngeal fascia, behind the upper part of the pharynx and in front of the arch of the atlas, being separated, however, from the latter by the Rectus capitis anticus major. Their afferents drain an extensive area, comprising the nasal fossæ, the naso-pharynx, and the Eustachian tubes; their efferents pass to the upper glands of the deep cervical group.

The *lymphatic vessels of the scalp* are divisible into (*a*) those of the frontal region, which terminate in the parotid glands; (*b*) those of the temporo-

FIG. 651.—Lymphatics of pharynx. (Poirier and Charpy.)



parietal region, which end in the parotid and posterior auricular glands; and (*c*) those of the occipital region, which terminate partly in the occipital glands and partly in a trunk which runs down along the posterior border of the Sterno-mastoid to end in the lower group of deep cervical glands.

The *lymphatic vessels of the pinna and external auditory meatus* are also divisible into three groups: (*a*) an anterior, from the outer surface of the pinna and anterior wall of the meatus to the parotid glands; (*b*) a posterior, from the margin of the pinna, the upper part of its inner surface, the internal surface and posterior wall of the meatus to the posterior auricular and upper deep cervical glands; (*c*) an inferior, from the floor of the meatus and from the lobule to the external jugular and upper deep cervical glands.

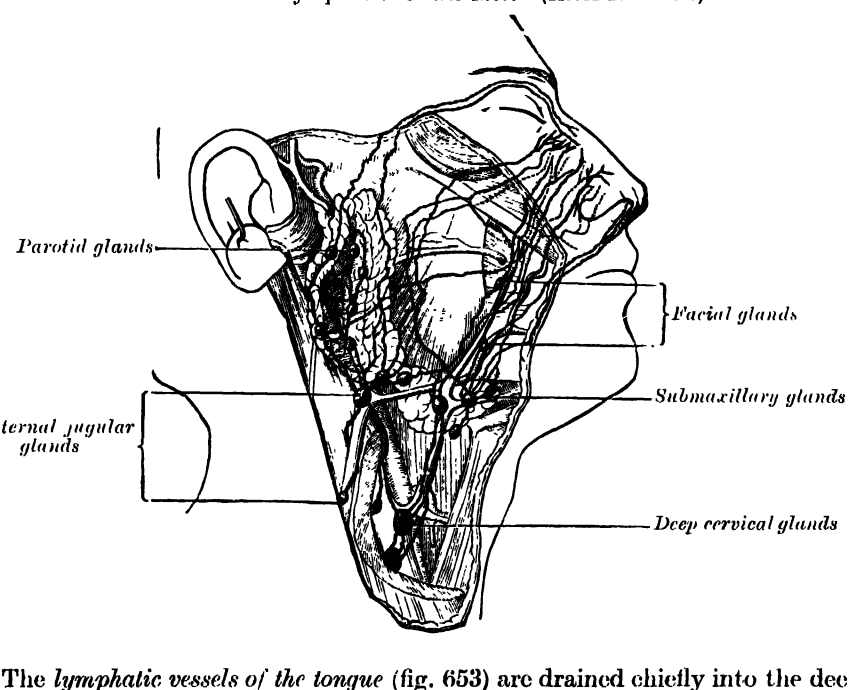
The *lymphatic vessels of the face* are more numerous than those of the scalp. Those from the eyelids and conjunctivæ terminate partly in the submaxillary, but mainly in the parotid glands. The vessels from the posterior part of the cheek also pass to the parotid glands, while those from the anterior portion of the cheek, the side of the nose, the upper lip, and the lateral portions of the lower lip terminate in the submaxillary glands. The deeper vessels from the temporal and zygomatic fossæ pass to the internal maxillary and upper deep cervical glands. The deeper vessels of the cheek and lips terminate, like the superficial, in the submaxillary glands. Both superficial and deep vessels of the central part of the lower lip run to the suprahyoid glands.

The *lymphatic vessels of the nasal fossæ* can be injected from the subdural and subarachnoid spaces. Those from the anterior parts of the fossæ communicate with the vessels of the nasal integument and terminate in the submaxillary glands; those from the posterior two-thirds of the fossæ and from the communicating air sinuses pass partly to the retropharyngeal and partly to the upper deep cervical glands.

Lymphatic vessels of the mouth.—The vessels of the gums terminate in the submaxillary glands; those of the hard palate are continuous in front with those of the upper gum, but pass backwards to pierce the Superior constrictor and end in the upper deep cervical and subparotid glands; those of the soft palate pass backwards and outwards, and terminate partly in the retropharyngeal and subparotid, and partly in the upper deep cervical glands. The vessels of the anterior part of the floor of the mouth pass either directly to the lower glands of the upper deep cervical group, or indirectly through the suprahyoid glands; from the rest of the floor of the mouth the vessels terminate in the submaxillary and upper deep cervical glands.

The *lymphatic vessels of the tonsil* pass to the upper deep cervical glands.

FIG. 652.—The lymphatics of the face. (After Küttner.)



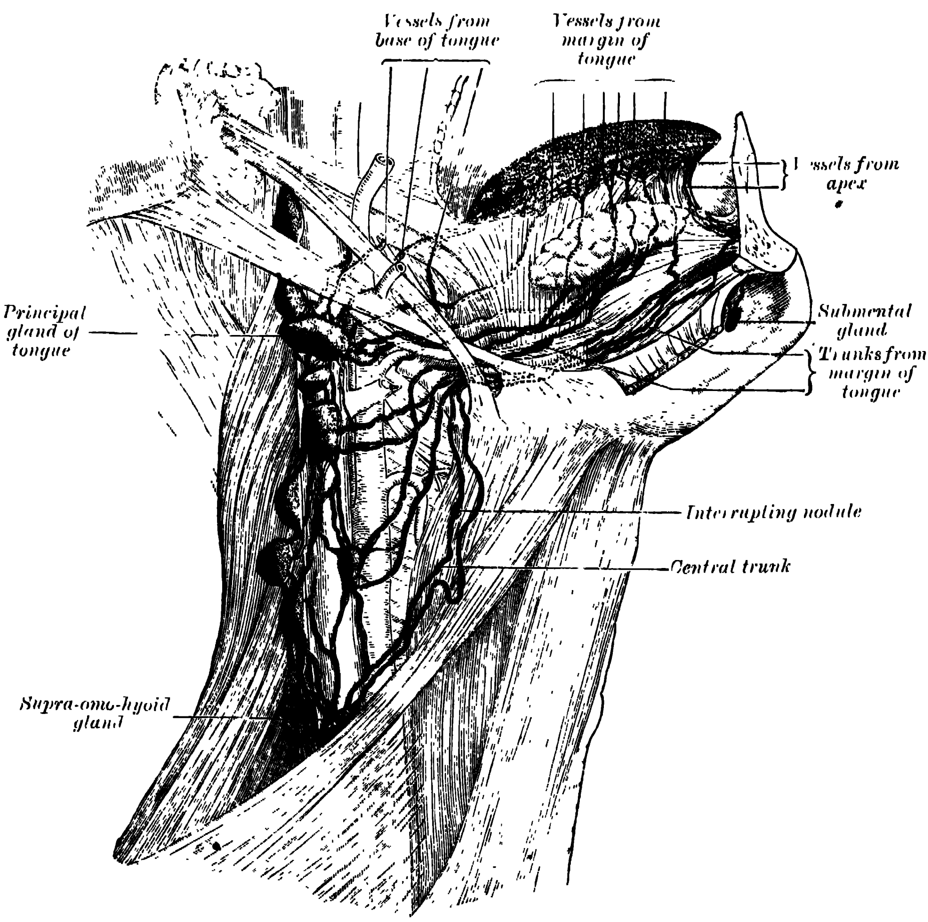
The *lymphatic vessels of the tongue* (fig. 653) are drained chiefly into the deep cervical glands lying between the posterior belly of the Digastric and the posterior belly of the Omo-hyoid; one gland situated at the bifurcation of the common carotid artery is so intimately associated with these vessels that it is known as the *principal gland of the tongue.* The vessels of the tongue have been divided into four groups: (1) apical, from the tip of the tongue to the suprahyoid glands and principal gland of tongue; (2) lateral, from the margin of the tongue—some of these pierce the Mylo-hyoid to terminate in the submaxillary glands, others pass down on the Hyo-glossus to the upper deep cervical; (3) basal, from the region of the circumvallate papillæ to the upper deep cervical glands; and (4) median, a few of which perforate the Mylo-hyoid to reach the submaxillary glands, while the majority turn round the posterior border of the muscle to enter the upper deep cervical glands.

The **lymphatic glands of the neck** include the following groups:

Submaxillary.		External jugular.
Suprahyoid.		Anterior cervical.
	Deep cervical.	

The **submaxillary glands** (lymphoglandulæ submaxillares) (fig. 652), three to six in number, are placed beneath the body of the mandible in the submaxillary triangle, and rest on the superficial surface of the submaxillary salivary gland. One gland (the *middle gland of Stahr*), which lies on the facial artery as it turns over the mandible, is the most constant of the series. Small lymphatic glands are sometimes found on the deep surface of the submaxillary gland. Their afferents drain the inner canthus of the eye, the cheek, the side of the nose, the upper lip, the outer part of the lower lip, the gums, and the anterior part of the margin of the tongue; efferent vessels from the facial and suprahyoid glands also enter the submaxillary glands. Their efferent vessels pass to the upper glands of the deep cervical group.

FIG. 653.—Lymphatics of the tongue. (Poirier.)



The **suprahyoid** or **submental glands** are situated close to the middle line of the neck between the anterior bellies of the two Digastric muscles. Their afferents drain the central portions of the lower lip and floor of the mouth and the tip of the tongue; their efferents pass partly to the submaxillary glands and partly to a gland of the deep cervical group situated on the internal jugular vein at the level of the cricoid cartilage.

The **external jugular glands** (lymphoglandulæ cervicales superficiales) lie in close relationship with the external jugular vein as it emerges from the parotid gland, and, therefore, superficial to the Sterno-mastoid. Their afferents drain the lower parts of the pinna and parotid region, while their efferents pass round the anterior margin of the Sterno-mastoid to join the upper deep cervical glands.

The **anterior cervical glands** form an irregular and inconstant group on the front of the larynx and trachea. They may be divided into : (*a*) a superficial set, placed on the anterior jugular vein ; (*b*) a deeper set, which is further subdivided into pre-laryngeal, on the crico-thyroid membrane, and pre-tracheal, on the front of the trachea. This deeper set drains the lower part of the larynx, the thyroid body, and the upper part of the trachea ; its efferents pass to the lower glands of the upper deep cervical group.

The **deep cervical glands** (lymphoglandulæ cervicales profundæ) (figs. 650, 653) are numerous and of large size ; they form a chain along the carotid sheath, lying by the side of the pharynx, œsophagus, and trachea, and extending from the base of the skull to the root of the neck. They are usually described in two groups : (1) an *upper* or *substerno-mastoid* group (lymphoglandulæ cervicales profundæ superiores) lying under the Sterno-mastoid in close relation with the spinal accessory nerve and the internal jugular vein, some of the glands lying in front of and others behind the vessel ; (2) a *lower* or *supraclavicular* group (lymphoglandulæ cervicales profundæ inferiores) extending beyond the posterior margin of the Sterno-mastoid into the supraclavicular triangle, where they are closely related to the brachial plexus and subclavian vein. A few minute glands are situated alongside the recurrent laryngeal nerves on the lateral aspects of the trachea and œsophagus. The *upper* deep cervical glands drain the occipital portion of the scalp, the pinna, and the back of the neck, the tongue, larynx, thyroid body, trachea, naso-pharynx, nasal fossæ, palate, and œsophagus. They receive also the efferent vessels from all the other glands of the head and neck, except those from the lower deep cervical group. The *lower* deep cervical glands drain the back of the scalp and neck, the superficial pectoral region, part of the arm (see page 775), and, occasionally, part of the upper surface of the liver. In addition, they receive vessels from the upper group. The efferents of the upper deep cervical glands pass partly to the lower group and partly to a trunk which unites with the efferent trunk of the lower deep cervical glands and forms the *jugular trunk* (truncus jugularis). This trunk, on the right side, ends in the junction of the internal jugular and subclavian veins, while on the left side it joins the thoracic duct.

The *lymphatic vessels of the skin and muscles of the neck* pass to the deep cervical glands. From the upper part of the *pharynx* the lymphatic vessels pass to the retropharyngeal, from the lower part to the deep cervical glands. From the *larynx* two sets of vessels arise, an upper and a lower. The vessels of the upper set pierce the thyro-hyoid membrane and join the upper deep cervical glands. Of the lower set, some pierce the crico-thyroid membrane and join the pre-tracheal and pre-laryngeal glands ; others run between the cricoid and first tracheal ring and enter the lower deep cervical glands. The lymphatic vessels of the *thyroid body* consist of two sets, an upper, which accompanies the superior thyroid artery and enters the upper deep cervical glands, and a lower, which runs partly to the pre-tracheal glands and partly to the small glands which accompany the recurrent laryngeal nerve. These latter glands receive also the lymphatic vessels from the cervical portion of the trachea.

Applied Anatomy.—The cervical glands are very frequently the seat of tuberculous disease. This condition is most usually set up by some lesion in those parts from which they receive their lymph. It is very desirable therefore for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery, while in order to eradicate them by operation a long and difficult dissection may be required.

LYMPHATICS OF THE UPPER EXTREMITY

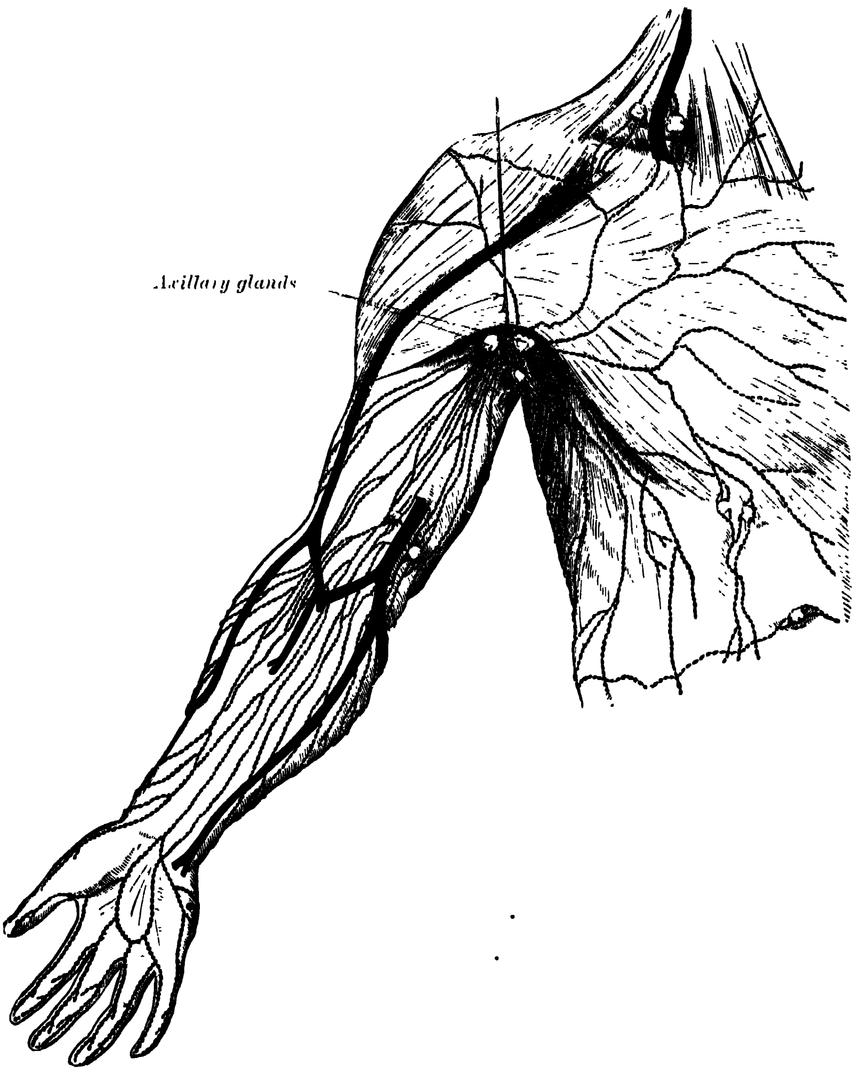
The **lymphatic glands of the upper extremity** (fig. 654) are divided into two sets, *superficial* and *deep*.

The **superficial lymphatic glands** are few and of small size. One or two are placed above the internal epicondyle of the humerus, near the basilic vein. Their afferents drain the inner three fingers, the inner portion of the hand,

and the superficial area over the ulnar side of the forearm; these vessels are, however, in free communication with the other lymphatic vessels of the forearm. Their efferents accompany the basilic vein and join the deeper vessels. One or two glands are found beside the cephalic vein, between the Pectoralis major and Deltoid, immediately below the clavicle. They are situated in the course of the external collecting trunks of the arm.

The **deep lymphatic glands** are chiefly grouped in the axilla, although a few may be found in the forearm, in the course of the radial, ulnar, and

FIG. 654.—The superficial lymphatics of the upper extremity.



interosseous vessels, and in the arm along the inner side of the middle part of the brachial artery.

The **axillary glands** (lymphoglandulæ axillares) (fig. 655) are of large size, vary from twenty to thirty in number, and may be arranged in the following groups:

1. An *external group* of from four to six glands lies in relation to the inner and posterior aspects of the axillary vein; the afferents of these glands drain the whole arm with the exception of that portion whose vessels accompany the cephalic vein. The efferent vessels pass partly to the central and

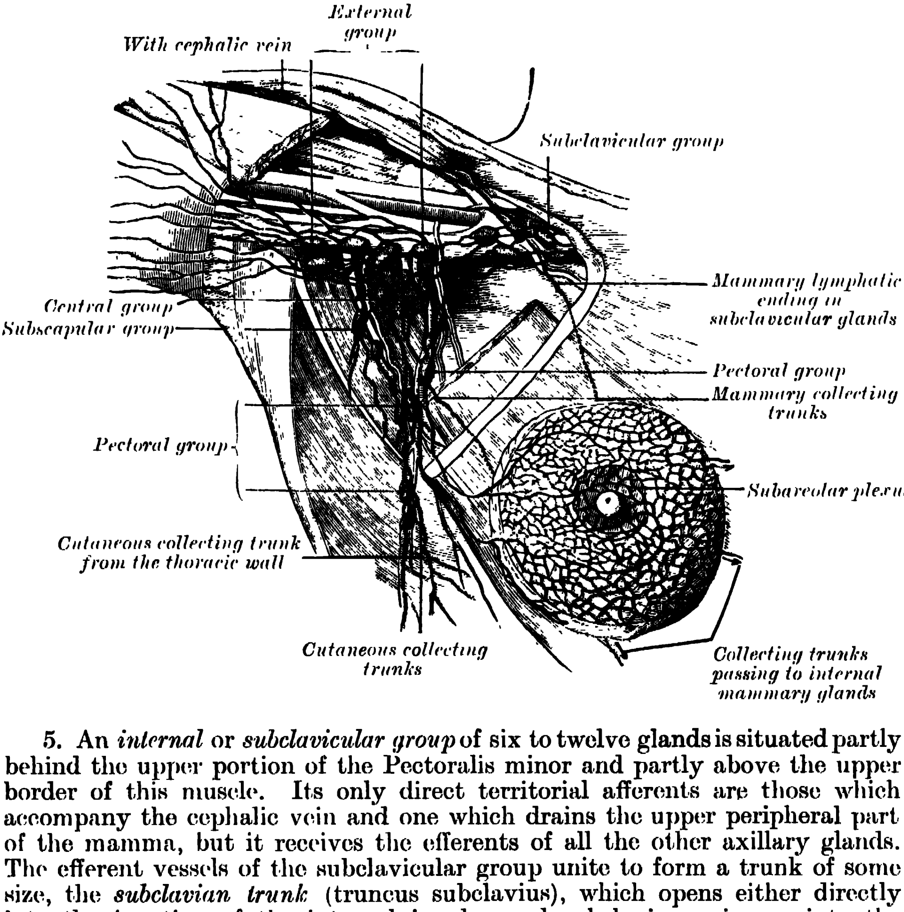
subclavicular axillary glands and partly to the lower deep cervical glands.

2. An *anterior* or *pectoral group* consists of four or five glands along the lower border of the Pectoralis minor, in relation with the long thoracic artery. Their afferents drain the skin and muscles of the anterior and lateral thoracic walls, and the mammary gland; their efferents pass partly to the central, and partly to the subclavicular axillary glands.

3. A *posterior* or *subscapular group* of six or seven glands is placed along the lower margin of the posterior wall of the axilla in the course of the subscapular artery. The afferents of this group drain the skin and muscles of the lower part of the neck and of the posterior thoracic wall; their efferents pass to the central group of axillary glands.

4. A *central* or *intermediate group* of three or four large glands is imbedded in the adipose tissue near the base of the axilla. Its afferents are the efferent vessels of all the preceding groups of axillary glands; its efferents pass to the subclavicular group.

FIG. 655.—Lymphatics of the mamma and the axillary glands (semi-diagrammatic). (Poirier and Charpy.)



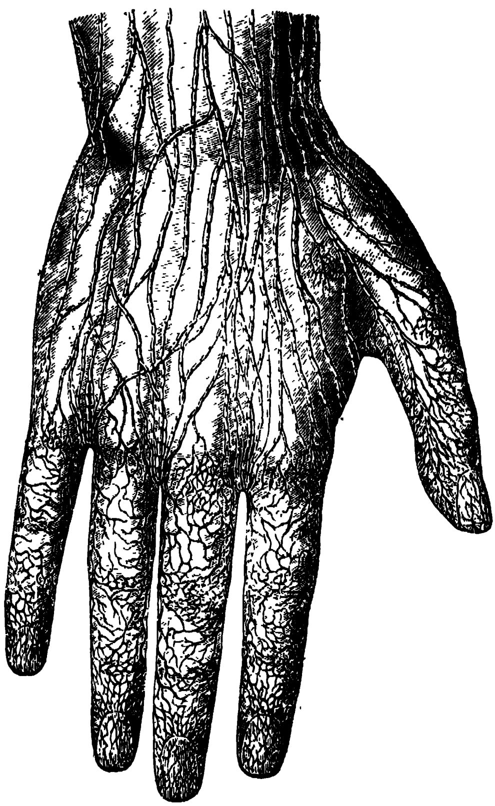
5. An *internal* or *subclavicular group* of six to twelve glands is situated partly behind the upper portion of the Pectoralis minor and partly above the upper border of this muscle. Its only direct territorial afferents are those which accompany the cephalic vein and one which drains the upper peripheral part of the mamma, but it receives the efferents of all the other axillary glands. The efferent vessels of the subclavicular group unite to form a trunk of some size, the *subclavian trunk* (truncus subclavius), which opens either directly into the junction of the internal jugular and subclavian veins or into the jugular lymphatic trunk: on the left side it may terminate in the thoracic duct. A few efferents from the subclavicular glands usually pass to the lower deep cervical glands.

Applied Anatomy.—In malignant disease or infectious processes implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the front and side of the abdomen, or the hand, forearm, and arm, enlargement of the axillary glands is very often found.

The *lymphatic vessels of the upper extremity* are divided into two sets, superficial and deep.

The *superficial lymphatic vessels* (fig. 656) commence in the lymphatic plexus which everywhere pervades the skin; the meshes of the plexus are much finer in the palm and on the flexor aspect of the digits than elsewhere. The digital plexuses are drained by a pair of vessels which run on the lateral aspect of each digit, and incline backwards to reach the dorsum of the hand. From the dense plexus of the palm, vessels pass in different directions, viz. upwards towards the wrist, downwards to join the digital vessels, inwards to join the vessels on the ulnar border of the hand, and outwards to those on the thumb. Several vessels from the central part of the plexus unite to form a trunk, which passes round the metacarpal bone of the index finger to join the vessels on the back of that digit and on the back of the thumb. Running upwards in front of and behind the wrist, the lymphatic vessels are collected into radial, median, and ulnar groups, which accompany respectively the cephalic, median and basilic veins in the forearm. A few of the ulnar lymphatics terminate in the supratrochlear glands, but the majority pass directly to the external group of axillary glands. Some of the radial vessels are collected into a trunk, which ascends with the cephalic vein to the glands between the Pectoralis major and Deltoid; the efferents from this group pass either to the subclavicular axillary glands or to the lower deep cervical glands.

Fig. 656.—Lymphatic vessels of the dorsal surface of the hand. (Sappey.)



The *deep lymphatic vessels* accompany the deep blood-vessels. In the forearm, they consist of four sets, corresponding with the radial, ulnar, and interosseous arteries; they communicate at intervals with the superficial lymphatics, and some of them end in the glands which are occasionally found beside the arteries. In their course upwards, a few end in the glands which lie upon the brachial artery; but most of them pass to the external group of axillary glands.

LYMPHATICS OF THE LOWER EXTREMITY

The **lymphatic glands of the lower extremity** consist of the anterior tibial gland, and the popliteal and inguinal glands.

The **anterior tibial gland** (lymphoglandula tibialis anterior) is small and inconstant. It lies on the interosseous membrane in relation to the upper part of the anterior tibial vessels, and constitutes a sub-station in the course of the anterior tibial lymphatic trunks.

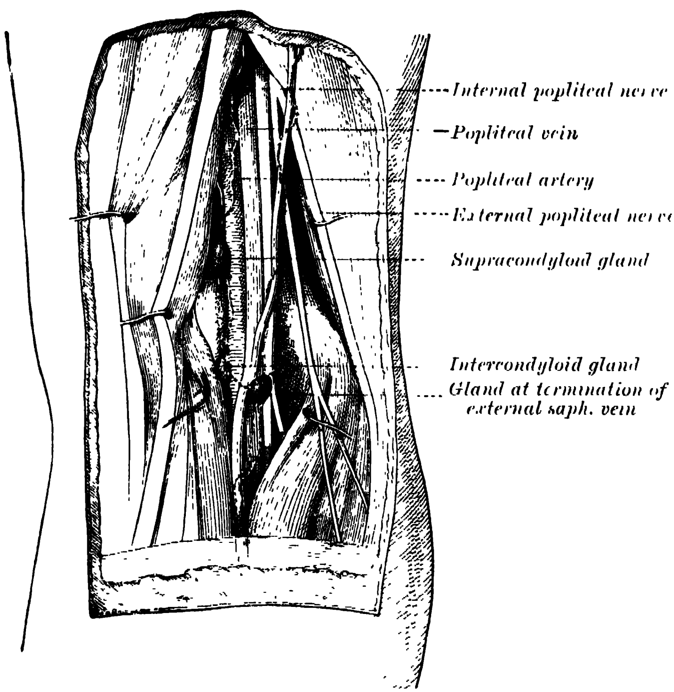
The **popliteal glands** (lymphoglandulæ popliteæ) (fig. 657), small in size and some six or seven in number, are imbedded in the fat contained in the popliteal space. One lies immediately beneath the popliteal fascia, near the

terminal part of the external saphenous vein, and drains the region from which this vein derives its tributaries. Another is placed between the popliteal artery and the posterior ligament of the knee; it receives the lymphatic vessels from the knee-joint together with those which accompany the articular arteries. The others lie at the sides of the popliteal vessels, and receive as afferents the trunks which accompany the anterior and posterior tibial vessels. The efferents of the popliteal glands pass almost entirely alongside the femoral vessels to the deep inguinal glands, but a few may accompany the internal saphenous vein, and end in the glands of the superficial inguinal group.

The **inguinal glands** vary from twelve to twenty in number, and are arranged in two groups, superficial and deep.

The *superficial inguinal glands* (fig. 658) lie in front of Scarpa's triangle, and are situated between the two layers of the superficial fascia. They may be divided into two groups, an upper and a lower, by a horizontal line at the level of the termination of the internal saphenous vein. The glands of the upper group (lymphoglandulæ inguinales) form a chain immediately below

FIG. 657.—Lymphatic glands of popliteal space. (Poirier and Charpy.)



Poupart's ligament. They receive as afferents lymphatic vessels from the integument of the penis, scrotum, perinæum, buttock, and abdominal wall below the level of the umbilicus. The glands of the lower group (lymphoglandulæ subinguinales) are placed on either side of the upper part of the internal saphenous vein, and their afferents consist of the superficial lymphatic vessels of the lower extremity; they also receive some of the vessels which drain the integument of the penis, scrotum, perinæum, and buttock.

The *deep inguinal glands* (lymphoglandulæ subinguinales profundæ) (fig. 659) vary from one to three in number, and are placed under the fascia lata, on the inner side of the femoral vein. When three are present, the lowest is situated just below the junction of the internal saphenous and femoral veins, the middle in the crural canal, and the highest in the outer part of the crural ring. The middle is the most inconstant of the three, but the highest one, the *gland of Cloquet or Rosenmüller*, is also frequently absent. They receive as afferents the deep lymphatic trunks which accompany the femoral vessels, the lymphatics from the glans penis vel clitoridis, and also some of the efferents from the superficial inguinal glands.

Applied Anatomy.—Inflammation and suppuration of the popliteal glands are most commonly due to a sore on the outer side of the heel.

The inguinal glands frequently become enlarged in diseases implicating the parts from which their lymphatics originate. Thus in malignant or syphilitic affections of the prepuce and penis, or labia majora, in cancer scroti, in abscess in the perinæum, or in similar diseases affecting the integument and superficial structures in those parts, or the sub-umbilical part of the abdominal wall, or the gluteal region, the upper chain of glands is almost invariably enlarged, the lower chain being implicated in diseases affecting the lower limb.

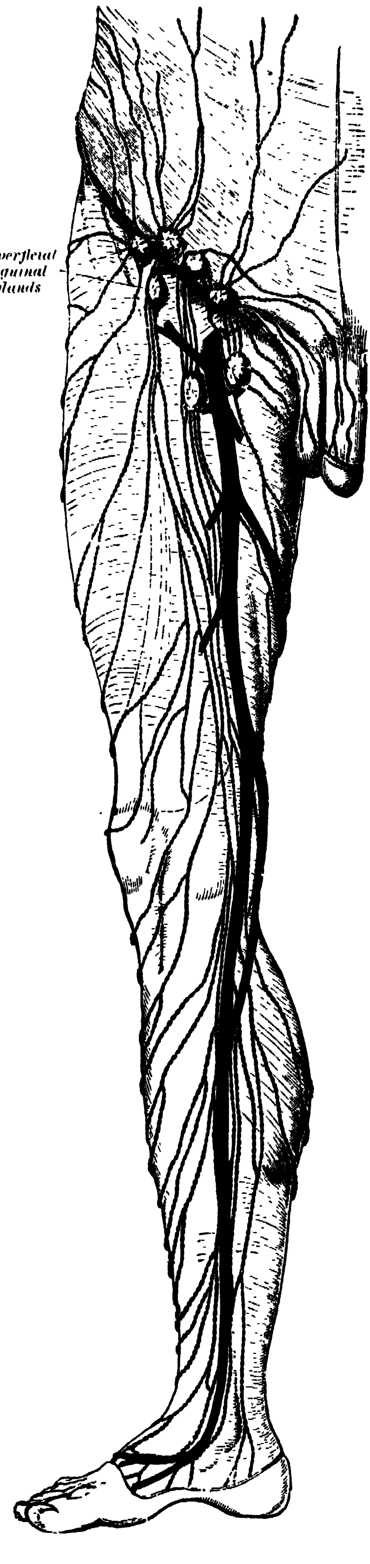
The *lymphatic vessels of the lower extremity* consist of two sets, superficial and deep, and in their distribution correspond closely with the veins.

The *superficial lymphatic vessels* lie in the superficial fascia, and are divisible into two groups: an internal, which follows the course of the internal saphenous vein; and an external, which accompanies the external saphenous. The vessels of the *internal group* are larger and more numerous than those of the external group, and commence on the inner side and dorsum of the foot; they pass both in front of and behind the inner ankle, run up the leg with the internal saphenous vein, pass with it behind the inner condyle of the femur, and accompany it to the groin, where they terminate in the inferior group of superficial inguinal lymphatic glands. The vessels of the *external group* arise from the outer side of the foot; some ascend in front of the leg, and, just below the knee, cross the tibia from without inwards, to join the lymphatics on the inner side of the thigh; others pass behind the outer malleolus, and, accompanying the external saphenous vein, enter the popliteal glands.

The *deep lymphatic vessels* are few in number, and accompany the deep blood-vessels. In the leg, they consist of three sets, the anterior tibial, posterior tibial, and peroneal, which accompany the corresponding blood-vessels, two or three with each artery; they ascend alongside the blood-vessels, and enter the lymphatic glands in the popliteal space.

The deep lymphatic vessels of the gluteal and ischial regions follow the course of the corresponding blood-vessels. Those accompanying the gluteal vessels end in a gland which lies on the intrapelvic portion of the gluteal artery near the upper border of the

Fig. 658.—The superficial lymphatics of the lower extremity.

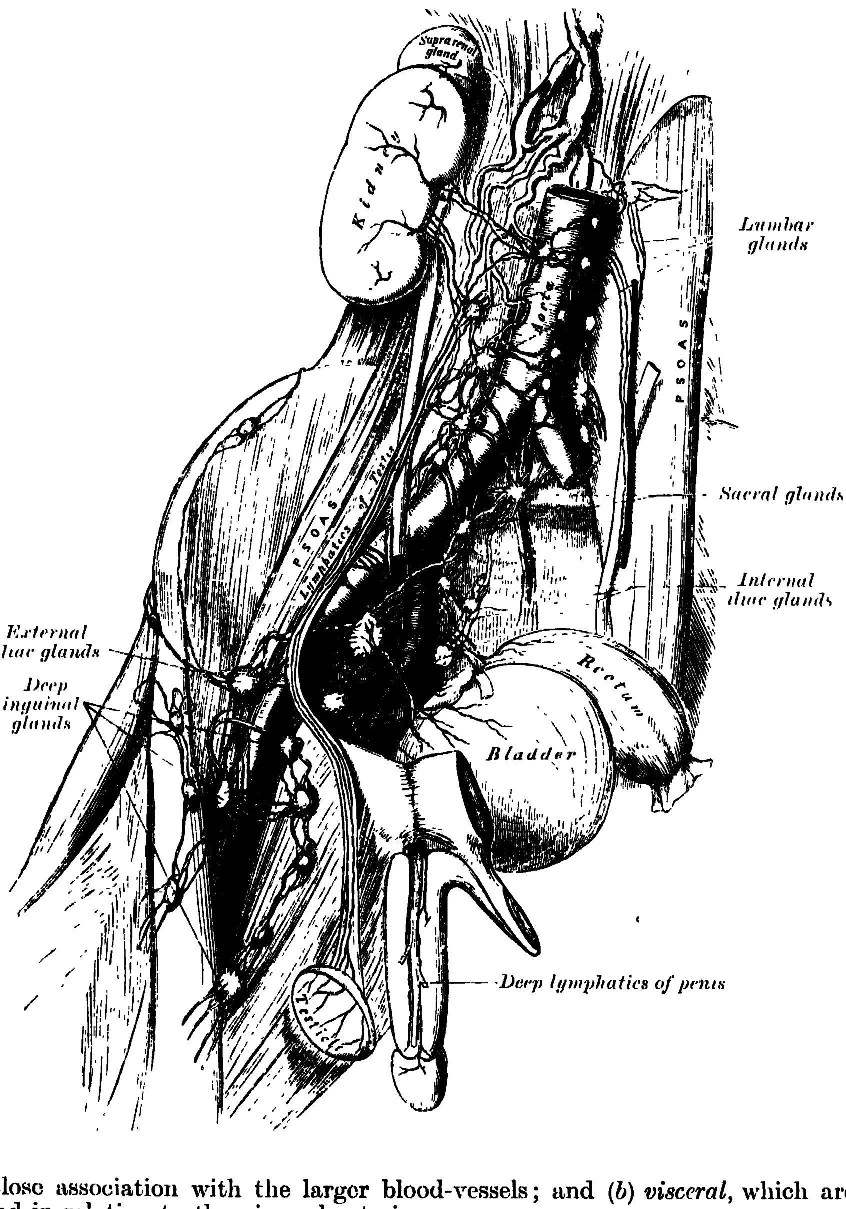


great sacro-sciatic notch. Those following the sciatic vessels traverse one or two small glands which lie below the Pyriformis muscle, and end in the internal iliac glands.

LYMPHATICS OF THE ABDOMEN AND PELVIS

The **lymphatic glands of the abdomen and pelvis** may be divided, from their situations, into (*a*) *parietal*, lying behind the peritoneum and

FIG. 659.—The deep lymphatic vessels and glands of the abdomen and pelvis.



in close association with the larger blood-vessels; and (*b*) *visceral*, which are found in relation to the visceral arteries.

The **parietal glands** (fig. 659) include the following groups:

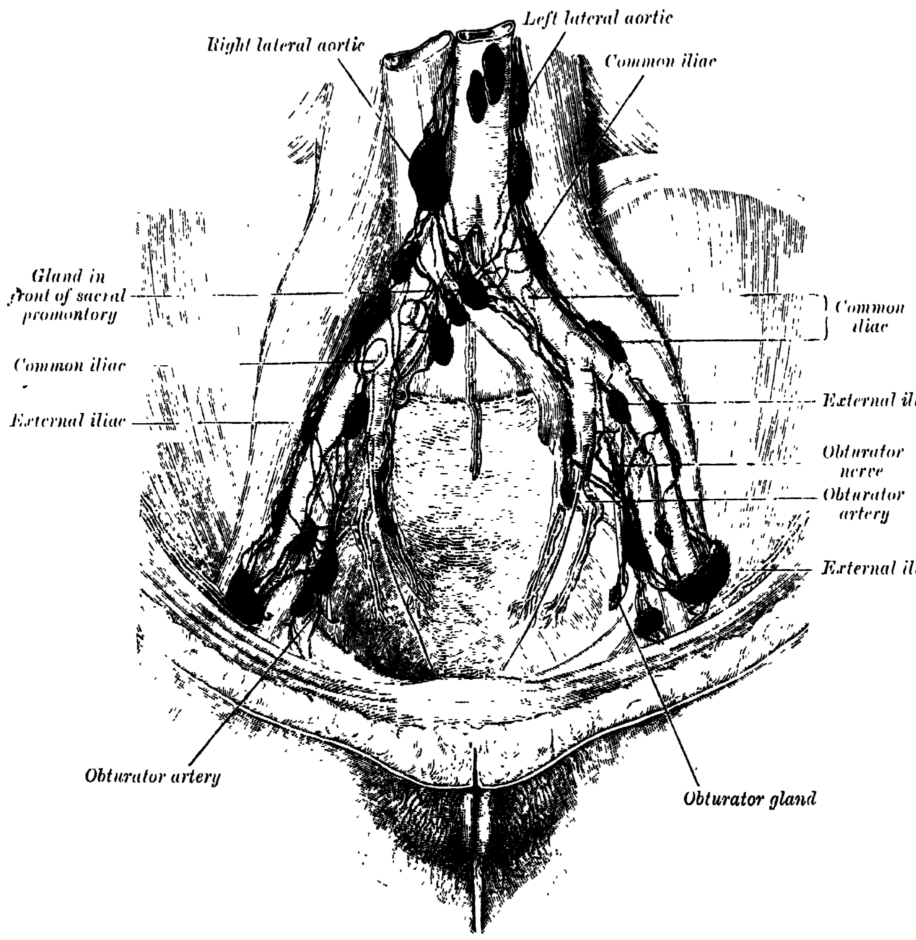
External iliac.
Internal iliac.
Common iliac.

Lumbar { Lateral aortic. Pre-aortic. Retro-aortic. }

The **external iliac glands,** from eight to ten in number, lie along the external iliac vessels. They are arranged in three groups, one on the outer, another on the inner, and a third on the anterior aspect of the vessels; the third group is, however, sometimes absent. Their principal afferents are derived from the superficial and deep inguinal glands, the deep lymphatics of the abdominal wall below the umbilicus and of the adductor region of the thigh, and the lymphatics from the glans penis vel clitoridis, the membranous urethra, the prostate, the base of the bladder, the cervix uteri, and upper part of the vagina.

Small chains of glands are sometimes found along the courses of the deep epigastric and deep circumflex iliac arteries, and an *obturator gland* is occasionally seen on the upper aspect of the obturator foramen.

FIG. 660.—Ilio-pelvic lymphatic glands. (Cunéo and Marcille.)



The **internal iliac** or **hypogastric glands** (lymphoglandulæ hypogastricæ) (figs. 660, 661) surround the internal iliac vessels, and receive the lymphatics corresponding to the distribution of the branches of the internal iliac artery: i.e. they receive lymphatics from all the pelvic viscera, from the deeper parts of the perinæum, including the membranous and penile portions of the urethra, and from the buttock and back of the thigh. The *sacral glands* are an isolated set of this group, placed in the concavity of the sacrum, in relation to the middle and lateral sacral arteries; they receive lymphatics from the rectum and posterior wall of the pelvis.

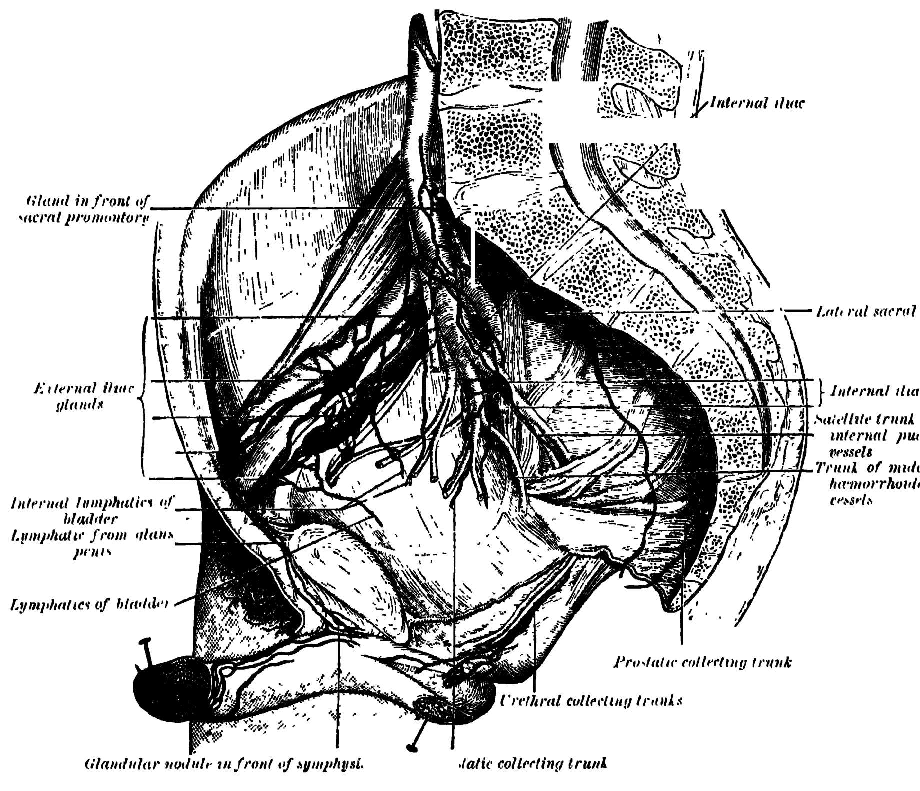
The efferents of the internal iliac group terminate in the common iliac glands.

The **common iliac glands,** four to six in number, are grouped in relation to the lateral and deep aspects of the common iliac artery, one or two being placed below the bifurcation of the aorta, in front of the fifth lumbar vertebra. They drain chiefly the internal and external iliac glands, and their efferents pass to the lateral aortic glands.

The **lumbar glands** (lymphoglandulæ lumbales) are very numerous, and consist of right and left lateral aortic, pre-aortic, and retro-aortic groups.

. The *right lateral aortic glands* are situated partly in front of the inferior vena cava, near the termination of the renal vein, and partly behind it on the origin of the Psoas, and on the right crus of the Diaphragm. The *left lateral aortic glands* form a chain on the left side of the abdominal aorta in front of the origin of the Psoas and left crus of the Diaphragm. The glands on either side receive (*a*) the efferents of the common iliac glands, (*b*) the lymphatics from the testicle in the male and from the ovary, Fallopian tube, and body

FIG. 661.—Ilio-pelvic glands (lateral view). (Cunéo and Marcille.)



of the uterus in the female ; (*c*) the lymphatics from the kidney and suprarenal gland ; and (*d*) the lymphatics draining the lateral abdominal muscles and accompanying the lumbar veins. Most of the efferent vessels of the lateral aortic glands converge to form the *right and left lumbar trunks* (trunci lumbales) which join the receptaculum chyli. but some enter the pre- and retro-aortic glands, and others pierce the crura of the Diaphragm to join the lower end of the thoracic duct. The *pre-aortic glands* lie in front of the aorta, and may be divided into *cœliac*, *superior mesenteric*, and *inferior mesenteric* groups, arranged around the origins of the corresponding arteries. They receive a few vessels from the lateral aortic glands, but their principal afferents are derived from the viscera supplied by the three arteries with which they are associated. Some of their efferents pass to the retro-aortic glands, but the majority unite to form a common trunk, the *truncus intestinalis*, which enters the receptaculum chyli. The *retro-aortic glands* are placed below the receptaculum chyli, on the bodies of the third and fourth lumbar vertebræ. They

receive lymphatic trunks from the lateral and pre-aortic glands, while their efferents terminate in the receptaculum chyli.

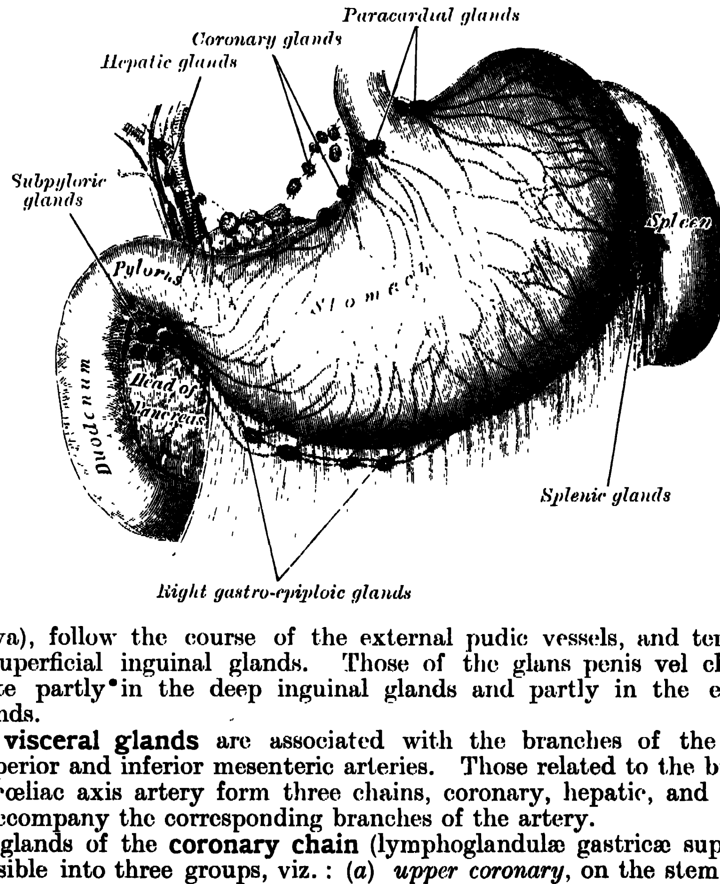
The *lymphatic vessels of the walls of the abdomen and pelvis* may be divided into two sets, superficial and deep.

The *superficial vessels* follow the course of the superficial blood-vessels and converge to the upper group of the superficial inguinal glands. Those derived from the integument of the front of the abdomen below the umbilicus follow the course of the superficial epigastric vessels, and those from the sides of the lumbar part of the abdominal wall pass along the crest of the ilium, with the superficial circumflex iliac vessels. The superficial lymphatic vessels of the gluteal region turn horizontally round the outer side of the buttock, and join the superficial inguinal glands.

The *deep vessels* run alongside the principal blood-vessels. Those of the parietes of the pelvis, which accompany the gluteal, sciatic, and obturator vessels, follow the course of the internal iliac artery, and ultimately join the lateral aortic glands.

Lymphatic vessels of the perinæum and external genitals.—The lymphatic vessels of the perinæum, of the integument of the penis, and of the scrotum

FIG. 662.—Lymphatics of stomach, &c. (Jamieson and Dobson.)



(or vulva), follow the course of the external pudic vessels, and terminate in the superficial inguinal glands. Those of the glans penis vel clitoridis terminate partly in the deep inguinal glands and partly in the external iliac glands.

The **visceral glands** are associated with the branches of the cœliac axis, superior and inferior mesenteric arteries. Those related to the branches of the cœliac axis artery form three chains, coronary, hepatic, and splenic, which accompany the corresponding branches of the artery.

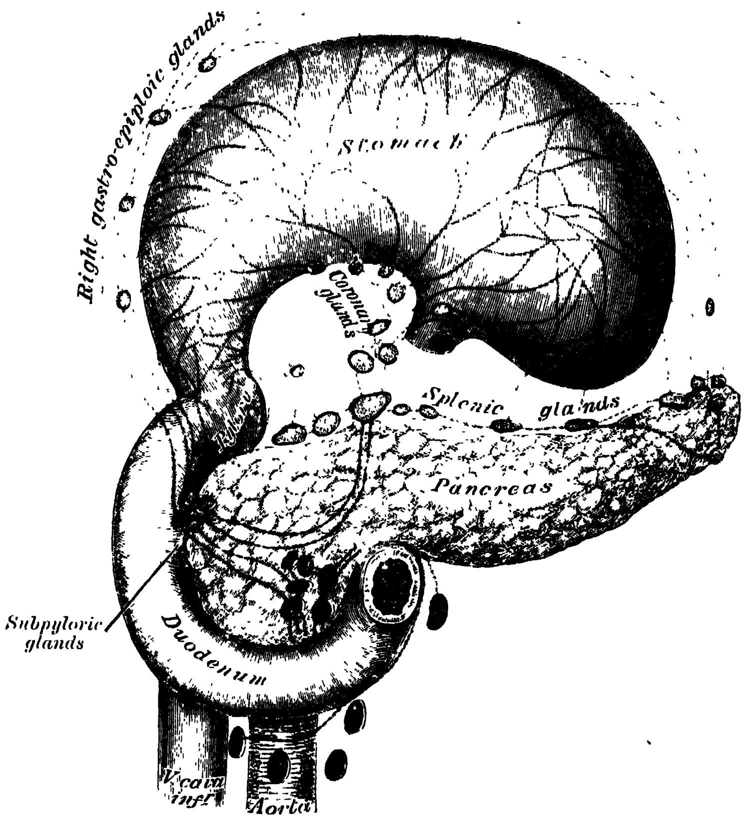
The glands of the **coronary chain** (lymphoglandulæ gastricæ superiores) are divisible into three groups, viz. : (*a*) *upper coronary*, on the stem of the artery ; (*b*) *lower coronary*, accompanying the descending branches of the artery along the cardiac half of the lesser curvature of the stomach, between the two layers of the small omentum ; and (*c*) *paracardial* 'outlying members of the coronary chain, disposed in a manner comparable to a chain of beads around the neck of the stomach' (Jamieson and Dobson).*

The glands of the coronary chain receive their afferents from the stomach ; their efferents pass to the cœliac group of pre-aortic glands.

* *Lancet*, April 20 and 27, 1907.

The glands of the **hepatic chain** (lymphoglandulæ hepaticæ) (fig. 662) consist of the following groups: (*a*) *hepatic*, on the stem of the hepatic artery, and extending upwards along the common bile-duct, between the two layers of the gastro-hepatic omentum, as far as the transverse fissure of the liver; the *cystic gland*, a member of this group, is placed near the neck of the gall-bladder; (*b*) *subpyloric*, four or five in number, in close relation to the bifurcation of the gastro-duodenal artery, in the angle between the first and second parts of the duodenum; an outlying member of this group is sometimes found above the duodenum on the pyloric artery; (*c*) *right gastro-epiploic* (lymphoglandulæ gastricæ inferiores), four to seven in number, between the two layers of the great omentum, along the pyloric half of the greater curvature of the stomach. The glands of the hepatic chain receive afferents from the stomach, duodenum, liver, gall-bladder, and pancreas; their efferents join the cœliac group of pre-aortic glands.

FIG. 663.—Lymphatics of stomach, &c. The stomach has been turned upwards. (Jamieson and Dobson.)



The **splenic glands** (lymphoglandulæ pancreaticolienales) (fig. 663) accompany the splenic artery, and are situated in relation to the posterior surface and upper border of the pancreas; one or two members of this group are found in the gastro-splenic omentum (Jamieson and Dobson, *op. cit.*). Their afferents are derived from the stomach, spleen, and pancreas; their efferents join the cœliac group of pre-aortic glands.

The **superior mesenteric glands** may be divided into three principal groups: mesenteric, ileo-colic, and meso-colic.

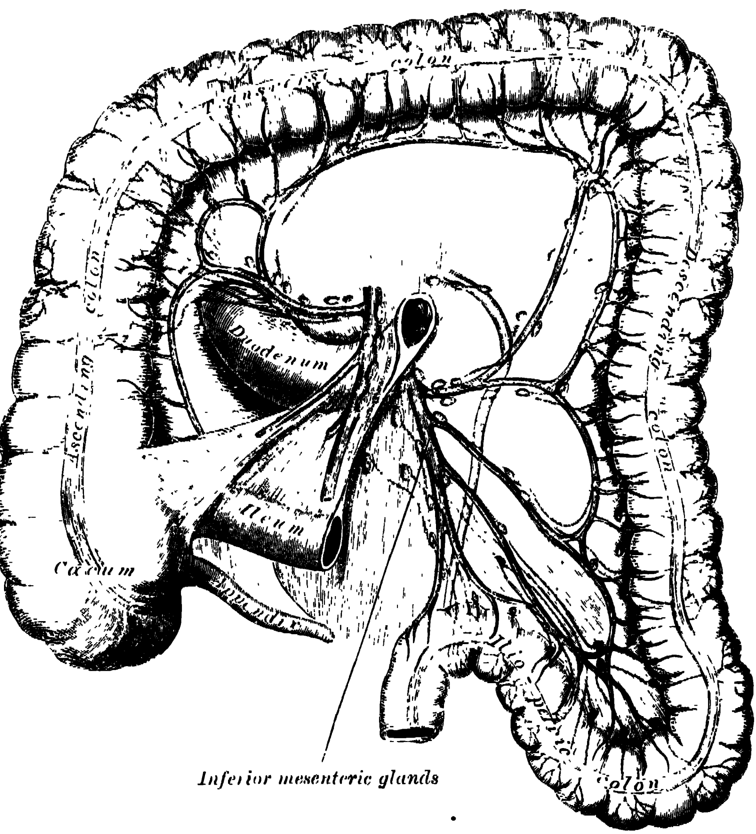
The *mesenteric glands* (lymphoglandulæ mesentericæ) (fig. 664) lie between the layers of the mesentery. They vary from one hundred to one hundred and fifty in number, and may be grouped into three sets, viz.: one lying close to the wall of the small intestine, amongst the terminal twigs of the superior

mesenteric artery ; a second, in relation to the loops and primary branches of the vessel ; and a third along the trunk of the artery.

Applied Anatomy.—Enlargement of the mesenteric lymphatic glands is seen in most diseased conditions of the intestinal tract, and is well marked in enteric fever, tuberculous ulceration or malignant growths of the bowel. The enlarged glands can often be palpated through the wall of the abdomen.

The *ileo-colic glands* (fig. 665), from ten to twenty in number, form a chain around the ileo-colic artery, but show a tendency to subdivision into two groups, one near the duodenum and another on the lower part of the trunk of the artery. Where the vessel divides into its terminal branches the chain is broken up into several groups, viz. : (*a*) *ileal*, in relation to the ileal branch of the artery ; (*b*) *anterior ileo-colic*, usually of three glands, in the ileo-colic fold, near the wall

FIG. 664.—Lymphatics of colon. (Jamieson and Dobson.)



of the cæcum ; (*c*) *posterior ileo-colic*, mostly placed in the angle between the ileum and the colon, but partly lying behind the cæcum at its junction with the ascending colon ; (*d*) *appendicular*, usually a single gland, between the layers of the meso-appendix, near its free edge ; (*e*) *right colic*, along the inner side of the ascending colon.

The *meso-colic glands* are numerous, and lie between the layers of the transverse meso-colon, in close relation to the transverse colon ; they are best developed in the neighbourhood of the hepatic and splenic flexures. One or two small glands are occasionally seen along the trunk of the right colic artery, and others are found in relation to the trunk and branches of the middle colic artery.

The superior mesenteric glands receive afferents from the jejunum, ileum, cæcum, vermiform appendix, and the ascending and transverse parts of the colon ; their efferents pass to the pre-aortic glands.

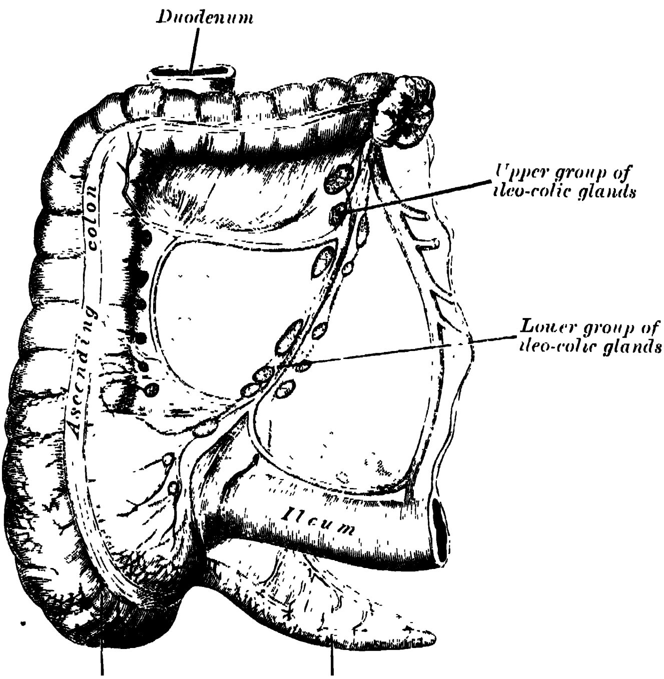
The **inferior mesenteric glands** (fig. 664) consist of: (*a*) small glands on the branches of the left colic and sigmoid arteries; (*b*) a group in the pelvic mesocolon, around the superior hæmorrhoidal artery; and (*c*) a *pararectal* group in contact with the muscular coat of the rectum. They drain the descending, iliac, and pelvic parts of the colon and the upper part of the rectum; their efferents pass to the pre-aortic glands.

The *lymphatic vessels of the abdominal and pelvic viscera* consist of: (1) those of the subdiaphragmatic portion of the alimentary canal and its associated glands, the liver and pancreas; (2) those of the spleen and suprarenal bodies; (3) those of the urinary organs; (4) those of the reproductive organs.

(1) The *lymphatic vessels of the subdiaphragmatic portion of the alimentary canal* are situated partly in the mucous membrane and partly in the seromuscular coats, but as the former system drains into the latter, the two may be considered as one.

The *lymphatic vessels of the stomach* (figs. 662, 663) are continuous at the cardiac end with those of the œsophagus, and at the pyloric end with those of

FIG. 665.—The lymphatics of cæcum and vermiform appendix, from the front. (Jamieson and Dobson.)



the duodenum. They mainly follow the blood-vessels, and may be arranged in four sets. Those of the first set accompany the branches of the coronary artery, receiving tributaries from a large area on either surface of the stomach, and terminate in the glands of the coronary chain. Those of the second set drain the fundus of the stomach on the left of a line drawn vertically from the œsophagus; they accompany, more or less closely, the vasa brevia and left gastro-epiploic arteries, and end in the splenic glands. The vessels of the third set drain the right portion of the greater curvature as far as the pyloric canal. and end in the right gastro-epiploic glands, the efferents of which pass to the subpyloric group. Those of the fourth set drain the pyloric canal and pass to the hepatic and subpyloric glands, and to the glands of the coronary chain.

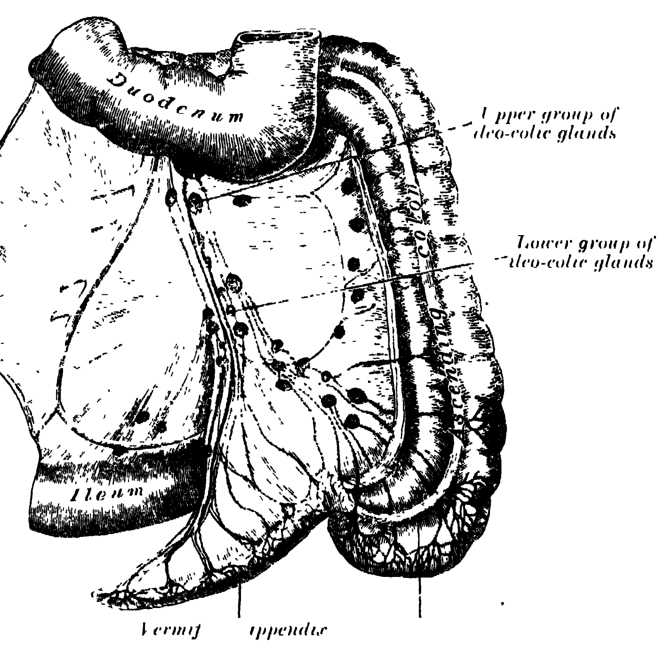
The *lymphatic vessels of the duodenum* consist of an anterior and a posterior set, which open into a series of small *pancreatico-duodenal glands* on the anterior and posterior aspects of the groove between the head of the pancreas and the duodenum. The efferents of these glands run in two directions, upwards to

the hepatic glands and downwards to the pre-aortic glands around the origin of the superior mesenteric artery.

The *lymphatic vessels of the jejunum and ileum* are termed *lacteals*, from the milk-white fluid they contain during intestinal digestion. They run between the layers of the mesentery and enter the mesenteric glands, the efferents of which terminate in the pre-aortic glands.

The *lymphatic vessels of the vermiform appendix and cæcum* (figs. 665, 666) are numerous, since in the wall of the appendix there is a large amount of adenoid tissue. From the body and tail of the appendix eight to fifteen vessels ascend between the layers of the meso-appendix, one or two being interrupted in the appendicular gland. On reaching the stem of the appendicular artery, they unite to form three or four vessels, which end partly in the lower and partly in the upper glands of the ileo-colic chain. The vessels from the root of the appendix and from the cæcum consist of an anterior and a posterior group. The anterior vessels pass in front of the cæcum, and end in the anterior ileo-colic glands, and in the upper and lower glands of the ileo-colic

FIG. 666.—The lymphatics of cæcum and vermiform appendix, from behind. (Jamieson and Dobson.)



chain; the posterior vessels ascend over the back of the cæcum and terminate in the posterior ileo-colic glands and in the lower glands of the ileo-colic chain.

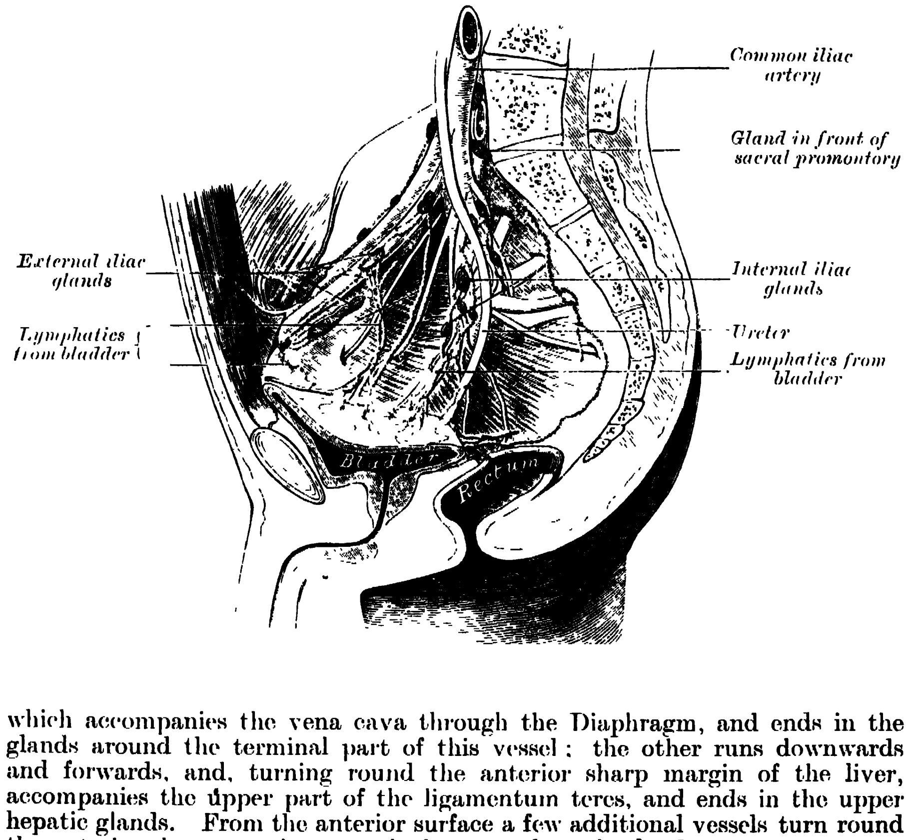
Lymphatic vessels of the colon.—The lymphatics of the ascending and transverse parts of the colon finally terminate in the mesenteric glands, after traversing the right colic and meso-colic glands. Those of the descending and ilio-pelvic parts of the colon are interrupted by the small glands on the branches of the left colic and sigmoid arteries, and ultimately end in the pre-aortic glands around the origin of the inferior mesenteric artery (fig. 664).

Lymphatic vessels of the anus, anal canal, and rectum.—The lymphatics from the *anus* pass forwards and end with those of the integument of the perinæum and scrotum in the superficial inguinal glands; those from the *anal canal* accompany the middle and inferior hæmorrhoidal arteries, and end in the internal iliac glands; while the vessels from the *rectum* traverse the pararectal glands and pass to those in the pelvic meso-colon; the efferents of the latter terminate in the pre-aortic glands around the origin of the inferior mesenteric artery.

The *lymphatic vessels of the liver* are divisible into two sets, superficial and deep. The former arise in the subperitoneal areolar tissue over the entire surface of the organ, and may be grouped into: (*a*) those on the convex surface, (*b*) those on the inferior surface.

(*a*) On the *convex surface*.—The vessels from the back part of this surface reach their terminal glands by three different routes: the vessels of the middle set, five or six in number, pass through the caval opening in the Diaphragm and end in one or two glands which are situated around the terminal part of the inferior vena cava; a few vessels from the left side pass backwards towards the œsophageal opening, and terminate in the paracardial glands of the coronary chain; the vessels from the right side, one or two in number, run on the abdominal surface of the Diaphragm, and, after crossing its right crus, terminate in the pre-aortic glands which surround the origin of the cœliac axis. From the portions of the right and left lobes adjacent to the falciform ligament, the lymphatic vessels converge to form two trunks, one of

FIG. 667.—Lymphatics of the bladder. (Cunéo and Marcille.)



which accompanies the vena cava through the Diaphragm, and ends in the glands around the terminal part of this vessel: the other runs downwards and forwards, and, turning round the anterior sharp margin of the liver, accompanies the upper part of the ligamentum teres, and ends in the upper hepatic glands. From the anterior surface a few additional vessels turn round the anterior sharp margin to reach the upper hepatic glands.

(*b*) On the *inferior surface*.—The vessels from this surface mostly converge to the transverse fissure, and accompany the deep lymphatics emerging from this fissure to the hepatic glands; one or two from the posterior parts of the right and Spigelian lobes accompany the inferior vena cava through the Diaphragm, and end in the glands round the terminal part of this vein.

The deep lymphatics converge to ascending and descending trunks. The ascending trunks accompany the hepatic veins and pass through the Diaphragm to end in the glands round the terminal part of the inferior vena cava. The descending trunks emerge from the transverse fissure, and end in the hepatic glands.

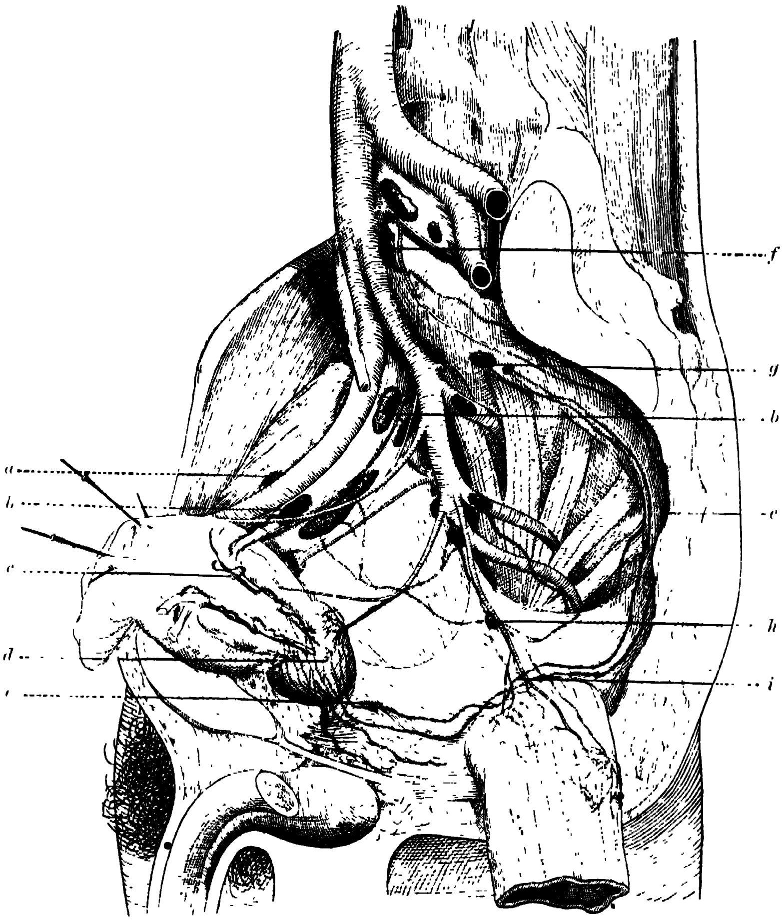
The *lymphatic vessels of the gall-bladder* pass to the hepatic glands in the transverse fissure of the liver; those of the *common bile-duct* to the hepatic glands alongside the duct and into the upper pancreatico-duodenal glands.

The *lymphatic vessels of the pancreas* follow the course of its blood-vessels. Most of them enter the glands of the splenic chain, but some end in the pancreatico-duodenal glands, and others in the pre-aortic glands, near the origin of the superior mesenteric artery.

(2) The *lymphatic vessels of the spleen and suprarenal glands.*

The *lymphatic vessels of the spleen*, both superficial and deep, pass to the splenic glands in the lieno-renal ligament.

FIG. 668.—Lymphatics of the prostate. (Cunéo and Marcille.)



a, b. External iliac glands. *c.* Vessel draining into external iliac glands. *d.* Retro-prostatic lymph-nodes. *e.* Vessels draining into gland on sacral promontory. *f.* Gland in front of sacral promontory. *g.* Lateral sacral glands. *h.* Middle hæmorrhoidal gland. *i.* Middle hæmorrhoidal lymphatic vessels.

The *lymphatic vessels of the suprarenal glands* usually accompany the suprarenal veins, and end in the lateral aortic glands; occasionally some of them pierce the crura of the Diaphragm and terminate in the glands of the posterior mediastinum.

(3) The *lymphatic vessels of the urinary organs.*

The *lymphatic vessels of the kidney* form three plexuses: one in the substance of the kidney, a second beneath its fibrous capsule, and a third in the perinephric fat; the second and third communicate freely with each other.

The vessels from the plexus in the kidney substance converge to form four or five trunks which issue at the hilus. Here they are joined by vessels

from the plexus under the capsule, and, following the course of the renal vein, end in the lateral aortic glands. The perinephric plexus is drained directly into the upper lateral aortic glands.

The *lymphatic vessels of the ureter* run in different directions. Those from its upper portion end partly in the efferent vessels of the kidney and partly in the lateral aortic glands; those from the portion immediately above the pelvic brim are drained into the common iliac glands; while the vessels from the intrapelvic portion of the tube join the efferents from the bladder, or terminate in the internal iliac glands.

The *lymphatic vessels of the bladder* (fig. 667) originate in two plexuses, an intra- and an extra-muscular, it being generally admitted that the mucous

Fig. 669.—Lymphatics of the uterus. (Cunéo and Marcille.)

membrane is devoid of lymphatics.* The efferent vessels are arranged in two groups, one from the anterior and another from the posterior surface of the bladder. The vessels from the *anterior* surface pass to the external iliac glands, but in their course minute glands are situated. These minute glands are arranged in two groups, an *anterior vesical* group, in front of the bladder, and a *lateral vesical*, in relation to the hypogastric artery. The vessels from the *posterior* surface pass to the internal, external, and common iliac glands; those draining the upper part of this surface traverse the lateral vesical glands.

The *lymphatic vessels of the prostate* (fig. 668) terminate chiefly in the

* Some authorities maintain that a plexus of lymphatic vessels does exist in the mucous membrane of the bladder (consult *Médecine opératoire des Voies urinaires*, par J. Albarran, Paris, 1909).

internal iliac and sacral glands, but one trunk from the posterior surface ends in the external iliac glands, and another from the anterior surface joins the vessels which drain the membranous part of the urethra.

Lymphatic vessels of the urethra.—The lymphatics of the *penile* portion of the urethra accompany those of the glans penis, and terminate with them in the deep inguinal and external iliac glands. Those of the *membranous and prostatic* portions, and those of the whole urethra in the female, pass to the internal iliac glands.

(4) *The lymphatic vessels of the reproductive organs.*

The *lymphatic vessels of the testes* consist of two sets, superficial and deep, the former commencing on the surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form several large trunks, which ascend with the spermatic cord, and, accompanying the spermatic vessels into the abdomen, terminate in the lateral aortic glands.

The *lymphatic vessels of the vas deferens* pass to the external iliac glands; those of the *vesiculæ seminales* partly to the internal and partly to the external iliac glands.

The *lymphatic vessels of the ovary* are similar to those of the testis, and ascend with the ovarian artery to the lateral aortic glands.

The *lymphatic vessels of the Fallopian tube* pass partly with those of the ovary and partly with those of the uterus.

The *lymphatic vessels of the uterus* (fig. 669) consist of two sets, superficial and deep, the former being placed beneath the peritoneum, the latter in the substance of the organ. The lymphatics of the cervix uteri run in three directions: transversely to the external iliac glands, postero-laterally to the internal iliac glands, and posteriorly to the common iliac glands. The majority of the vessels of the body and fundus of the uterus pass outwards in the broad ligaments, and are continued up with the ovarian vessels to the lateral aortic glands; a few, however, run to the external iliac glands, and one or two to the superficial inguinal glands. In the unimpregnated uterus, the lymphatic vessels are very small, but during gestation are greatly enlarged.

The *lymphatic vessels of the vagina* are carried in three directions: those of the upper part to the external iliac glands, those of the middle part to the internal iliac glands, and those of the lower part to the common iliac glands. On the course of those from the middle and lower parts small glands are situated. Some lymphatics from the lower part of the vagina join those of the vulva and pass to the superficial inguinal glands. The lymphatics of the vagina anastomose with those of the cervix uteri, vulva, and rectum, but not with those of the bladder.

LYMPHATICS OF THE THORAX

The **lymphatic glands of the thorax** may be divided into parietal and visceral—the former being situated in the thoracic wall, the latter in relation to the viscera.

The **parietal lymphatic glands** include the internal mammary, intercostal and diaphragmatic glands.

1. The **internal mammary glands** are placed at the anterior extremities of the intercostal spaces, by the side of the internal mammary artery. They derive afferents from the mammary gland, from the deeper structures of the anterior abdominal wall above the level of the umbilicus, from the upper surface of the liver through a small group of glands which lie behind the ensiform cartilage, and from the deeper parts of the anterior portion of the thoracic wall. Their efferents usually unite to form a single trunk on either side; this may open directly into the junction of the internal jugular and subclavian veins, or that of the right side may join the right subclavian trunk, and that of the left the thoracic duct.

2. The **intercostal glands** (lymphoglandulæ intercostales) occupy the posterior parts of the intercostal spaces, in relation to the intercostal vessels. They receive the deep lymphatics from the postero-lateral aspect of the chest; some of these vessels are interrupted by small lateral intercostal glands. The efferents of the glands in the lower four or five spaces unite to form a trunk,

which descends and opens either into the receptaculum chyli or into the commencement of the thoracic duct. The efferents of the glands in the upper spaces of the left side terminate in the thoracic duct; those of the corresponding right spaces, in the right lymphatic duct.

3. The **diaphragmatic glands** lie on the thoracic aspect of the Diaphragm, and consist of three sets, anterior, middle, and posterior.

The *anterior* set consists of (*a*) two or three small glands behind the base of the ensiform cartilage, which receive afferents from the convex surface of the liver, and (*b*) one or two glands on either side near the junction of the seventh rib with its cartilage, which receive lymphatic vessels from the front part of the Diaphragm. The efferent vessels of the anterior set pass to the internal mammary glands.

The *middle* set consists of two or three glands on either side close to where the phrenic nerves enter the Diaphragm. On the right side some of the glands of this group lie within the fibrous sac of the pericardium, on the front of the termination of the inferior vena cava. The afferents of this set are derived from the middle part of the Diaphragm, those on the right side also receiving afferents from the convex surface of the liver. Their efferents pass to the posterior mediastinal glands.

The *posterior* set consists of a few glands situated on the back of the diaphragmatic crura, and connected on the one hand with the lumbar glands and on the other with the posterior mediastinal glands.

The *superficial lymphatic vessels of the thoracic wall* ramify beneath the skin and converge to the axillary glands. Those over the Trapezius and Latissimus dorsi run forwards and unite to form about ten or twelve trunks which end in the subscapular group. Those over the pectoral region, including the vessels from the skin covering the peripheral part of the mamma, run backwards, and those over the Serratus magnus upwards, to the pectoral group. Others near the lateral margin of the sternum pass inwards between the rib cartilages and end in the internal mammary glands, while the vessels of opposite sides anastomose across the front of the sternum. A few vessels from the upper part of the pectoral region pass upwards over the clavicle to the supraclavicular group of cervical glands.

The *lymphatic vessels of the mammary gland* originate in a plexus in the interlobular spaces and on the walls of the galactophorous ducts. Those from the central part of the gland pass to an intricate plexus situated beneath the areola, a plexus which receives also the lymphatics from the skin over the central part of the gland and those from the areola and nipple. Its efferents are collected into two trunks which pass to the pectoral group of axillary glands. The vessels which drain the inner part of the mammary gland pierce the thoracic wall and end in the internal mammary glands, while a vessel has occasionally been seen emerging from the upper part of the gland and, piercing the Pectoralis major, to terminate in the subclavicular glands (fig. 655).

The *deep lymphatic vessels of the thoracic wall* consist of:

1. The lymphatics of the muscles which lie on the ribs: most of these terminate in the axillary glands, but some from the Pectoralis major pass to the internal mammary glands.

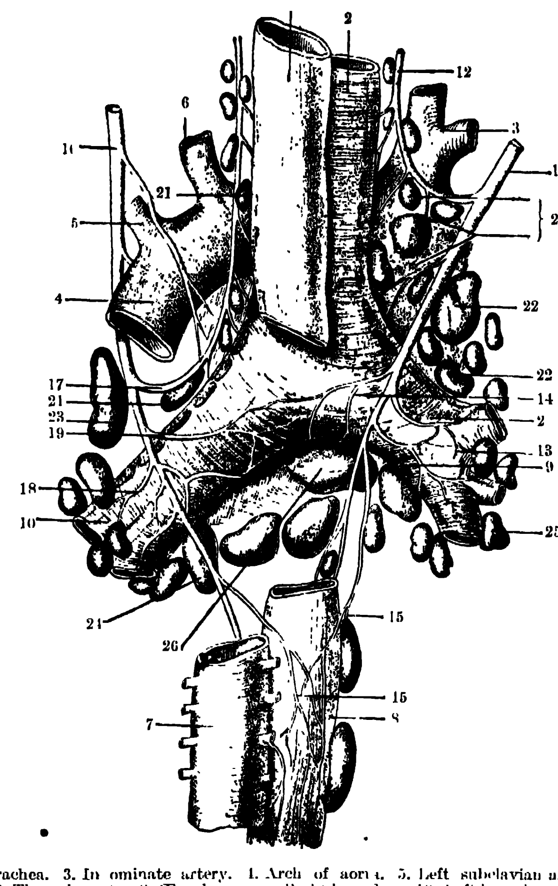
2. The intercostal lymphatic vessels which drain the Intercostal muscles and parietal pleura. Those draining the External intercostal muscles run backwards and, after receiving the vessels which accompany the posterior branches of the intercostal arteries, terminate in the posterior intercostal glands. Those of the Internal intercostal muscles and parietal pleura consist of a single trunk in each space. These trunks run forwards in the subpleural tissue and the upper six open separately into the internal mammary glands or into the vessels which unite them: those of the lower spaces unite to form a single trunk which terminates in the lowest of the internal mammary glands.

3. The *lymphatic vessels of the Diaphragm*, which form two plexuses, one on its thoracic and another on its abdominal surface. These plexuses anastomose freely with each other, and are best marked on the parts covered respectively by the pleuræ and peritoneum. That on the thoracic surface communicates with the lymphatics of the costal and mediastinal parts of the pleura, and its efferents consist of three groups: (*a*) anterior, passing to the glands which lie near the junction of the seventh rib with its cartilage; (*b*) middle, to

the glands on the œsophagus and to those around the termination of the inferior vena cava; and (c) posterior, to the glands which surround the aorta at the point where this vessel leaves the thoracic cavity.

The plexus on the abdominal surface is composed of fine vessels, and anastomoses with the lymphatics of the liver and, at the periphery of the Diaphragm, with those of the subperitoneal tissue. The efferents from the right half of this plexus terminate partly in a group of glands on the trunk of the corresponding inferior phrenic artery, while others end in the right lateral aortic glands. Those from the left half of the plexus pass to the pre- and lateral aortic glands and to the glands on the terminal portion of the œsophagus.

FIG. 670.—Disposition and relations of the tracheo-bronchial lymphatic glands. (From a figure designed by M. Hallé, and printed in 'La Clinique Médicale,' tome iv.)



1. Œsophagus. 2. Trachea. 3. Innominate artery. 4. Arch of aorta. 5. Left subclavian artery. 6. Left common carotid artery. 7. Thoracic aorta. 8. Œsophagus. 9. Right bronchus. 10. Left bronchus. 11. Right vagus nerve. 12. Right recurrent laryngeal nerve. 13, 14. Right posterior pulmonary plexus. 15. Œsophageal plexus. 16. Left vagus nerve. 17. Left recurrent laryngeal nerve. 18, 19. Left posterior pulmonary plexus. 20. Glands accompanying right recurrent laryngeal nerve. 21. Glands accompanying left recurrent laryngeal nerve. 22. Right tracheo-bronchial glands. 23. Left tracheo-bronchial glands. 24, 25. Interbronchial glands. 26. Glands below bifurcation of trachea.

The **visceral lymphatic glands** consist of three groups, viz. anterior mediastinal, posterior mediastinal, and tracheo-bronchial.

The **anterior mediastinal glands** (lymphoglandulæ mediastinales anteriores) are placed in the anterior part of the superior mediastinum, in front of the arch of the aorta and in relation to the innominate veins and the large arterial trunks which arise from the aortic arch. They receive afferents from the thymus gland and pericardium, and from the internal mammary glands; their efferents unite with those of the tracheo-bronchial glands, to form the right and left broncho-mediastinal trunks.

The **posterior mediastinal glands** (lymphoglandulæ mediastinales posteriores) lie behind the pericardium in relation to the œsophagus and descending thoracic aorta. Their afferents are derived from the œsophagus, the posterior part of the pericardium, the Diaphragm, and the convex surface of the liver. Their efferents mostly terminate in the thoracic duct, but some join the tracheo-bronchial glands.

The **tracheo-bronchial glands** (fig. 670) form three main groups in relation to the bifurcation of the trachea—one on either side of the trachea above the bronchi, and one in the angle between the bronchi (lymphoglandulæ tracheales); other glands, termed *interbronchial* (lymphoglandulæ bronchiales), are found at the points of division of the larger bronchi. The afferents of the tracheo-bronchial glands drain the lungs and bronchi, the thoracic part of the trachea and the heart; some of the efferents of the posterior mediastinal glands also terminate in this group. Their efferent vessels ascend upon the trachea and unite with efferents of the internal mammary and anterior mediastinal glands to form the *right* and *left broncho-mediastinal trunks.* The right broncho-mediastinal trunk may join the right lymphatic duct, and the left the thoracic duct, but more frequently they open independently of these ducts into the junction of the internal jugular and subclavian veins of their own side.

Applied Anatomy.—In all town-dwellers there are continually being swept into these glands from the bronchi and alveoli large quantities of the dust and black carbonaceous pigment that are so freely inhaled in cities. At first the glands are moderately enlarged, firm, inky black and gritty on section; later they enlarge still further, often becoming fibrous from the irritation set up by the minute foreign bodies with which they are crammed, and may break down into a soft slimy mass or may calcify. In tuberculosis of the lungs these glands are practically always infected; they enlarge, being filled with tuberculous deposits that may soften, or become fibrous, or calcify. Not infrequently an enlarged tuberculous gland perforates into a bronchus, discharging its contents into the tube. When this happens there is great danger of acute pulmonary tuberculosis, the infecting gland-substance being rapidly spread throughout the bronchial system by the coughing its presence in the air-passages excites.

The *lymphatic vessels of the thoracic viscera* consist of those of the heart and pericardium, lungs and pleura, thymus, and œsophagus.

The *lymphatic vessels of the heart* consist of two plexuses, (*a*) deep, immediately under the endocardium, and (*b*) superficial, subjacent to the visceral pericardium. The deep plexus opens into the superficial, the efferents of which form right and left collecting trunks. The *left* trunks, two or three in number, ascend in the anterior interventricular furrow, receiving, in their course, afferents from both ventricles. On reaching the auriculo-ventricular furrow they are joined by a large trunk from the back of the heart, and then unite to form a single vessel which ascends between the pulmonary artery and the left auricle and ends in one of the tracheo-bronchial glands. The *right* trunk receives its afferents from the right auricle and from the right border and posterior surface of the right ventricle. It ascends in the posterior auriculo-ventricular groove and then runs forward in the auriculo-ventricular groove, and passes up behind the pulmonary artery, to end in one of the tracheo-bronchial glands.

The *lymphatic vessels of the lungs* originate in two plexuses, a superficial and a deep. The superficial plexus is placed beneath the visceral pleura. The deep accompanies the branches of the pulmonary vessels and the ramifications of the bronchi. In the case of the larger bronchi the deep plexus consists of two networks, one, submucous, beneath the mucous membrane, and another, peribronchial, outside the walls of the bronchi. In the smaller bronchi there is but a single plexus, which extends as far as the bronchioles, but fails to reach the alveoli, in the walls of which there are no traces of lymphatic vessels. The superficial efferents turn round the borders of the lungs and the margins of their fissures, and converge to end in some glands situated at the hilus; the deep efferents are conducted to the hilus along the pulmonary vessels and bronchi, and end in the tracheo-bronchial glands. Little or no anastomosis occurs between the superficial and deep lymphatics of the lungs, except in the region of the hilus.

The *lymphatic vessels of the pleura* consist of two sets—one in the visceral and another in the parietal part of the membrane. Those of the visceral pleura drain into the superficial efferents of the lung, while the lymphatics of the parietal pleura have three modes of ending, viz. : (*a*) those of the costal portion join the lymphatics of the Internal intercostal muscles and so reach the internal mammary glands ; (*b*) those of the diaphragmatic part are drained by the efferents of the Diaphragm ; while (*c*) those of the mediastinal portion terminate in the posterior mediastinal glands.

The *lymphatic vessels of the thymus gland* terminate in the superior mediastinal, tracheo-bronchial, and internal mammary glands.

The *lymphatic vessels of the œsophagus* form a plexus round that tube, and the collecting vessels from the plexus drain into the posterior mediastinal glands.

NEUROLOGY

THE **Nervous System** is the most complicated and the most highly organised of the various systems which make up the human body. It may be divided into two parts, central and peripheral.

The **central nervous system** consists of (*a*) an upper expanded portion, the *brain*, contained within the cranium, and (*b*) a lower, elongated, nearly cylindrical portion, the *spinal cord*, lodged in the vertebral canal; the two portions are continuous with one another at the level of the upper border of the atlas.

The **peripheral nervous system** consists of a series of nerves by which the central nervous system is connected with the various tissues of the body. For descriptive purposes these nerves may be arranged in two groups, *cerebro-spinal* and *sympathetic*, the arrangement, however, being an arbitrary one, since the two groups are intimately connected and closely intermingled. The cerebro-spinal nerves are forty-three in number on either side—twelve *cranial*, attached to the brain, and thirty-one *spinal*, to the spinal cord. They are associated with the functions of the special and general senses and with the voluntary movements of the body. The sympathetic nerves transmit the impulses which regulate the movements of the viscera, determine the calibre of the blood-vessels and control the phenomena of secretion. In relation with them are two rows of *central ganglia*, situated one on either side of the middle line in front of the vertebral column; these ganglia are intimately connected with the spinal cord and nerves, and are also joined to each other by vertical strands of nerve-fibres so as to constitute a pair of knotted cords, the *gangliated cords of the sympathetic*, which reach from the base of the skull to the coccyx. The sympathetic nerves issuing from the ganglia form three great prevertebral plexuses which supply the thoracic, abdominal, and pelvic viscera; in relation to the walls of these viscera intricate nerve plexuses and numerous *peripheral ganglia* are found.

The nervous system is built up of nervous and non-nervous tissues—the former consisting of nerve-cells and nerve-fibres; the latter, of neuroglia and blood-vessels, together with certain enveloping membranes.

The minute structure of the nervous elements, and of the neuroglia, has been described in the chapter on Histology (pp. 42 to 55); and an outline of the development of the nervous system furnished in that on Embryology (pp. 115 to 128). It may be stated here, however, that, in its earliest condition, the nervous system consists of cells only, and that the nerve-fibres arise as outgrowths from the cells.

The embryonic nerve-cells, or *neuroblasts*, as they are termed, are at first spherical, but soon become pear-shaped, and the attenuated end of each cell grows out to form a slender process, the *axon*, while from the body of the cell other processes, termed *dendrites*, arise. The axon may run for a shorter or longer distance as the axis cylinder of a nerve-fibre, or may break up at once into numerous delicate filaments, as in the Golgi cell, type II. Dendrites and axons are alike conductors of nervous impulses: the former, however, convey them to, the latter from, the nerve-cells; in other words, the dendrites form the paths of reception, the axons those of transmission.

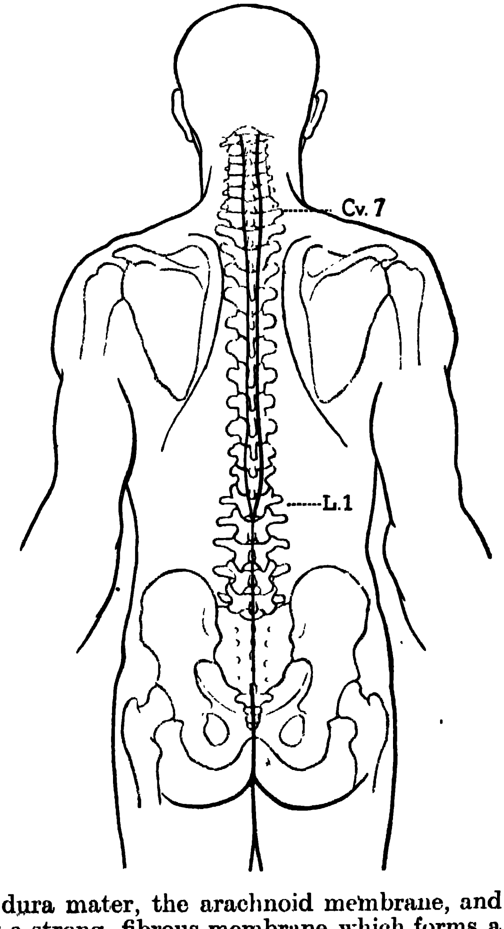
The nerve-cell and its processes collectively constitute what is termed a *neuron*, and Waldeyer formulated the theory that the nervous system is built up of numerous neurons, 'anatomically and genetically independent of

one another.' According to this theory (*neuron theory*) the processes of one neuron only come into contact, and are never in direct continuity, with those of other neurons; while impulses are transmitted from one nerve-cell to another through these points of contact. This theory is based on the following facts, viz.: (1) embryonic nerve-cells or neuroblasts are entirely distinct from one another; (2) when nervous tissues are stained by the Golgi method no continuity is seen even between neighbouring neurons; and (3) when degenerative changes occur in nervous tissue, either as the result of disease or experiment, they never spread from one neuron to another, but are limited to the individual neurons, or groups of neurons, primarily affected. It must, however, be added that within the past few years the validity of the neuron theory has been called in question by certain eminent histologists, who maintain that by the employment of more delicate histological methods, minute fibrils can be followed from one nerve-cell into another.

The Spinal Cord

The **spinal cord** (medulla spinalis) forms the elongated, nearly cylindrical, part of the central nervous system which occupies the upper two-thirds of the vertebral canal. Its average length in the male is about eighteen inches (45 cm.), in the female about seventeen inches (42–43 cm.), while its weight amounts to a little over an ounce. It extends from the level of the upper border of the atlas to that of the lower border of the first, or upper border of the second, lumbar vertebra (fig. 671). Above, it is directly continuous with the hind-brain; below, it ends in a conical extremity, the *conus medullaris*, from the apex of which a delicate filament, the *filum terminale*, is continued downwards as far as the first segment of the coccyx (fig. 672).

Fig. 671.—Showing the relation of the spinal cord to the dorsal surface of the trunk. The vertebræ, &c., are outlined in red.



The position of the spinal cord varies with the movements of the vertebral column, its lower extremity being drawn slightly upwards when the column is flexed. It also varies at different periods of life: up to the third month of fœtal life the cord is as long as the canal in which it lies, but from this stage onwards the vertebral column elongates more rapidly than the cord, so that by the end of the fifth month the cord terminates at the base of the sacrum, and at birth about the level of the third lumbar vertebra.

The spinal cord does not nearly fill the canal in which it lies, being ensheathed by three protective membranes, separated from each other by two concentric spaces. The three membranes are named from without inwards the dura mater, the arachnoid membrane, and the pia mater. The *dura mater* is a strong, fibrous membrane which forms a wide, tubular sheath around the cord; this sheath extends below the termination of the cord and ends in a pointed *cul de sac* at the level of the lower

border of the second sacral vertebra. The dura mater is separated from the wall of the vertebral canal by a quantity of loose areolar tissue and a plexus of veins, while between it and the subjacent arachnoid membrane is a capillary interval, the *subdural space*, which contains a small quantity of fluid, probably of the nature of lymph. The *arachnoid membrane* is a thin, transparent sheath, separated from the pia mater by a comparatively wide interval, the *subarachnoid space*, which is filled with cerebro-spinal fluid. The *pia mater* closely invests the cord and sends delicate septa into its substance; a

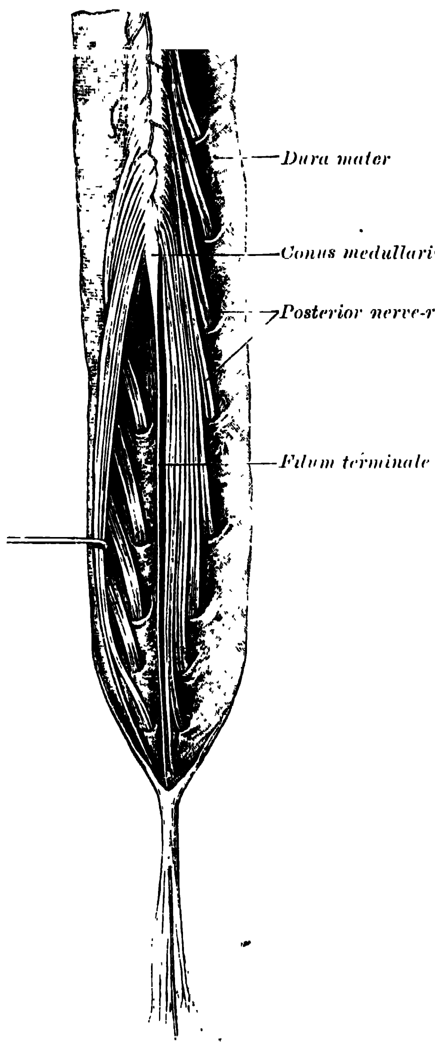
Fig. 673.—Cauda equina and filum terminale seen from behind. The dura mater has been opened and spread out, and the arachnoid membrane has been removed.



narrow band, the *ligamentum denticulatum*, extends along each of its lateral surfaces, and is attached by a series of pointed processes to the inner surface of the dura mater.

Thirty-one pairs of spinal nerves spring from the lateral aspects of the spinal cord, each nerve having an anterior or ventral, and a posterior or dorsal root, the latter being distinguished by the presence of an oval swelling, the *spinal ganglion*, which contains numerous nerve-cells. Each root consists of several bundles of nerve-fibres, and as these bundles pass inwards to reach the lateral aspect of the cord they diverge from each other so that the attachment of the nerve-root extends for some distance along the side of the cord. The pairs

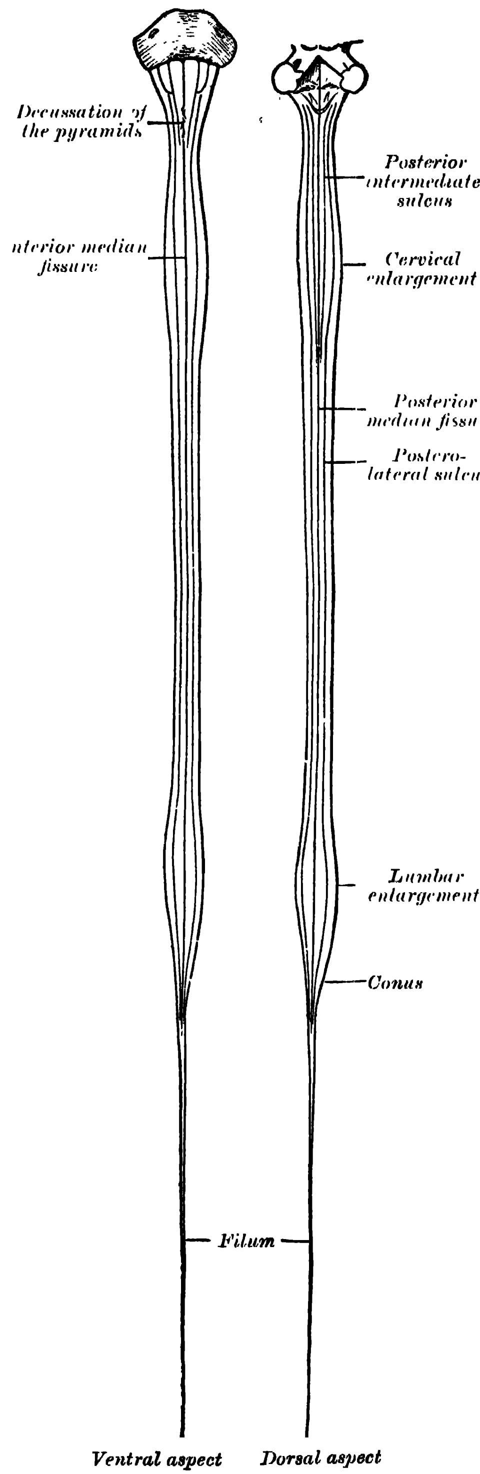
of spinal nerves are grouped as follows: cervical 8, thoracic 12, lumbar 5, sacral 5, coccygeal 1, and, for convenience of description, the cord is divided into cervical, thoracic, lumbar and sacral regions, corresponding with these different groups of nerves.

Although no trace of transverse segmentation is visible on the surface of the spinal cord it is convenient to regard it as being built up of a series of superimposed *spinal segments* or *neuromeres*, each of which has a length equivalent to the extent of attachment of a pair of spinal nerves. Since the distance between the successive pairs of nerves varies in different parts of the cord, it follows that the spinal segments are of varying lengths; thus, in the cervical region they average about thirteen millimetres, in the mid-thoracic region about twenty-six millimetres, while in the lumbar and sacral regions they diminish rapidly from about fifteen millimetres at the level of the first pair of lumbar nerves to about four millimetres opposite the attachments of the lower sacral nerves.

As a consequence of the unequal rate of growth of the spinal cord and vertebral column, the nerve-roots, which at first passed transversely outwards to reach their respective intervertebral foramina, become more and more oblique in direction from above downwards, so that the lower part of the tubular sheath of dura mater is occupied by the lumbar and sacral nerves, which descend almost vertically to reach their points of exit. From the appearance these nerves present at their attachment to the cord and from their great length they are collectively termed the *cauda equina* (fig. 673).

The *filum terminale* is a delicate filament, about eight inches in length, prolonged downwards from the apex of the conus medullaris. It consists of two parts, an upper and a lower. The upper part, or *filum terminale internum*, measures about six inches in length and reaches as far as the lower border of the second sacral vertebra. It is contained within the tubular sheath of dura

FIG. 674.—Diagrams of the spinal cord.



mater, and is surrounded by the nerves forming the cauda equina, from which it can be readily recognised by its bluish-white colour. The lower part, or *filum terminale externum*, is closely invested by, and is adherent to, the dura mater; it extends downwards from the apex of the sheath and is attached to the back of the first segment of the coccyx. The filum terminale consists mainly of fibrous tissue, continuous above with that of the pia mater. Adhering to its outer surface, however, are a few strands of nerve-fibres which probably represent rudimentary second and third coccygeal nerves; further, the central canal of the spinal cord extends downwards into it for two or three inches.

Enlargements.—The spinal cord is not quite cylindrical, being slightly flattened from before backwards; nor is it of uniform circumference throughout, but presents two swellings or enlargements, an upper or cervical, and a lower or lumbar (fig. 674).

The *cervical enlargement* (intumescentia cervicalis) is the more pronounced of the two, and corresponds with the attachments of the large nerves which supply the upper limbs. It extends from about the third cervical to the second thoracic vertebra, its maximum circumference (about thirty-eight millimetres) being on a level with the origin of the sixth pair of cervical nerves.

The *lumbar enlargement* (intumescentia lumbalis) gives attachment to the nerves which supply the lower limbs. It commences about the level of the ninth thoracic vertebra, and reaches its maximum circumference, of about thirty-three millimetres, opposite the last thoracic vertebra, below which it tapers rapidly into the conus medullaris.

Fissures and sulci (fig. 675).—A pair of median fissures, anterior and posterior, dip into the substance of the cord, and incompletely divide it into two symmetrical parts, which are joined across the middle line by a commissural band of nervous matter.

The *anterior median fissure* (fissura mediana anterior) is wider and shallower than the posterior: it has an average depth of three millimetres, but this is increased in the lower part of the cord. It contains a double fold of pia mater, and its floor is formed by a transverse band of white substance, the *white commissure* (commissura anterior alba), which is perforated by blood-vessels on their way to or from the central part of the cord.

The *posterior median fissure* (sulcus medianus posterior) is not an actual fissure like the anterior; it does not contain a fold of pia mater, but merely a septum of neuroglia which is intimately united with the neuroglia in the adjacent parts of the cord, and for this reason it would be more correct to name it the *posterior median septum*. It reaches rather more than halfway into the substance of the cord, and its depth varies from four to six millimetres, but diminishes in the lower part of the cord.

On either side of the posterior median fissure, and at a short distance from it, the posterior nerve-roots are attached to the cord along a vertical furrow named the *sulcus lateralis posterior*. The portion of the cord which lies between this sulcus and the posterior median fissure is named the *posterior column* (funiculus posterior). In the cervical and upper thoracic regions this column presents a longitudinal furrow, the *sulcus intermedius posterior*: this marks the position of a septum which extends into the posterior column and subdivides it into two fasciculi—an inner, named the *fasciculus gracilis* or *tract of Goll*; and an outer, the *fasciculus cuneatus* or *tract of Burdach* (see fig. 681). The portion of the cord which lies in front of the postero-lateral sulcus is termed the *antero-lateral column*. The anterior nerve-roots, unlike the posterior, are not attached in linear series, and their position of exit is not marked by a sulcus. They arise by separate bundles which spring from the anterior horn of grey matter and, passing forward through the white matter, emerge over an area of some slight width. The outermost of these bundles is generally taken as a dividing line which separates the antero-lateral column into two parts, viz. an *anterior column* (funiculus anterior), between the anterior median fissure and the outermost of the anterior nerve-roots; and a *lateral column* (funiculus lateralis), between the exit of these roots and the postero-lateral sulcus. In the upper part of the cervical region of the cord a series of nerve-roots passes outwards through the lateral column; these unite to form the spinal portion of the spinal accessory nerve, which runs upwards and enters the cranial cavity through the foramen magnum.

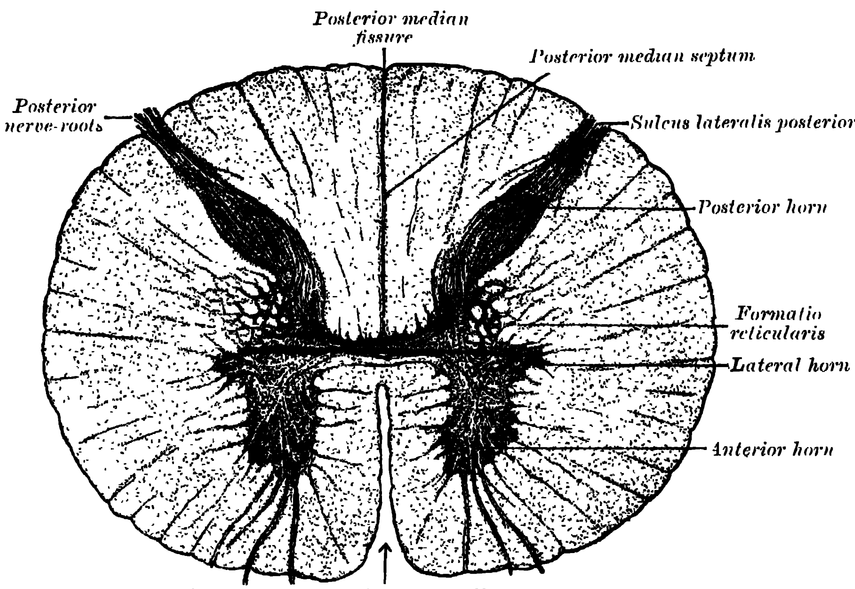
Internal Structure of the Spinal Cord

On examining a transverse section of the cord (fig. 675) it is seen to consist of grey and white nervous matter, the former being enclosed within the latter.

Grey matter.—The grey matter (substantia grisea) consists of two symmetrical portions, one in each half of the cord: these are joined across the middle line by a transverse band, termed the *grey commissure* (commissura grisea), through which runs a minute canal, the *canalis centralis* of the cord, just visible to the naked eye. Each half of the grey substance is shaped in the form of a comma or crescent, the concavity of which is directed outwards; and these, together with the intervening grey commissure, present on transverse section the appearance of the letter H. An imaginary line drawn transversely through the central canal serves to divide each crescent into an anterior or ventral, and a posterior or dorsal cornu.

The **anterior cornu** (columna anterior) is directed forwards, and is broad and of a rounded or quadrangular shape. Its posterior part is termed the *base*, and its anterior part the *head*, but these are not differentiated from each other by any well-defined constriction. It is separated from the surface of

Fig. 675.—Transverse section of the spinal cord in the mid-thoracic region.

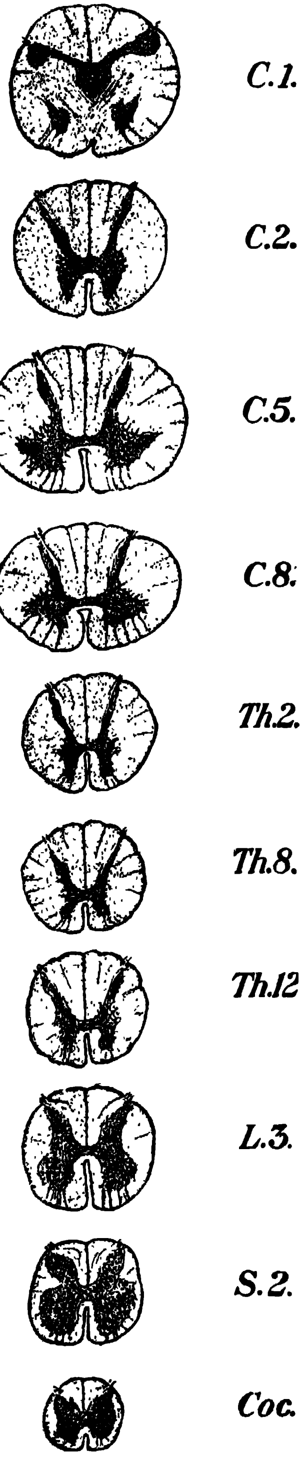


the cord by a layer of white matter which is traversed by the bundles of the anterior nerve-roots. In the thoracic region, the postero-external part of the anterior cornu projects outwards as a triangular field, which is named the **lateral cornu** (columna lateralis).

The **posterior cornu** (columna posterior) is long and slender, and is directed backwards and outwards: it reaches almost as far as the postero-lateral sulcus, from which it is separated by only a thin layer of white substance, the *tract of Lissauer*. It consists of a *base*, which is directly continuous with the corresponding part of the anterior horn; a *neck* (cervix columnæ post.) or slightly constricted portion, which is succeeded by an oval or fusiform area, termed the *head* (caput columnæ post.), of which the summit (apex columnæ post.) approaches the postero-lateral sulcus. The head is capped by a V-shaped or crescentic mass of translucent, gelatinous neuroglia, termed the *substantia gelatinosa of Rolando*, which contains not only neuroglia-cells, but numerous small nerve-cells. Between the anterior and posterior cornua the grey matter extends as a series of processes for some distance into the lateral column, to form a network called the *formatio reticularis*.

The quantity of grey matter, as well as the form which it assumes on transverse section, varies markedly at different levels. It is small, not only in amount but relatively to the surrounding white substance, in the thoracic region. Its amount is greatly increased in the cervical and lumbar enlargements: in the latter, and especially in the conus medullaris, its proportion to the white matter is greatest (fig. 676). In the cervical region its posterior cornu remains comparatively narrow, while its anterior is broad and expanded; in the thoracic region, both cornua are attenuated, and the lateral horn is evident; in the lumbar enlargement, both cornua are expanded; while in the conus medullaris the grey matter assumes the form of two oval masses, one in each half of the cord, connected together by a broad grey commissure.

FIG. 676.—Transverse sections of the spinal cord at different levels.



The **central canal** runs in the grey commissure throughout the entire length of the cord. The part of the grey commissure in front of the canal is named the *anterior grey commissure*; that behind it, the *posterior grey commissure*. The former is thin, and is in contact anteriorly with the white commissure: it contains a couple of longitudinal veins, one on either side of the middle line. The posterior grey commissure reaches from the central canal to the posterior median septum, and is thinnest in the thoracic region, and thickest in the conus medullaris. The central canal is continued upwards through the lower part of the medulla oblongata, and opens into the fourth ventricle of the brain; below, it reaches for a short distance into the filum terminale. In the lower part of the conus medullaris it exhibits a fusiform dilatation, the *ventriculus terminalis*; * this has a vertical measurement of from eight to ten millimetres, is triangular on cross section with its base directed forwards, and tends to undergo obliteration after the age of forty.

Throughout the cervical and thoracic regions the central canal is situated in the anterior third of the cord: in the lumbar enlargement it is near the middle, and in the conus medullaris it approaches the posterior surface. It is filled with cerebro-spinal fluid, and is lined by ciliated, columnar epithelium, outside which is an encircling band of gelatinous substance, the *substantia gelatinosa centralis*. This gelatinous substance consists mainly of neuroglia, but contains a few nerve cells and fibres; it is traversed by processes from the deep ends of the columnar ciliated cells which line the central canal (fig. 677).

Structure of the grey matter.—The grey matter consists of neuroglia, together with numerous nerve-cells and nerve-fibres. Throughout the greater part of the grey matter the neuroglia presents the appearance of a sponge-

* *Archiv für micro. Anat.* 1875.

like network, but around the central canal and on the heads of the posterior cornua it consists of the gelatinous substance already referred to (fig. 677). The nerve-cells in the grey matter are multipolar, and vary greatly in size and shape (fig. 678). They consist of: (1) motor cells of large size, which are situated in the anterior horn, and are especially numerous in the cervical and lumbar enlargements; the axons of nearly all these cells pass out to form the anterior nerve-roots, but before leaving the white substance they frequently give off collaterals, which re-enter and ramify in the grey matter.* (2) Cells of small or medium size, whose axons do not emerge from the cord but pass into the white matter; here some assume an

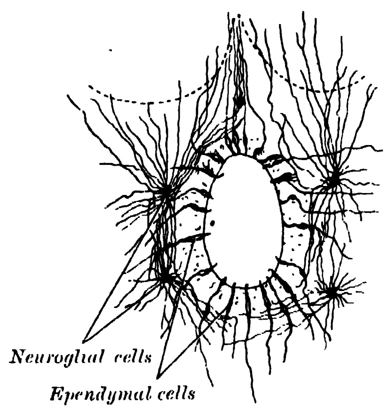

Fig. 678.—Cells of spinal cord. (Poirier.)

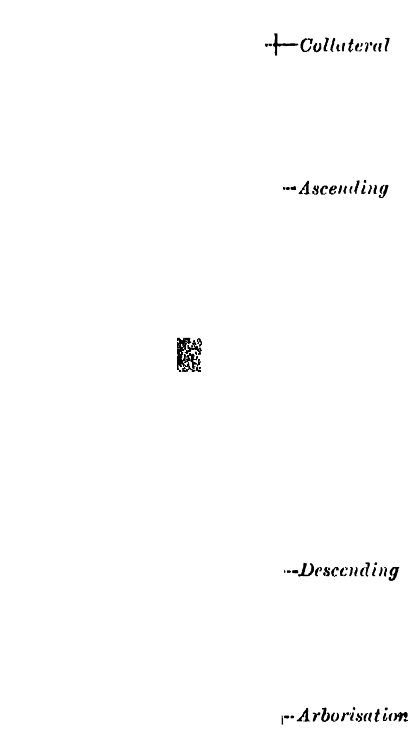

Diagram showing in longitudinal section the intersegmental neurons of the spinal cord. The grey and white parts correspond respectively to the grey and white substance of the spinal cord.

ascending, and others a descending course, but most of them divide in a T-shaped manner into descending and ascending processes. They give off collaterals which enter and ramify in the grey matter, and the terminations of the axons behave in a similar manner. The lengths of these axons vary greatly: some are short and pass only between adjoining segments of the cord, while others are longer and connect more distant segments. These cells and their processes constitute a series of *association* or *intersegmental neurons*, which link together the different parts of the cord. The axons of most of these cells are confined to that side of the cord in which the nerve-cells are situated, but some cross to the opposite side through the anterior commissure, and are termed *crossed commissural fibres*. Some of these latter end directly in the grey matter, while others enter the white matter, in which they ascend or descend for varying distances, before finally terminating in the grey matter. (3) Cells of the type II. of Golgi, limited to the posterior horn, and found in the substantia gelatinosa of Rolando, whose axons are short and entirely confined to the grey matter, in which they break up into numerous fine filaments.

* Lenhossek and Cajal found that in the chick embryo the axons of a few of these nerve-cells passed backwards through the posterior cornu, and emerged as the *motor fibres* of the *posterior nerve-roots*. These fibres are said to control the peristaltic movements of the intestine. Their presence, in man, has not yet been determined.

Most of the nerve-cells are arranged in longitudinal columns, which appear as groups on transverse section (figs. 679, 680).

Nerve-cells in the anterior horn.—The nerve-cells in the anterior horn are arranged in columns of varying length, and appear in groups in successive transverse sections of the cord. The longest of these cell-columns occupies the mesial part of the anterior horn, and is named the *antero-mesial*: it is absent only in the fifth lumbar, the first sacral and the upper part of the second sacral segments (Bruce).* Behind it is a *dorso-mesial* column of small cells, which extends from the second thoracic to the first lumbar segment, and is also present in the first, sixth, and seventh cervical segments.

In the cervical and lumbar enlargements, where the anterior horn is expanded in a lateral direction, the following additional columns are present: viz.: (*a*) *antero-lateral*, in the fourth, fifth, and sixth cervical and the second

thoracic segments, and in the lower four lumbar and upper two sacral segments; (*b*) *postero-lateral*, in the lower five cervical, lower four lumbar, and upper three sacral segments; (*c*) *post-postero-lateral*, in the last cervical, first thoracic, and upper three sacral segments; and (*d*) a *central*, in the lower four lumbar and upper two sacral segments. Solitary cells are scattered throughout the base of the anterior horn, the axons of some of which form crossed commissural fibres, while others constitute the motor fibres of the posterior nerve-root. (See footnote, page 801).

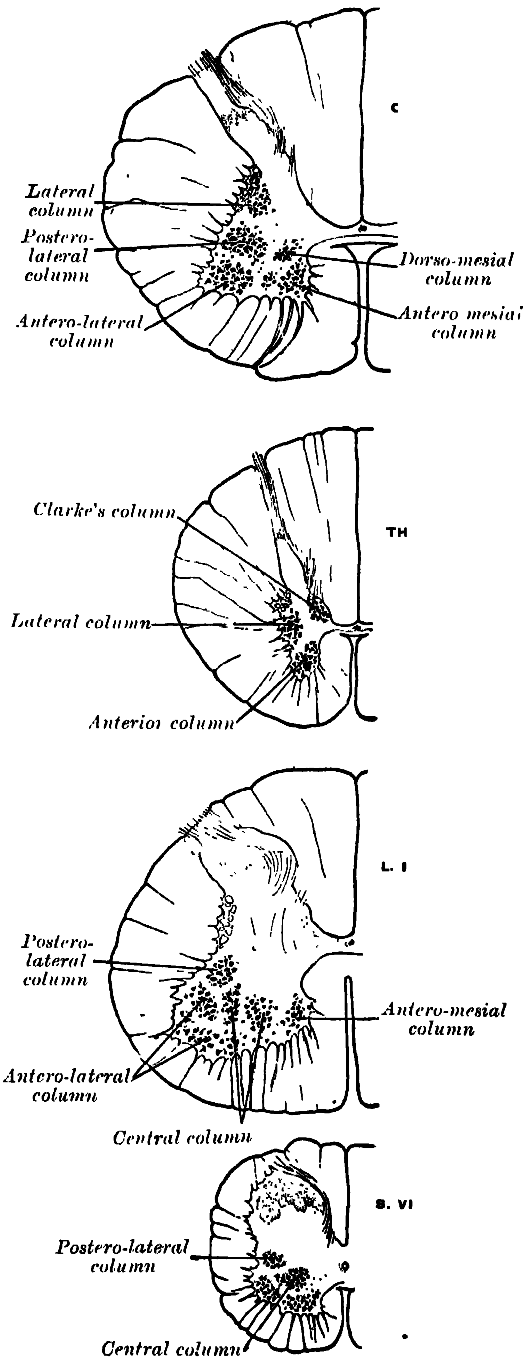
Nerve-cells in the lateral horn.—These form a column which is best marked where the lateral horn of grey matter is differentiated, viz. in the thoracic region; but it can be traced throughout the entire length of the cord,† in the form of groups of small cells which are situated in the anterior part of the

* *Topographical Atlas of the Spinal Cord.* 1901.

† According to Bruce and Pirie (*B.M.J.* Nov. 17, 1906) this column extends from the middle of the eighth cervical segment to the lower part of the second lumbar or the upper part of the third lumbar segment.

formatio reticularis. The cells of this column are fusiform or star-shaped, and of a medium size: the axons of some of them pass into the anterior nerve-roots, by which they are carried to the sympathetic nerves; while those of others pass into the anterior and lateral columns, where they become longitudinal.

Fig. 680.—Transverse sections of the spinal cord at different levels to show the arrangement of the principal cell-columns.



Nerve-cells in the posterior horn.—1. The *column of Clarke* (*posterior vesicular column*).—This occupies the inner part of the base of the posterior horn, and appears on transverse section as a well-defined oval area. It commences below at the level of the second or third lumbar nerve, and reaches its maximum size opposite the twelfth thoracic nerve. Above the level of the ninth thoracic nerve its size diminishes, and the column terminates opposite the last cervical or first thoracic nerve. It is represented, however, in the other regions of the cord by scattered cells, which become aggregated to form a *cervical nucleus* opposite the third cervical nerve, and a *sacral nucleus* in the middle and lower part of the sacral region. Its cells are of medium size, and of an oval or pyriform shape; their axons pass into the peripheral part of the lateral column of the same side, and there ascend, under the name of the *direct* or *ascending cerebellar tract*. 2. *Nerve-cells in the substantia gelatinosa of Rolando.*—These are arranged in three zones: a posterior or marginal zone, composed of large triangular or fusiform cells; an intermediate zone of small fusiform cells; and an anterior zone of star-shaped cells. The axons of these cells pass into the lateral and posterior columns, and there assume a vertical course. In the anterior zone some Golgi cells are found whose short axons ramify in the grey matter. 3. *Solitary cells* of varying form and size are scattered throughout the posterior horn. Some of these are grouped to form

the *posterior basal column* in the base of the posterior horn and on the outer side of Clarke's column. The posterior basal column is well marked in the gorilla (Waldeyer), but is ill-defined in man. The axons of these cells pass partly to the posterior and lateral columns of the same side, and partly through the anterior commissure to the lateral column of the opposite side. Before leaving the grey matter, a considerable number run longitudinally for a varying distance in the head of the posterior horn, forming what is termed the *longitudinal fasciculus* of the posterior horn.

A few star-shaped or fusiform nerve-cells of varying size are found in the substantia gelatinosa centralis. Their axons pass into the lateral column of the same, or of the opposite side.

The nerve-fibres in the grey matter form a dense interlacement of minute fibrils among the nerve-cells. This interlacement is formed partly of axons which pass from the cells in the grey matter to enter the white columns or nerve-roots; partly of the axons of Golgi's cells which ramify only in the grey substance; and partly of collaterals from the nerve-fibres in the white columns, which, as already stated, enter the grey matter and ramify within it.

White matter.—The white matter of the spinal cord consists of medullated nerve-fibres imbedded in a sponge-like network of neuroglia, and is arranged in three columns: anterior, lateral, and posterior. The anterior column lies between the anterior median fissure and the outermost of the anterior nerve-roots; the lateral column between the outermost of the anterior nerve-roots and the postero-lateral sulcus; and the posterior column between the postero-lateral sulcus and the posterior median fissure (fig. 681). The fibres vary greatly in thickness, the smallest being found in the fasciculus gracilis, the tract of Lissauer, and inner part of the lateral column; while the largest are situated in the anterior column, and in the peripheral part of the lateral column. Some of the nerve-fibres assume a more or less transverse direction, as for example those which cross from side to side in the anterior commissure, but the majority pursue a longitudinal course and are divisible into (1) those which connect the cord with the brain and convey impulses to or from the latter, and (2) those which are confined to the spinal cord and link together its different segments (i.e. intersegmental or association fibres).

Nerve-tracts.—The longitudinal fibres are grouped into more or less definite bundles or fasciculi. These are not recognisable from each other in the normal state of the cord, and their existence has been determined by the following methods: (1) A. Waller discovered that if a bundle of nerve-fibres be cut, the portions of the fibres which are separated from their cells rapidly degenerate and become atrophied, while the cells and the parts of the fibres connected with them undergo little alteration.* This is known as *Wallerian degeneration*. Similarly, if a group of nerve-cells be destroyed, the fibres arising from them undergo degeneration. Thus, if the cells of the cerebral cortex which give origin to the motor impulses be destroyed, or if the fibres arising from these cells be severed, a *descending* degeneration from the seat of injury takes place in the fibres. In the same manner, if a spinal ganglion be destroyed, or the fibres which pass from it into the spinal cord be cut, an *ascending* degeneration will extend along these fibres into the spinal cord. (2) By tracing the development of the nervous system, it has been observed that at first the nerve-fibres are merely naked axis-cylinders, and that they do not all acquire their medullary sheaths at the same time; hence the fibres can be grouped into different bundles according to the dates at which they receive their medullary sheaths. (3) Various methods of staining nervous tissue are of great value in tracing the course and mode of termination of the axis-cylinder processes.

Tracts in the anterior column.—The principal tract in this column is the *direct pyramidal* (fasciculus corticospinalis anterior), which is usually small, but varies inversely in size with the crossed pyramidal tract. It lies close

* Somewhat later a change, termed *chromatolysis*, takes place in the nerve-cells, and consists of a breaking down and an ultimate disappearance of the Nissl bodies. Further, the body of the cell is swollen, the nucleus displaced towards the periphery, and the part of the axon still attached to the altered cell is diminished in size and somewhat atrophied. Under favourable conditions the cell is capable of reassuming its normal appearance, and its axon may grow again.

to the anterior median fissure, and is present only in the upper part of the cord; gradually diminishing in size as it descends, it terminates about the middle of the thoracic region. It consists of descending fibres which arise from cells in the motor area of the cerebral hemisphere of the same side, and which, as they run downwards in the cord, cross in succession through the white commissure to the opposite side, where they end by arborising around the motor cells in the anterior cornu.

In addition to the direct pyramidal tract there are strands of fibres in the anterior column, which connect certain ganglia in the brain with the grey matter of the spinal cord. The most important of these is the *vestibulo-spinal tract*, which occupies chiefly the marginal part of the column and is mainly derived from the cells of Deiter's nucleus, i.e. the chief terminal nucleus of the vestibular division of the eighth cranial nerve. Of the other descending fibres some pass downwards from the corpora quadrigemina and others are continuous with the posterior longitudinal bundle.

The remaining fibres of the anterior column constitute what is termed the *anterior basis bundle* (fasciculus anterior proprius). It consists of (*a*) longitudinal intersegmental fibres which arise from cells in the grey matter, more especially from those of the mesial group of the anterior horn, and, after a longer or shorter course, re-enter the grey matter; (*b*) fibres from the grey matter of the opposite side, which cross in the anterior commissure; (*c*) fibres arising from cells of the cerebellum and extending down the cord to terminate round the cells of the anterior horn—these fibres constitute an irregular tract disposed in the peripheral portions of the anterior and lateral basis bundles (*descending cerebello-spinal tract of Löwenthal*); and (*d*) fibres of the anterior nerve-roots which run obliquely forwards to reach the surface of the cord.

Tracts in the lateral column.—1. Descending tracts.—(*a*) The *crossed pyramidal tract* (fasciculus corticospinalis dorsalis) extends throughout the entire length of the cord, and on transverse section appears as an oval area in front of the posterior horn and on the mesial side of the direct cerebellar tract. It consists of fibres which arise from cells in the motor area of the cerebral hemisphere of the opposite side. They pass downwards in company with those of the direct pyramidal tract through the same side of the brain as that from which they originate, but, unlike those of the direct pyramidal tract, they cross to the opposite side in the medulla oblongata and descend in the lateral column of the cord; they end by arborising around the motor cells in the anterior horn.*

The crossed and direct pyramidal tracts constitute the motor fasciculi of the spinal cord and have their origins in the motor cells of the cerebral cortex. They descend through the internal capsule of the cerebrum, traverse the crus cerebri and pons Varolii and enter the anterior pyramid of the medulla oblongata. In the lower part of the medulla some two-thirds of them cross the middle line and run downwards in the lateral column as the crossed pyramidal tract, while the remaining fibres do not cross the middle line, but are continued into the same side of the cord, where they form the direct pyramidal tract. The fibres of the latter tract, however, have been seen to cross the middle line in the anterior commissure of the cord and thus the motor fibres from one side of the brain ultimately reach the opposite side of the cord. The proportion of fibres which cross in the medulla oblongata is not a constant one and thus the direct and crossed pyramidal tracts vary inversely in size. Sometimes the direct pyramidal tract is absent, and in such cases it may be presumed that the decussation of the pyramidal fibres in the medulla oblongata has been complete. The fibres of these two tracts do not acquire their medullary sheaths until after birth. In some animals the pyramidal fibres are situated in the posterior column of the cord.

(*b*) The *rubro-spinal tract* (tract of Monakow) lies on the ventral aspect of the crossed pyramidal tract and on transverse section appears as a somewhat

* It is probable (Schäfer, *Proc. Physiolog. Soc.* 1899) that the fibres of the direct and crossed pyramidal tracts are not related in this direct manner with the cells of the anterior horn. They terminate by arborising round the cells at the base of the posterior horn and the cells of Clarke's column, which in turn link them to the motor cells in the anterior horn, usually of several segments of the cord. In consequence of these interposed neurons the fibres of the pyramidal tracts correspond not to individual muscles, but to associated groups of muscles.

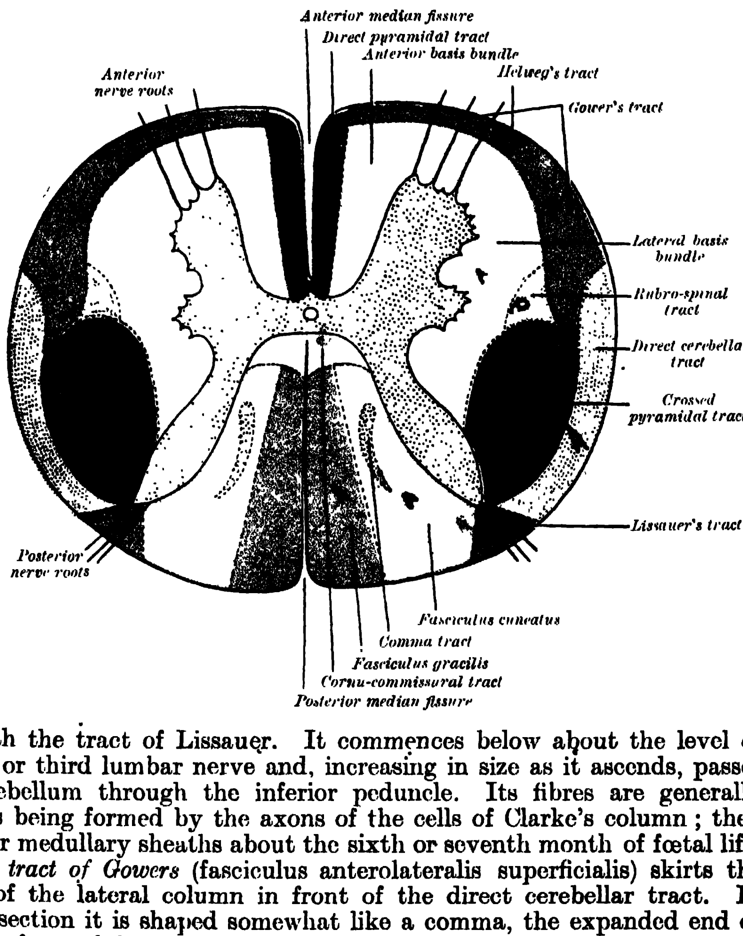
triangular area. Its fibres descend from the mid-brain, where they have their origin in the red nucleus of the tegmentum of the opposite side.

(*c*) The *tecto-spinal tract* originates in the upper quadrigeminal body of the opposite side, and its fibres are partly intermingled with those of the rubro-spinal tract, and are partly contained in the anterior column.

(*d*) The *olivo-spinal tract* or tract of Helweg arises in the vicinity of the inferior olivary body in the medulla oblongata and is seen only in the cervical region of the cord, where it forms a small triangular area at the periphery of the cord close to the outermost of the anterior nerve-roots. Its exact origin and its mode of ending have not yet been definitely made out.

2. **Ascending tracts.**—(*a*) The *direct cerebellar tract of Flechsig* (tractus spinocerebellaris dorsalis) is situated at the periphery of the posterior part of the lateral column of the cord, and on transverse section appears as a flattened band which extends as far forwards as a line drawn transversely through the central canal. Internally it is in contact with the crossed pyramidal tract,

FIG. 681.—Diagram of the principal tracts in the spinal cord.



behind, with the tract of Lissauer. It commences below about the level of the second or third lumbar nerve and, increasing in size as it ascends, passes to the cerebellum through the inferior peduncle. Its fibres are generally regarded as being formed by the axons of the cells of Clarke's column; they receive their medullary sheaths about the sixth or seventh month of fœtal life.

(*b*) The *tract of Gowers* (fasciculus anterolateralis superficialis) skirts the periphery of the lateral column in front of the direct cerebellar tract. In transverse section it is shaped somewhat like a comma, the expanded end of which lies in front of the crossed pyramidal tract while the tail reaches forwards into the anterior column. Its fibres come from the opposite side of the cord and cross in the anterior commissure; they are derived from the cells of Clarke's column and from the cells of the posterior horn. The tract of Gowers commences about the level of the third pair of lumbar nerves, and, increasing in size as it ascends, can be followed upwards into the medulla oblongata and pons. It consists of three fasciculi: (1) the *fasciculus spinocerebellaris ventralis*, the largest of the three, which passes to the cerebellum by way of its superior peduncles; (2) the *spino-thalamic tract*, which ends in the thalamus,

and is sometimes termed the *secondary sensory tract*; and (3) the *spino-tectal tract*, which passes to the corpora quadrigemina.

(*c*) The *tract of Lissauer* is a small strand situated in relation to the tip of the posterior horn close to the entrance of the posterior nerve-roots. It consists of fine fibres which do not receive their medullary sheaths until towards the close of fœtal life. It is usually regarded as being formed by some of the fibres of the posterior nerve-root, which ascend for a short distance in the tract and then enter the posterior horn, but since its fibres are myelinated later than those of the posterior nerve-roots, and do not undergo degeneration in locomotor ataxia, they are probably intersegmental in character.

(*d*) The *lateral basis bundle* constitutes the remainder of the lateral column, and the portion of it which lies next the grey matter is sometimes named the *lateral limiting zone*. It is continuous in front with the anterior basis bundle, and the two together constitute the *antero-lateral ground bundle*. It consists chiefly of intersegmental fibres which arise from cells in the grey matter, and, after a longer or shorter course, re-enter the grey matter and ramify in it. Some of its fibres are, however, continued upwards into the brain under the name of the dorsal or posterior longitudinal fasciculus.

Tracts in the posterior column.—This column comprises two main tracts, viz. the fasciculus gracilis, and the fasciculus cuneatus. These are separated from each other in the cervical and upper thoracic regions by the postero-intermediate septum, and consist mainly of ascending fibres derived from the posterior nerve-roots.

The *fasciculus gracilis* (tract of Goll) is wedge-shaped on transverse section, and lies next the posterior median fissure, its base being at the surface of the cord, and its apex directed towards the posterior grey commissure. It increases in size from below upwards, and consists of long thin fibres derived from the posterior nerve-roots, which ascend as far as the medulla oblongata, where they end in the nucleus gracilis.

The *fasciculus cuneatus* (tract of Burdach) is triangular on transverse section, and lies between the fasciculus gracilis and the posterior cornu, its base corresponding with the surface of the cord. Its fibres, larger than those of the fasciculus gracilis, are mostly derived from the same source, viz. the posterior nerve-roots. Some ascend for only a short distance in the tract, and, entering the grey matter, come into close relationship with the cells of Clarke's column; while others can be traced as far as the medulla oblongata, where they end in the gracile and cuneate nuclei.

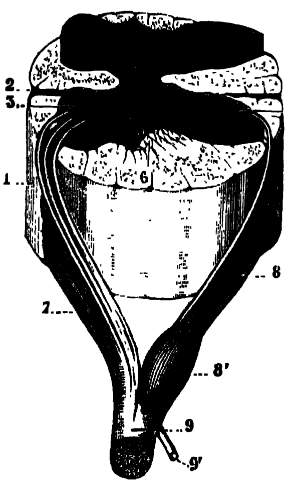
Occupying the ventral part of the posterior column is a strand of fibres termed the *cornu-commissural tract*. It is somewhat triangular on transverse section, and occupies the angle between the posterior grey commissure and the posterior cornu. It is best marked in the lumbar region, but can be traced into the thoracic and cervical regions. Its fibres, derived from the cells of the posterior horn, divide into ascending and descending branches which re-enter and ramify in the grey matter. It has been found to preserve its integrity in certain cases of locomotor ataxia.

Descending fibres in the posterior column (fig. 682).—The posterior column contains some descending fibres which occupy different parts of the column at

different levels. In the cervical and upper thoracic regions, they appear as a comma-shaped strand (*descending comma tract* of Schultze) in the outer part of the fasciculus cuneatus, the blunt end of the comma being directed towards the posterior grey commissure; in the lower thoracic region they form a thin band (*dorsal peripheral band*) on the posterior surface of the column; in the lumbar region, they are situated by the side of the posterior median fissure, and here appear on section as a semi-elliptical bundle, which, together with the corresponding bundle of the opposite side, forms the *oval area of Flechsig*; while in the conus medullaris they assume the form of a *triangular strand* in the postero-internal part of the fasciculus gracilis. These descending fibres are mainly intersegmental in character, and derived from cells in the posterior horn, but some may consist of the descending branches of the posterior nerve-roots. The descending comma tract was supposed to belong to the second category, but against this view is the fact that it does not undergo descending degeneration when the posterior nerve-roots are destroyed.

Roots of the spinal nerves.—As already stated, each spinal nerve possesses two roots, an anterior and a posterior, which are attached to the surface of the cord opposite the corresponding horn of grey matter (fig. 683); their fibres become medullated about the fifth month of fœtal life.

FIG. 683.—A spinal nerve with its anterior and posterior roots. (Testut.)



1. A portion of the spinal cord viewed from the left side. 2. Anterior median fissure. 3. Anterior horn. 4. Posterior horn. 5. Lateral horn. 6. Formatio reticularis. 7. Anterior root. 8. Posterior root, with 8', its ganglion. 9. Spinal nerve; 9', its posterior division.

The *anterior nerve-roots* consist of *efferent* fibres, which are the axons of the nerve-cells in the ventral part of the anterior horn. A short distance from their origins, these axons are invested by medullary sheaths and, passing forwards and slightly outwards, emerge on the surface of the cord in two or three irregular rows over an area which measures about three millimetres in width.

The *posterior root* of each spinal nerve comprises some six or eight fasciculi which are attached in linear series along the postero-lateral sulcus. It consists of afferent fibres which arise from the nerve-cells in the spinal ganglia. Each ganglion-cell, at first round or oval, is elongated into two processes, an internal (axon) and an external (dendrite), and so becomes a bipolar nerve-cell. These two processes gradually undergo approximation, and finally arise from a single stem in a T-shaped manner. The internal processes of the ganglion-cells grow into the cord as the posterior roots of the spinal nerves, while the external are directed towards the periphery.

The posterior nerve-root enters the cord in two chief bundles, mesial and lateral. The *mesial* strand passes directly into the fasciculus cuneatus: it consists of coarse fibres, which acquire their medullary sheaths by the fifth month of intra-uterine life. The *lateral* strand is sometimes divided into an intermediate and an external bundle. The intermediate bundle consists of coarse fibres, which enter the gelatinous substance of Rolando; while the external is composed of fine fibres, which assume a longitudinal direction in the tract of Lissauer; the latter do not acquire their medullary sheaths until after birth.

Having entered the cord, all the fibres of the posterior nerve-roots divide into ascending and descending branches, and these in their turn give off collaterals which enter the grey matter (fig. 684). The descending fibres are short, and soon enter the grey matter. The ascending fibres are grouped into long, short, and intermediate: the long fibres ascend in the fasciculus gracilis and fasciculus cuneatus as far as the medulla, where they end by arborising around the cells of the gracile and cuneate nuclei; the short fibres run upwards for a distance

of only five or six millimetres, and enter the grey matter; while the intermediate fibres, after a somewhat longer course, have a similar destination. All the fibres which enter the grey matter end by arborising around its nerve-cells, those of intermediate length being especially associated with the cells of Clarke's column.

The course taken by the fibres of the posterior nerve-roots has been arrived at by dividing the nerve-roots between their ganglia and their entrance into

FIG. 684.—Dorsal roots entering cord and dividing into ascending and descending branches. (Van Gehuchten.)

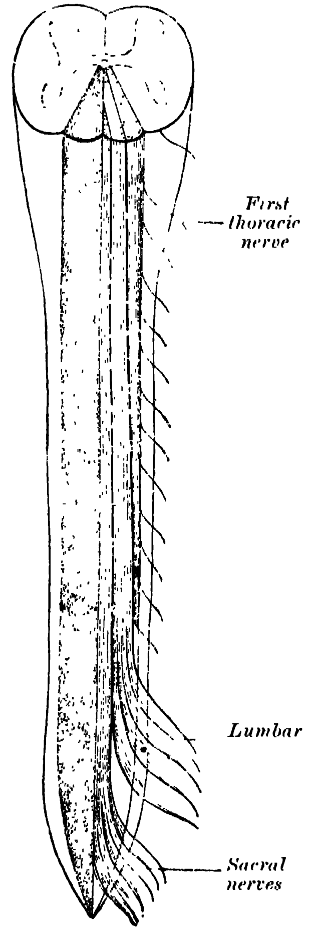
FIG. 685.—Formation of the fasciculus gracilis. (Poirier.)



Spinal cord viewed from behind. To the left, the fasciculus gracilis is shaded. To the right, the drawing shows that the fasciculus gracilis is formed by the long fibres of the posterior roots, and that in this tract the sacral nerves lie next the mesial plane, the lumbar to their outer side, and the thoracic still more laterally.

the spinal cord, and by subsequently examining the degenerated areas. It has been determined that the fibres pursue an oblique course upwards, being situated at first in the outer part of the fasciculus cuneatus: higher up, they occupy the middle of this fasciculus, having been displaced inwards by the accession of other entering fibres; while still higher, they pass into, and are continued upwards in, the fasciculus gracilis. The upper cervical fibres do not reach this fasciculus, but are entirely confined to the fasciculus cuneatus. The degeneration method proves that the localisation of these fibres is very precise: the sacral nerves lie in the inner part of the fasciculus gracilis and near its periphery; the lumbar nerves to their outer side; the thoracic nerves still more laterally; while the cervical nerves are confined to the fasciculus cuneatus (fig. 685).

The **development** of the spinal cord is described in the section on Embryology (page 115)

Applied Anatomy.—Several cases have been recorded * in which a local doubling of the spinal cord has taken place. The condition is probably due to some interference with the development of the medullary tube in the embryo; in a few it was associated

* For a complete analysis of these cases consult paper by Bruce, Stuart McDonald, and Pirie, *Review of Neurology and Psychiatry*, Jan. 1906.

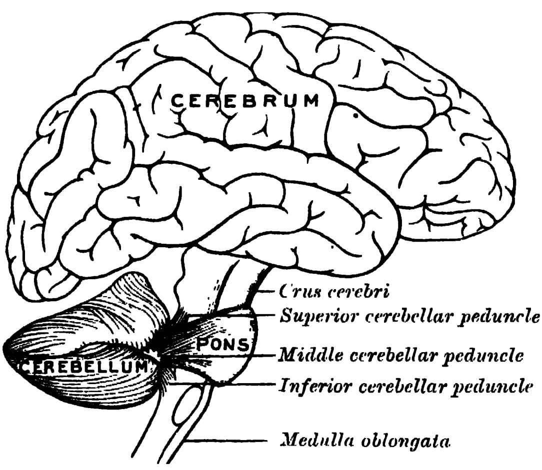
with spina bifida, while in one recent case * the two parts were separated by a dermoid tumour. Other *congenital abnormalities* of the spinal cord occur in connection with spina bifida (see page 201), and also in *syringomyelia*. In this latter chronic condition an abnormal proliferation of the spinal neuroglia takes place, generally near the central canal and in the cervical enlargement, and later this mass becomes absorbed, leaving an irregular cavity in its place. This gives rise to a number of interesting signs and symptoms, such as analgesia (or insensitiveness to pain), inability to distinguish between cold and heat, progressive atrophy in the muscles of the hands and arms, trophic changes in the bones and joints, and painless whitlows. Severe *injuries* to the cord may occur in fractures or fracture-dislocations of the vertebral column anywhere above the second lumbar vertebra. If the cord is completely crushed or torn across, total paralysis and anæsthesia of all parts of the body drawing their nerve supply from below the injured spot will follow, with loss of control over the actions of the bladder and rectum. The higher up such a lesion occurs, the worse the prognosis. Thus, when the cord is crushed by fracture of the atlas or axis, the vital centres in the medulla will be injured, and death occurs at once. If the origin of the phrenic nerve—mainly the fourth cervical—just escape in a case where the neck is broken, respiration will have to be carried on by the Diaphragm alone, and death is likely to ensue before long from pulmonary complications. When the back is broken in the lower thoracic region, life is not immediately threatened; but unless the patient is carefully nursed, death may follow at any time from the development of bed-sores in the anæsthetic area, or from septic infection spreading up the ureters into the kidneys and secondary to the cystitis that is so prone to occur in patients who have no control over the bladder. *Inflammation* of the spinal cord, or *spinal myelitis*, sometimes follows influenza or one of the acute specific fevers. A transverse patch of such myelitis extending completely across the cord produces more or less complete interruption of the passage of nervous impulses through it. Hence it will occasion more or less complete paralysis and anæsthesia of the parts of the body obtaining their nerve-supply from below it, and, in addition, a zone of cutaneous hyperæsthesia at its level, in consequence of the irritation of the sensory fibres entering the inflamed region of the cord. The disease mainly attacking children, and known as *infantile spinal paralysis*, or *acute anterior poliomyelitis*, is a bacterial infection of the pia mater that spreads into the cord along the blood-vessels, and destroys groups of the motor neurons aggregated in the anterior cornua. Destruction of the cells causes rapid and permanent paralysis of the muscles innervated, and groups of muscles in one or more of the limbs are commonly picked out for attack. The affected limbs are thus partially paralysed, and their subsequent growth and nutrition both suffer. Further, the muscles that normally antagonise the affected groups of muscles, finding their actions unopposed, tend to assume a state of spastic contraction. In consequence, much dwarfing and deformity follow later, and may demand for their relief such operations as tenotomy, the transplantation of tendons, or even amputation.

THE BRAIN

General Considerations and Divisions

The brain, or encephalon, is contained within the cranium, and constitutes the upper, greatly expanded part of the central nervous system. In its early embryonic condition it consists of three hollow vesicles, termed the *fore-brain*, the *mid-brain*, and the *hind-brain*; and the parts derived from each of these can be recognised in the adult (fig. 686). Thus, in the process of development the wall of the hind-brain (rhombencephalon) undergoes modification to form the medulla oblongata, the pons Varolii, and cerebellum, while its cavity is expanded to form the fourth ventricle. The mid-brain (mesencephalon) forms but a small part of the adult

Fig. 686.—Scheme showing the connections of the several parts of the brain. (After Schwalbe.)



* Harriehausen, *D. Ztschrft. f. Nervenheilk.*, Bd. 36, Hft. 3 and 4, S. 268.

brain : its cavity becomes the aqueduct of Sylvius, which serves as a tubular communication between the third and fourth ventricles ; while its walls are thickened to form the corpora quadrigemina and crura cerebri, which constitute the bond of union of the fore-brain with the hind-brain. The fore-brain undergoes great modification : its anterior part (telencephalon) expands laterally in the form of two hollow vesicles the cavities of which become the lateral ventricles, while the surrounding walls form the cerebral hemispheres and their commissures ; the cavity of the posterior part of the fore-brain (diencephalon) forms the greater part of the third ventricle, and from its walls are developed most of the structures which bound that cavity. Further details regarding these important changes are given in the chapter on Embryology (page 118).

THE HIND-BRAIN

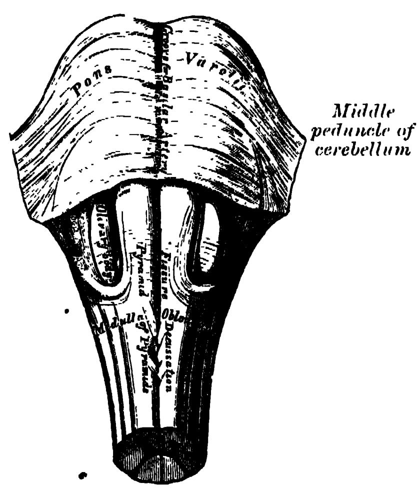
The **hind-brain** or **rhombencephalon** occupies the posterior fossa of the cranial cavity and lies below a fold of dura mater, the tentorium cerebelli. It consists of (*a*) the *myelencephalon*, which comprises the medulla oblongata and the lower part of the fourth ventricle ; (*b*, the *metencephalon*, which includes the pons, cerebellum, and upper part of the fourth ventricle ; and (*c*) the *isthmus rhombencephali*, a constricted portion immediately adjoining the mesencephalon, which comprises the superior peduncles of the cerebellum and the valve of Vieussens.

The Medulla Oblongata

The **medulla oblongata,** or **bulb,** forms the lowest and smallest division of the brain ; its structure, however, is extremely complex, since it gives attachment to many of the cranial nerves, and forms the connecting link between the spinal cord below and the cerebrum and cerebellum above.

It extends from the lower margin of the pons Varolii to a plane passing transversely below the decussation of the pyramids and above the first pair of cervical nerves ; this plane corresponds with the upper border of the atlas behind, and the middle of the odontoid process of the axis in front, and at this level the medulla oblongata is continuous with the spinal cord. Its anterior surface is separated from the basi-occiput and the upper part of the odontoid process of the axis by the membranes of the brain and the occipito-axial ligaments. Its posterior surface is received into the fossa between the hemispheres of the cerebellum, and the upper portion of it forms the lower part of the floor of the fourth ventricle. The vertebral arteries pass upwards and forwards in relation to its lateral aspects ; they then curve forwards on to its anterior surface and unite at the lower border of the pons Varolii to form the basilar artery.

Fig. 687.—Medulla oblongata and pons Varolii. Anterior surface.

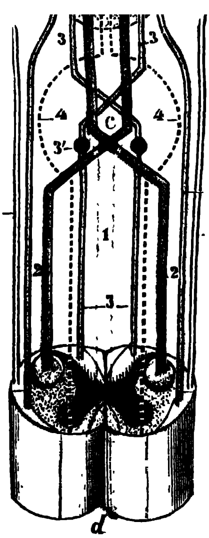


The medulla oblongata (fig. 687) is pyramidal in shape, its broad extremity being directed upwards towards the pons Varolii, while its narrow, lower end is continuous with the spinal cord. It measures rather over an inch in length, a little less than an inch in breadth at its widest part, and about half an inch in thickness ; while it weighs about a quarter of an ounce. The central canal of the spinal cord is prolonged into its lower half, and then opens into the cavity of the fourth ventricle ; and the medulla may therefore be divided into a lower *closed part* containing the central canal, and an upper *open part* corresponding with the lower portion of the fourth ventricle. Its anterior and posterior surfaces are marked by median fissures, which are continuous with the corresponding fissures of the spinal cord.

The **anterior fissure** (fissura mediana anterior) contains a fold of pia mater, and extends along the entire length of the medulla: it terminates at the lower border of the pons Varolii in a small triangular expansion, the *foramen cæcum*. Its lower part is interrupted by bundles of fibres which cross obliquely from one side to the other, and constitute the *pyramidal decussation*. Some fibres, termed the *anterior external arcuate fibres*, emerge from the fissure above this decussation and curve outwards and upwards over the lateral aspect of the medulla.

The **posterior fissure** (fissura mediana posterior) is a narrow groove which exists only in the closed part of the medulla; it becomes gradually shallower from below upwards, and finally terminates about the middle of the medulla, where the central canal of the cord expands into the cavity of the fourth ventricle.

FIG. 688.—Decussation of pyramids. Scheme showing passage of various tracts from cord to medulla. (Testut.)



a. Pons Varolii. *b*. Medulla from the front. *c*. Decussation of the pyramids. *d*. Section of cervical part of cord. 1. Direct pyramidal tract (in red). 2. Crossed pyramidal tract (in red). 3. Sensory tract (fasciculi gracilis et cuneatus) (in blue). 3'. Gracile and cuneate nuclei. 4. Antero-lateral ground bundle (in dotted line). 5. Pyramid. 6. Fillet. 7. Posterior longitudinal fasciculus. 8. Gowers' tract (in blue). 9. Direct cerebellar tract (in yellow).

These two fissures divide the closed part of the medulla into symmetrical halves, each half presenting elongated eminences which, on surface view, are continuous with the columns of the cord. In the open part of the medulla the halves are separated by the anterior median fissure, and by a median *raphe* which extends from the bottom of the fissure to the floor of the fourth ventricle. Further, certain of the cranial nerves pass through the substance of the medulla, and are attached to its surface in series with the roots of the spinal nerves; thus, the fibres of the hypoglossal nerve represent the upward continuation of the anterior nerve-roots, and emerge in linear series from a furrow termed the *pre-olivary* or *antero-lateral sulcus* (sulcus lateralis anterior). Similarly, the spinal accessory, vagus, and glosso-pharyngeal nerves correspond with the posterior nerve-roots, and are attached to the bottom of a sulcus named the *postero-lateral sulcus* (sulcus lateralis posterior). Advantage is taken of this arrangement to subdivide each half of the medulla into three areas, anterior, middle, and posterior. Although these three areas appear to be directly continuous with the corresponding columns of the cord, it must be pointed out that they do not necessarily contain the same fibres, since some of the nerve-tracts of the cord terminate in the medulla, while others alter their course in passing through it.

The **anterior area** (fig. 687) is named the **pyramid** (pyramis), and lies between the anterior fissure and the antero-lateral sulcus. Its upper extremity is slightly constricted, and between it and the pons the fibres of the sixth nerve emerge; a little below the pons it becomes enlarged and prominent, and finally tapers into the anterior column of the cord, with which, at first sight, it appears to be directly continuous.

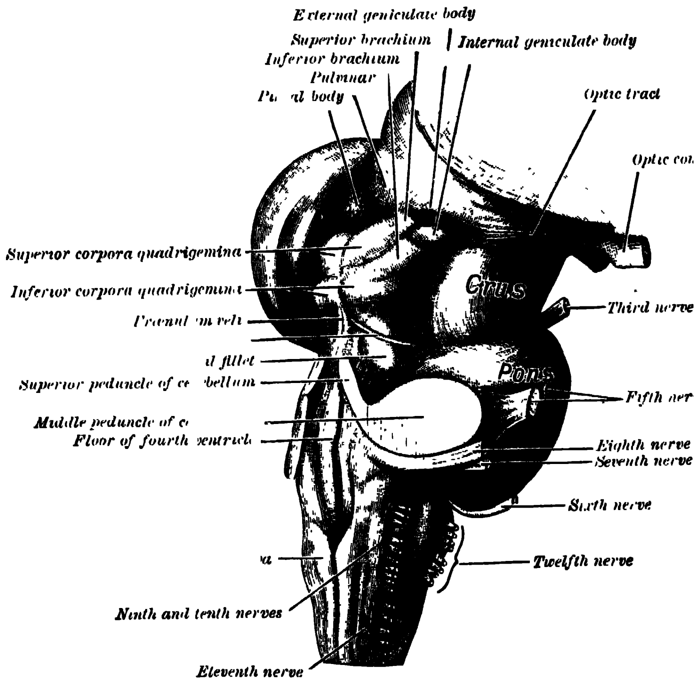
The two pyramids constitute the great motor strands of the medulla, since they contain the motor fibres which pass from the brain to the spinal cord. When these pyramidal fibres are traced downwards, it is found that some two-thirds, or more, of them leave the anterior pyramid in successive bundles, and decussate in the anterior median fissure with corresponding bundles

derived from the opposite pyramid, forming what is termed the *motor or pyramidal decussation* (decussatio pyramidum). Having crossed the middle line, they pass down in the posterior part of the lateral column as the crossed pyramidal tract. The remaining fibres—i.e. those which occupy the outer part of the pyramid—do not cross the middle line, but are carried downwards as the direct pyramidal tract (fig. 688) into the anterior column of the same side.

The greater part of the basis bundle of the anterior column of the cord is continued upwards through the medulla oblongata as a strand, which is termed the *posterior longitudinal fasciculus.*

The **lateral area** (fig. 689) is limited in front by the antero-lateral sulcus and the roots of the hypoglossal nerve, and behind by the postero-lateral sulcus and the roots of the spinal accessory, vagus, and glosso-pharyngeal nerves. Its upper part consists of a prominent oval mass which is named the *olivary body*, while its lower part is of the same width as the lateral column of the

FIG. 689.—Hind- and mid-brains ; postero-lateral view.



cord, and appears on the surface to be a direct continuation of it. As a matter of fact, only a portion of the lateral column is continued upwards into this area, for the crossed pyramidal tract passes into the pyramid of the opposite side, and the direct or ascending cerebellar tract is carried into the restiform body in the posterior area. The remainder of the lateral column, which consists chiefly of the basis bundle and the tract of Gowers, can be traced into the lateral area. Most of these fibres dip beneath the olivary body and disappear from the surface ; but a small strand remains superficial, and passes up between the olivary body and the postero-lateral sulcus. At the upper end of this strand is a depression or fossa, in which the auditory nerve is seen.

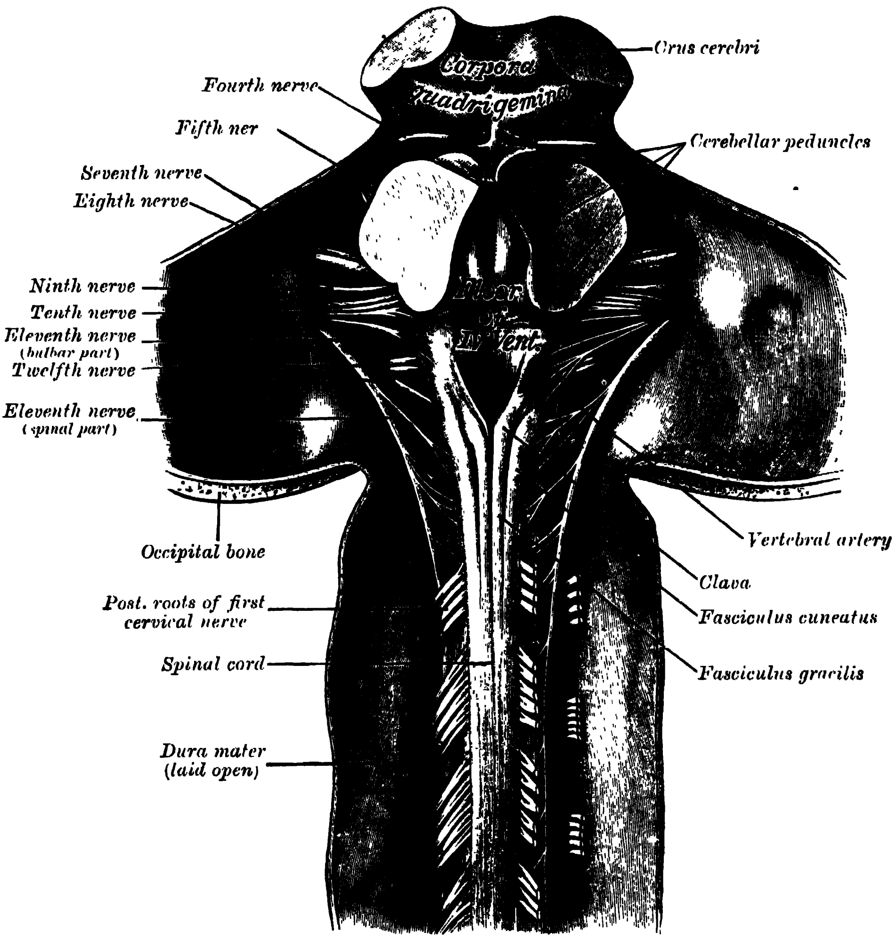
The **olivary body** (oliva) is situated on the outer side of the pyramid, from which it is separated by the antero-lateral or pre-olivary sulcus, and the fibres of the hypoglossal nerve. Behind, it is separated from the postero-lateral sulcus by the small superficial strand of the lateral column already referred to. It measures about half an inch in length, and between its upper end and the pons there is a slight depression to which the roots of the seventh

nerve are attached. The external arcuate fibres wind across the lower part of the pyramid and olivary body to enter the restiform body.

The **posterior area** (fig. 690) lies behind the postero-lateral sulcus and the roots of the spinal accessory, vagus, and the glosso-pharyngeal nerves, and, like the lateral area, is divisible into a lower and an upper portion.

The *lower part* is limited behind by the posterior median fissure, and consists of the *fasciculus gracilis* and the *fasciculus cuneatus*. The fasciculus gracilis is a narrow white band placed parallel to and along the side of the posterior median fissure, and separated from the fasciculus cuneatus by the postero-intermediate furrow and septum. The gracile and cuneate fasciculi are at first vertical in direction; but at the lower part of the floor of the fourth

FIG. 690.—Upper part of spinal cord and hind- and mid-brains; posterior aspect, exposed *in situ*.



ventricle they diverge from the middle line in a V-shaped manner, and each presents an elongated swelling. That on the fasciculus gracilis is named the *clava*, and is produced by a subjacent nucleus of grey matter, the *nucleus gracilis*; that on the fasciculus cuneatus is termed the *cuneate tubercle*, and is likewise caused by a grey nucleus, named the *nucleus cuneatus*. The fibres of these fasciculi terminate by arborising around the cells in their respective nuclei. A third elevation, termed the *fasciculus of Rolando*, is seen in the lower part of the posterior area of the medulla. It lies on the lateral aspect of the fasciculus cuneatus, and is not represented by a corresponding elevation in the cord. It is produced by the substantia gelatinosa of Rolando, which is separated from the surface of the medulla by a band of nerve-fibres which

form the lower sensory, or spinal, root of the fifth nerve. Narrow below, the fasciculus gradually expands above, and terminates, about half an inch below the pons, in a tubercle, the *tubercle of Rolando*.

The *upper part* of the posterior area of the medulla is occupied by the *restiform body* (*corpus restiforme*), a thick rope-like strand which is situated between the lower part of the floor of the fourth ventricle and the roots of the ninth and tenth nerves. The restiform bodies connect the cord and medulla with the cerebellum, and are named the *inferior peduncles of the cerebellum*. As they pass upwards, they diverge from each other, and assist in forming the lower parts of the lateral boundaries of the fourth ventricle; higher up, they are directed backwards, each passing to the corresponding cerebellar hemisphere. Near where they enter the cerebellum they are crossed by several strands of fibres, which extend inwards over the floor of the fourth ventricle, and are named the *striæ acusticæ*. At first sight the restiform body appears to be formed by the upward continuation of the fasciculus gracilis and fasciculus cuneatus; this, however, is not so, as it is probable that all the fibres of these fasciculi end in the gracile and cuneate nuclei. The constitution of the restiform body will be subsequently discussed.

Internal structure of the medulla oblongata.—Although the external form of the medulla oblongata bears a certain resemblance to that of the upper

FIG. 691.—Section of the medulla through the lower part of the decussation of the pyramids. (Testut.)

part of the cord, its internal structure differs widely from that of the latter, and this for the following principal reasons: (1) certain tracts of fibres which extend from the cord to the brain, and *vice versa*, undergo a rearrangement in their passage through the medulla; (2) others which exist in the cord terminate in the medulla; (3) new strands originate in the grey matter of the medulla and pass to different parts of the brain; (4) the grey matter, which in the cord forms a continuous H-shaped column, becomes greatly modified and subdivided in the medulla, in which also new masses of grey matter are added; (5) on account of the opening-out of the central canal of the cord, certain parts of the grey matter, which in the cord were more or less centrally situated, are displayed in the floor of the fourth ventricle; (6) lastly, the medulla is intimately associated with many of the cranial nerves, some arising from, and others terminating in, nuclei within its substance.

The internal structure of the medulla is best studied by examining series of transverse and of longitudinal sections (figs. 695, 696). A short description of the course taken by the principal tracts, and of the arrangement of the grey matter, will now be given.

The pyramidal tracts.—The division of the pyramids of the medulla into direct and crossed pyramidal tracts, and the course of these tracts in the cord,

have already been described. In passing to reach the lateral column of the opposite side, the fibres of the crossed pyramidal tracts extend backwards through the anterior cornua, and the head of each of these horns is separated from its base (figs. 691, 692). The base retains its position in relation to the ventral aspect of the central canal, and, when the latter opens into the fourth ventricle, appears in the floor of that cavity close to the middle line, where it forms the nuclei of the twelfth and sixth nerves; while above the level of the ventricle it exists as the nuclei of the third and fourth nerves in relation to the floor of the aqueduct of Sylvius. The head of the cornu is pushed outwards and forms an elongated column, the *nucleus ambiguus*, which gives origin from below upwards to the bulbar part of the spinal accessory and the motor fibres of the vagus and glosso-pharyngeal, and still higher to the motor fibres of the seventh and fifth nerves.

The **fasciculus gracilis** and **fasciculus cuneatus** constitute the posterior sensory fasciculi of the spinal cord; they are prolonged upwards into the lower part of the medulla oblongata, where they terminate respectively in the nucleus gracilis and nucleus cuneatus. These two nuclei are continuous, in front, with the central grey matter of the cord, and may be regarded as dorsal projections of this, each being covered superficially by the fibres of the corresponding fasciculus. On transverse section (fig. 694), the nucleus gracilis appears as a single, more or less quadrangular mass, while the nucleus cuneatus consists of two parts: a larger, somewhat triangular, *internal nucleus*, composed of small or medium sized cells, and a smaller *external nucleus* containing large cells.

The fibres of the fasciculus gracilis and fasciculus cuneatus end by arborising around the cells of these nuclei, which therefore may be regarded as the nuclei of termination of the posterior sensory fasciculi (fig. 693). From the cells of the nuclei new fibres take origin, some of which are continued as the posterior external arcuate fibres into the restiform body, and through it to the cerebellum, but most of which pass forwards through the neck of the posterior horn, thus cutting off the head from the base of the horn. Curving forwards and inwards, they decussate in the middle line with the corresponding fibres of the opposite side, and run upwards immediately behind the pyramidal

fibres, as a flattened band, named the *fillet* or *lemniscus*. The decussation of these sensory fibres is situated above that of the motor fibres, and is named the *sensory decussation* or the *decussation of the fillet* (decussatio lemniscorum). The fillet is joined by the spino-thalamic tract or secondary sensory fasciculus

FIG. 695.—Section of the medulla oblongata at about the middle of the olivary body. (Schwalbe.)

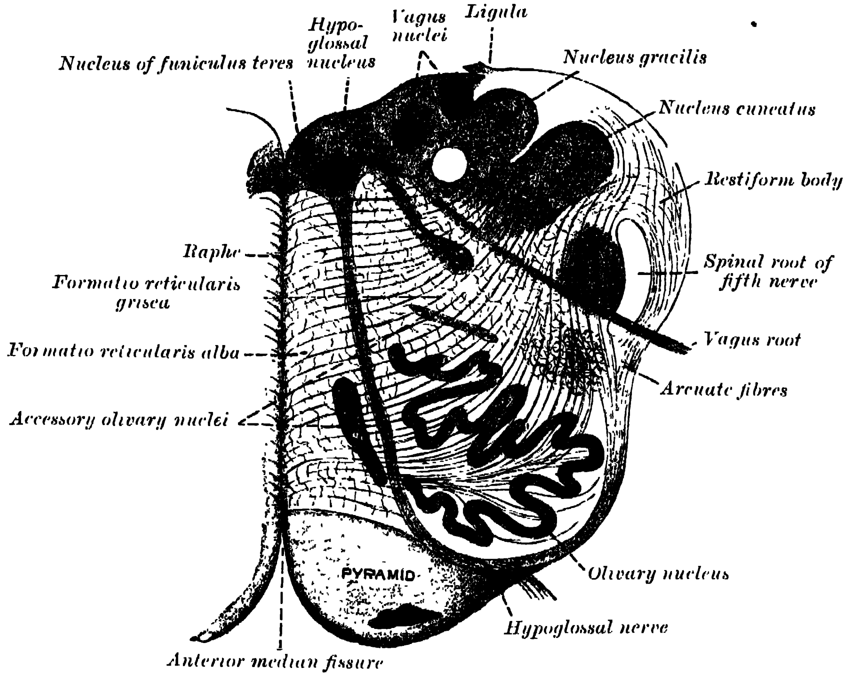

FIG. 696.—Transverse section of medulla oblongata at the middle of the olivary body.

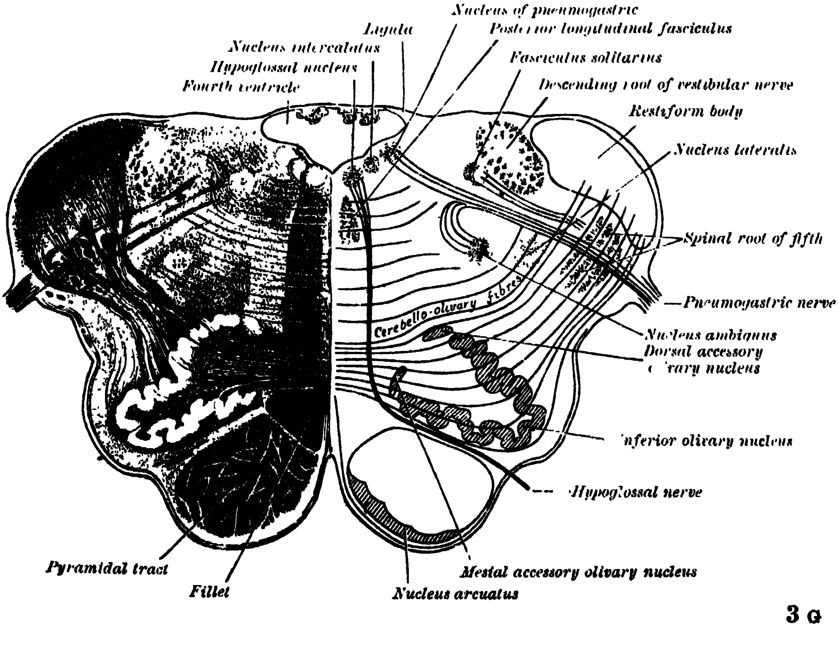
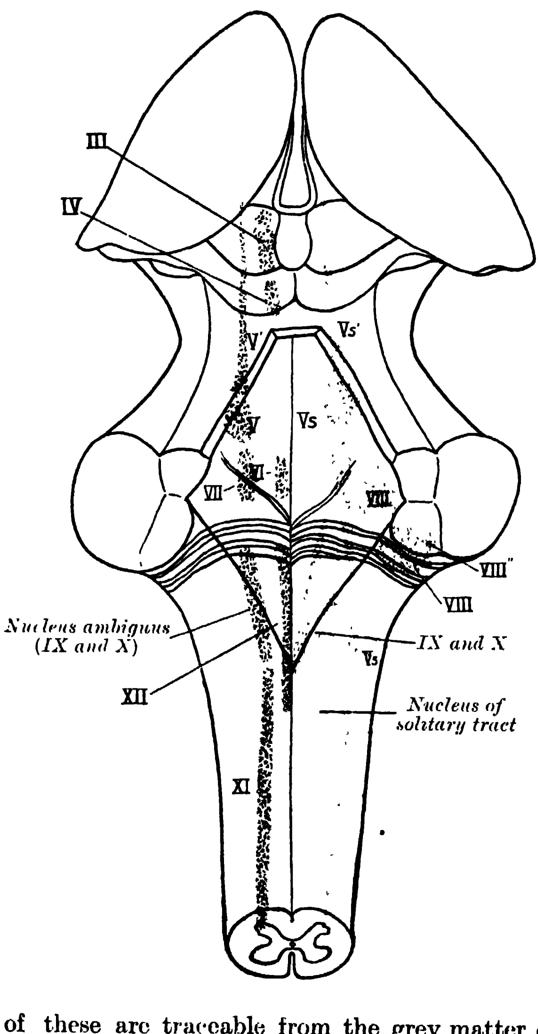


(p. 806), the fibres of which are derived from the cells of the grey matter of the opposite side of the spinal cord.

The base of the posterior horn at first lies on the dorsal aspect of the central canal, but when the latter opens into the fourth ventricle, it appears in the lateral part of the floor of that cavity. It forms the nuclei of termination of the sensory fibres of the vagus and glosso-pharyngeal, and is associated with the vestibular part of the auditory nerve and the sensory root of the seventh nerve (pars intermedia of Wrisberg). Still higher, it forms a mass of pigmented cells—the *locus cœruleus*—in which some of the sensory fibres of the fifth nerve appear to terminate. The head of the posterior horn forms a long continuous column, in which the fibres of the spinal or lower sensory root of the fifth nerve largely terminate.

Fig. 697.—The cranial nerve nuclei schematically represented; dorsal view. Motor nuclei in red; sensory in blue. (The olfactory and optic centres are not represented.)



The direct or ascending cerebellar tract leaves the lateral area of the medulla; most of its fibres are carried backwards into the restiform body of the same side, and through it are conveyed to the cerebellum; but some run upwards with the fibres of the fillet, and, reaching the inferior quadrigeminal bodies, undergo decussation, and are carried to the cerebellum through its superior peduncle.

The basis bundles of the anterior and lateral columns largely consist of intersegmental fibres, which link together the different segments of the cord; they assist in forming the formatio reticularis of the medulla, and many of them are accumulated into a strand which runs up close to the median raphe between the fillet and the floor of the fourth ventricle. This strand is named the *dorsal* or *posterior longitudinal fasciculus*, and will be again referred to.

Grey matter of the medulla oblongata (figs. 695, 696).—In addition to the gracile and cuneate nuclei, there are several others which require consideration. Some of these are traceable from the grey matter of the spinal cord, while others are unrepresented in the cord.

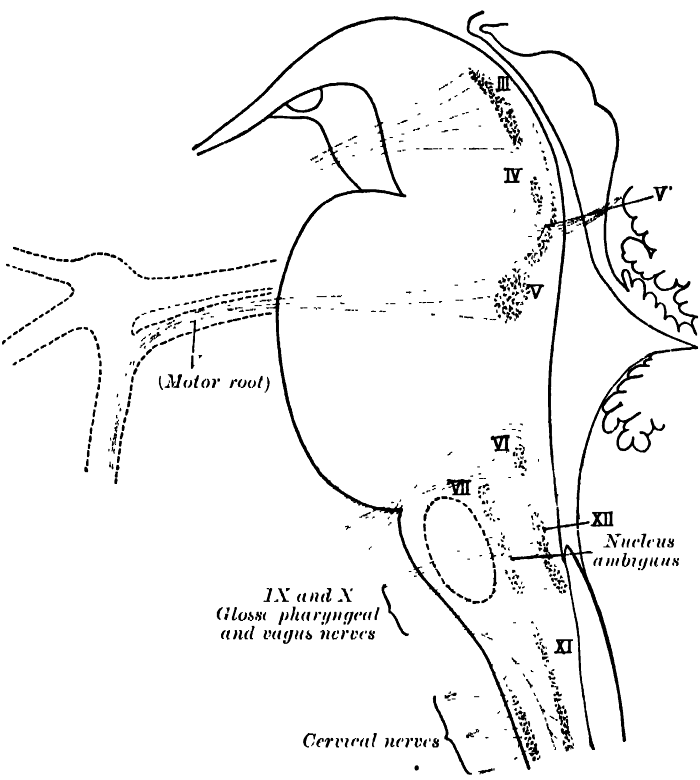
1. The *hypoglossal nucleus* is derived from the base of the anterior horn; in the lower closed part of the medulla it is situated on the ventro-lateral aspect of the central canal; but in the upper part it approaches the floor of the fourth ventricle, where it lies close to the middle line, under an eminence named the *trigonum hypoglossi* (fig. 710). The nucleus measures about three-quarters of an inch in length, and consists of large multipolar nerve-cells, the axons of which constitute the roots of the hypoglossal nerve. These

nerve-roots, pass forward between the anterior and lateral areas of the medulla, and emerge from the preolivary sulcus.

2. The *motor nucleus* (figs. 697, 698) common to the *glosso-pharyngeal*, *vagus*, and bulbar portion of the *spinal accessory* nerves, is named the *nucleus ambiguus*. It represents the head of the anterior horn, lies deeply in the formatio reticularis grisea, and extends throughout nearly the whole length of the medulla.

3. The *sensory nucleus* (figs. 697, 699), or nucleus of termination of the sensory fibres of the *glosso-pharyngeal* and *vagus*, represents the base of the posterior horn. It measures nearly three-quarters of an inch in length, and in the lower, closed part of the medulla is situated behind the hypoglossal nucleus; whereas in the upper, open part it lies to the outer side of that nucleus, and corresponds to an eminence, named the *trigonum vagi*, in the floor of the fourth ventricle.

FIG. 698.—Nuclei of origin of cranial motor nerves schematically represented; lateral view.



4. The *nuclei of the auditory nerve* are described on page 825.

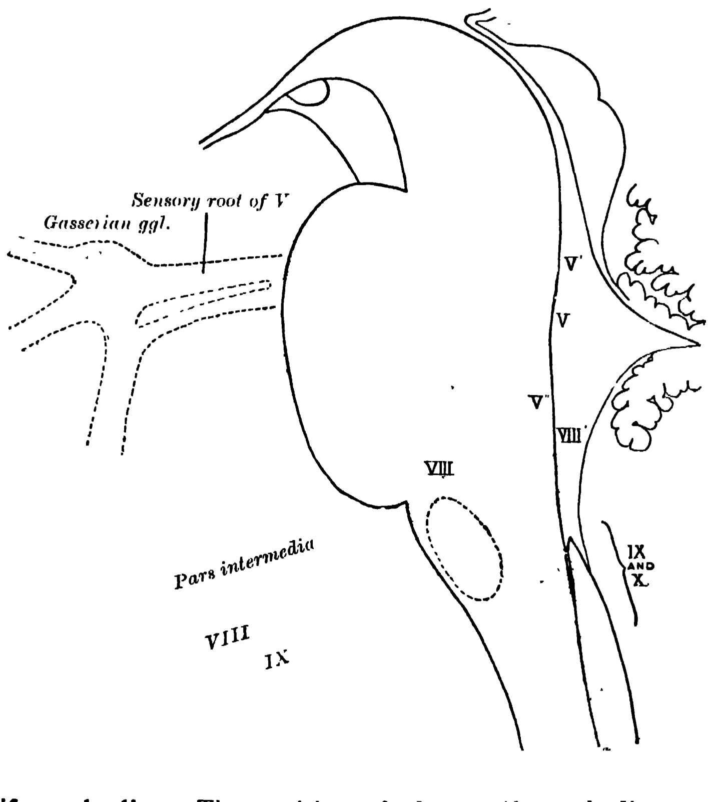
5. The *olivary nuclei* (fig. 695) are three in number on either side of the middle line, viz. the inferior olivary nucleus, and the mesial and dorsal accessory olivary nuclei; they consist of small, round, yellowish cells and numerous fine nerve-fibres. (*a*) The *inferior olivary nucleus* (nucleus olivaris inferior) is the largest of these, and is situated within the olivary body. It consists of a grey folded lamina arranged in the form of an incomplete capsule, which opens internally by an aperture called the *hilus*, emerging from which are numerous fibres which collectively constitute the *peduncle of the olive*. (*b*) The *mesial accessory olivary nucleus* (nucleus olivaris accessorius medialis) lies between the inferior olivary nucleus and the anterior pyramid, and forms a curved lamina, the concavity of which is directed outwards. The fibres of the hypoglossal nerve, as they traverse the medulla, pass between the mesial accessory and the inferior olivary nuclei. (*c*) The *dorsal accessory olivary nucleus* (nucleus olivaris accessorius dorsalis) is the smallest of the three, and

appears on transverse section as a curved lamina on the dorsal aspect of the inferior olivary nucleus.

The inferior olivary nucleus is connected—(1) with that of the opposite side by fibres which cross through the raphe; (2) with the anterior horn of the same side of the spinal cord by a strand of fibres termed the *spino-olivary tract*; (3) with the thalamus of the cerebrum by the *cerebro-olivary tract* which passes through the pons Varolii and tegmentum; (4) with the opposite cerebellar hemisphere by the *cerebello-olivary tract*, the fibres of which pass across the raphe and turn backwards to enter the deep part of the restiform body. Removal of one cerebellar hemisphere is followed by atrophy of the opposite olivary nucleus.

6. The *nucleus arcuatus* will be described with the anterior external arcuate fibres (page 821).

FIG. 699. — Primary terminal nuclei of the afferent (sensory) cranial nerves schematically represented; lateral view. The olfactory and optic centres are not represented.



Restiform bodies.—The position of the restiform bodies, or inferior peduncles of the cerebellum, has already been described (page 815). Each restiform body comprises: (1) the direct or ascending cerebellar tract from the lateral column of the cord; (2) descending cerebellar fibres, many of which are disseminated throughout the peripheral part of the anterior and lateral columns of the cord, while others are conducted to the motor nuclei of the cranial nerves; and (3) the arcuate fibres (fibræ arcuatæ) which are arranged in three sets, viz. the internal arcuate fibres, and the anterior and posterior external arcuate fibres.

The *internal arcuate fibres* form the deeper and larger part of the restiform body. They decussate in the middle line of the medulla, and having reached the opposite side, terminate partly in the gracile and cuneate nuclei, while many of them enter the hilus of the inferior olivary nucleus, and constitute the cerebello-olivary tract already described (fig. 700).

The *anterior external arcuate fibres* vary as to their prominence in different cases: in some they form an almost continuous layer covering the pyramid and olivary body, while in others they are barely visible on the surface. They arise from the cells of the gracile and cuneate nuclei, and passing forwards through the formatio reticularis, decussate in the middle line. Most of them reach the surface by way of the anterior median fissure, and arch outwards and backwards over the pyramid. Reinforced by others which emerge between the pyramid and olivary body, they pass backwards over the olivary body and lateral area of the medulla, and enter the outer part of the restiform body. They thus connect the cerebellum with the gracile and cuneate nuclei of the opposite side. As the fibres arch across the pyramid, they enclose a small nucleus which lies in front and to the inner side of the pyramid. This is named the *nucleus arcuatus*, and is directly continuous above with the nuclei pontis in the pons Varolii: it contains small fusiform cells, around which some of the arcuate fibres terminate, and from which others arise.

The *posterior external arcuate fibres* also take origin in the gracile and cuneate nuclei; they do not undergo decussation, but pass to the restiform body of the same side.

Nucleus arcuatus. 14. Pneumogastric. 15. Hypoglossal.

Formatio reticularis (fig. 701). This term is applied to the coarse reticulum which occupies the anterior and lateral areas of the medulla, and is seen when transverse sections are examined. It is situated behind the pyramid and olivary body, extending laterally as far as the restiform bodies, and dorsally to within a short distance of the floor of the fourth ventricle. The reticulum is caused by the intersection of bundles of fibres running at right angles to each other, some being longitudinal, others more or less transverse in direction. The formatio reticularis presents a different appearance in the anterior area from what it does in the lateral area; in the former, there is an almost entire absence of nerve-cells, and hence this part is known as the *reticularis alba*; whereas nerve-cells are numerous in the lateral area, and as a consequence it presents a grey appearance, and is termed the *reticularis grisea*.

In the substance of the formatio reticularis are two small nuclei of grey matter: one is situated near the dorsal aspect of the hilus of the inferior olivary nucleus, and is named the *inferior central nucleus*, or *nucleus of Roller*; the other lies between the olivary body and the spinal root of the fifth nerve, and is termed the *nucleus lateralis*.

In the reticularis alba the longitudinal fibres form two well-defined strands, viz. : (1) the *fillet*, which lies close to the raphe, immediately behind the fibres of the pyramid ; and (2) the *posterior longitudinal fasciculus*, which is continued upwards from the antero-lateral ground bundle of the spinal cord, and, in the upper part of the medulla, lies between the fillet and the grey matter in the floor of the fourth ventricle. The longitudinal fibres in the reticularis grisea are

derived from the lateral column of the cord after the crossed pyramidal tract has passed over to the opposite side, and the direct cerebellar tract has entered the restiform body. They form indeterminate fibres, with the exception of a bundle named the *fasciculus solitarius*, which is made up of descending fibres of the vagus and glosso-pharyngeal nerves. The transverse fibres of the formatio reticularis are the arcuate fibres already described (pages 820, 821).

Applied Anatomy.—In *bulbar paralysis*, which is really a special form of a progressive degeneration affecting the whole efferent or motor tract, the disease begins with impairment of the movements of the lips, tongue, pharynx, and larynx, due to degeneration of the motor cells in the nuclei of the medulla. Speech and swallowing become difficult, and the saliva dribbles from the open mouth. Other groups of muscles soon become involved, and death often occurs from 'aspiration pneumonia,' set up by food that has accidentally passed down the trachea.

THE PONS

The **pons** (pons Varolii) or fore part of the hind-brain is situated in front of the cerebellum. From its superior surface the crura cerebri emerge, one on either side of the middle line. Curving round each crus, close to the upper surface of the pons, a thin white band, the *tænia pontis*, is frequently seen ; it passes into the cerebellum between the middle and superior peduncles. Behind and below, the pons is continuous with the medulla oblongata, from which it is separated on its ventral surface by a furrow in which the sixth, seventh, and eighth cranial nerves appear.

Its *ventral* or *anterior surface* is very prominent, markedly convex from side to side, less so from above downwards. It consists of transverse fibres arched like a bridge across the middle line, and gathered on either side into a compact mass which forms the middle peduncle of the cerebellum. It rests upon the posterior surface of the basi-sphenoid, and is limited above and below by well-defined borders. It presents, in the middle line, a furrow (*sulcus basilaris*) for the lodgment of the basilar artery; this furrow is bounded on either side by an eminence—the *pyramidal eminence*—caused by the passage of the pyramidal fibres downwards through the substance of the pons. Outside these eminences, near the upper border of the pons, the fifth nerves make their exit, each consisting of a smaller, internal, motor root, and a larger, external, sensory root; a vertical line, drawn on either side immediately outside the fifth nerve, may be taken as the boundary between the ventral surface of the pons and the middle peduncle of the cerebellum.

FIG. 702.—Vertical transverse section of the pons, at its upper part. (Testut.)

Section of superior cerebellar peduncle. 9. Mesial fillet. 9′. Lateral fillet. 10, 10. Transverse fibres of pons. 11, 11. Pyramidal fibres. 12. Raphe. V. Trigeminal.

Its *dorsal* or *posterior surface*, triangular in shape, is hidden by the cerebellum, and is bounded laterally by the superior cerebellar peduncles. It forms the upper part of the floor of the fourth ventricle, with which it will be described.

Structure (fig. 702).—Transverse sections of the pons show that it is composed of two parts which differ from each other in appearance and structure: thus, the ventral portion consists for the most part of fibres arranged in transverse and longitudinal bundles, together with a small amount of grey matter; while the dorsal portion is a continuation of the reticular formation of the medulla oblongata, and is called the tegmental portion, as most of its constituents are continued into the tegmentum of the crus cerebri.

The *ventral part* of the pons (pars basilaris pontis) consists of—(*a*) superficial and deep transverse fibres, (*b*) longitudinal fibres, and (*c*) some small nuclei of grey matter, termed the nuclei pontis.

The *superficial transverse fibres* (fibræ pontis superficiales) constitute a rather thick layer on the ventral surface of the pons, and are collected into a large rounded bundle on either side of the middle line. This bundle, with the addition

of some transverse fibres from the deeper part of the pons, forms the middle peduncle of the corresponding half of the cerebellum.

The *deep transverse fibres* (fibræ pontis profundæ) partly intersect and partly lie on the dorsal aspect of the pyramidal fibres. They course to the lateral border of the pons, and assist the superficial transverse fibres in forming the middle peduncle of the cerebellum. The further connections of the transverse fibres will be discussed with the anatomy of the cerebellum.

The *longitudinal fibres* (fasciculi longitudinales) are derived from the crura cerebri, and enter the upper surface of the pons. They stream downwards on either side of the middle line in larger or smaller bundles, separated from each other by the deeper transverse fibres; these longitudinal bundles cause a forward projection of the superficial transverse fibres, and thus give rise to the pyramidal eminences on the ventral surface. Some of these fibres end in the nuclei pontis, and others, after decussating, in the motor nuclei of the fifth, sixth, seventh, and twelfth nerves; but most of them are carried through the pons, and at its lower surface are collected into the pyramids of the medulla. The fibres which end in the motor nuclei of the cranial nerves are derived from the cells of the cerebral cortex, and bear the same relation to the motor cells of the cranial nerves that the pyramidal fibres bear to the motor cells in the anterior horn of the cord.

The *nuclei pontis* are continuous with the arcuate nuclei in the medulla, and consist of small groups of multipolar nerve-cells which are scattered between the bundles of transverse fibres.

The *tegmental* or *dorsal part* (pars dorsalis pontis) of the pons is chiefly composed of an upward continuation of the reticular formation and grey matter of the medulla. It is subdivided into lateral halves by a median raphe, which however does not extend into the ventral part of the pons, being obliterated by the transverse fibres.

The tegmental portion of the pons consists of transverse and longitudinal fibres, and also contains important grey nuclei. The transverse fibres in the lower part of the pons are collected into a distinct strand, named the *corpus trapezoideum*. This consists of fibres which arise from the cells of the ventral or accessory auditory nucleus, and will be referred to in connection with the cochlear division of the auditory nerve. In the substance of the corpus trapezoideum is a collection of nerve-cells, which constitutes the *trapezoid nucleus*. The longitudinal fibres, which are continuous with those of the medulla, are mostly collected into two bundles on either side. One of these lies between the corpus trapezoideum and the reticular formation, and forms the upward prolongation of the *fillet*; the second is situated near the floor of the fourth ventricle, and is the *posterior longitudinal fasciculus*. Other longitudinal fibres, which are more diffusely distributed, arise from the cells of the grey matter of the pons.

The greater part of the dorsal portion of the pons is a continuation upward of the formatio reticularis of the medulla, and, like it, presents the appearance of a network, in the meshes of which are numerous nerve-cells. Besides these scattered nerve-cells, there are some important masses of grey matter which require mention, viz. the superior olivary nucleus and the nuclei of the fifth, sixth, seventh, and eighth nerves (fig. 697).

1. The *superior olivary nucleus* (nucleus olivaris superior) is a small mass of grey matter situated on the dorsal surface of the outer part of the corpus trapezoideum. Rudimentary in man, but well developed in certain animals, it exhibits the same structure as the inferior olivary nucleus, and is situated immediately above it. Some of the fibres of the corpus trapezoideum end by arborising around the cells of this nucleus, while others arise from these cells.

2. *Nuclei of the fifth nerve.*—The nuclei of the fifth nerve in the pons are two in number: a motor and a sensory. The *motor nucleus* is situated in the upper part of the pons, close under its dorsal surface and along the line of the lateral margin of the fourth ventricle. The axis-cylinder processes of its cells form a portion of the motor root of the fifth nerve: the remaining fibres of the motor root of this nerve are formed by a tract which arises from the grey matter of the floor of the Sylvian aqueduct, and hence is named the *Sylvian* or *mesencephalic root*. The *sensory nucleus* lies external to the motor one, and beneath the superior peduncle of the cerebellum. Some of the sensory fibres

of the fifth nerve terminate in this nucleus; but the greater number descend, under the name of the lower sensory or spinal root, to end in the substantia gelatinosa of Rolando. The roots, motor and sensory, of the fifth nerve pass through the substance of the pons and emerge near the upper margin of its ventral surface.

3. The *nucleus of the sixth nerve* is a circular mass of grey matter situated close to the floor of the fourth ventricle, above the striæ acusticæ and subjacent to the eminentia teres: it lies a little external to the ascending part of the seventh nerve. The fibres of the sixth nerve pass forward through the entire thickness of the pons on the mesial side of the superior olivary nucleus, and between the outer bundles of the pyramidal fibres, and emerge in the furrow between the lower border of the pons and the pyramid of the medulla.

4. The *nucleus of the seventh nerve* is situated deeply in the reticular formation of the pons, on the dorsal aspect of the superior olivary nucleus, and the roots of the nerve derived from it pursue a remarkably tortuous course in the substance of the pons. At first they pass backwards and inwards until they reach the floor of the fourth ventricle, close to the median groove, where they are collected into a round bundle. This passes upwards and forwards, producing an elevation (fasciculus teres) in the floor of the ventricle, and then takes a sharp bend, and arches outwards through the substance of the pons to emerge at its lower border in the interval between the olivary and restiform bodies of the medulla.

5. The *nuclei of the auditory nerve*.—The auditory nerve consists of a cochlear and a vestibular division. The fibres of the cochlear division end in two nuclei: (*a*) the *lateral cochlear nucleus*, which corresponds to the tuberculum acusticum on the dorso-lateral surface of the restiform body; and (*b*) the *ventral* or *accessory cochlear nucleus*, which is placed between the two divisions of the nerve, on the ventral aspect of the restiform body. The nuclei in which the vestibular division ends are (*a*) the *dorsal* or *chief vestibular* nucleus, which corresponds to the trigonum acustici in the floor of the fourth ventricle; the caudal end of this nucleus is sometimes termed the *descending* or *spinal vestibular nucleus*; (*b*) the *nucleus of Deiters*, consisting of large cells and situated in the lateral angle of the floor of the fourth ventricle; the dorso-lateral part of this nucleus is sometimes termed the *nucleus of Bechterew*.

Applied Anatomy.—Injury to the pons, such as may occur on the occlusion or rupture of one of its blood-vessels, often gives rise to a special train of symptoms that is almost diagnostic. Pontine lesions are characterised mainly by 'alternate paralyses'; that is to say, by paralysis of one of the motor cerebral nerves on one side, and of the limbs on the other side of the body. Thus a hæmorrhage into the lower part of the pons might cause paralysis of the face ('lower segment paralysis') on the same side, from destruction of the facial nucleus or nerve-root, and paralysis of the arm and leg on the opposite side from injury to the adjacent pyramidal tract. In the same way, paralysis of the External rectus muscle of one eye and of the Internal rectus of the other ('conjugate paralysis' of the muscles turning the two eyes in one direction) and often paralysis of one side of the face as well, together with palsy of the limbs on the opposite side of the body, may be found when the lesion occurs about the nucleus of the sixth nerve. Hearing is often unaffected in pontine lesions, possibly because the central auditory tract occupies a ventral and external position in the pons.

The Cerebellum

The **cerebellum** constitutes the largest part of the hind-brain. It lies behind the pons Varolii and medulla oblongata, while between its central portion and these structures is the cavity of the fourth ventricle. It rests on the inferior occipital fossæ, while above it is a fold of dura mater, named the tentorium cerebelli, which separates it from the tentorial surface of the cerebrum. It is somewhat oval in form, but constricted mesially and flattened from above downwards, its greatest diameter being from side to side. Its surface is not convoluted like that of the cerebrum, but is traversed by numerous curved furrows or sulci, which vary in depth at different parts, and separate the laminæ of which it is composed.

Lobes of the cerebellum.—The cerebellum consists of three parts, a median and two lateral, which are continuous with each other, and are substantially the same in structure. The median portion is constricted, and is called the *worm* or *vermis*, from the annulated appearance which it presents owing to transverse ridges and furrows upon it; the lateral expanded portions are named the

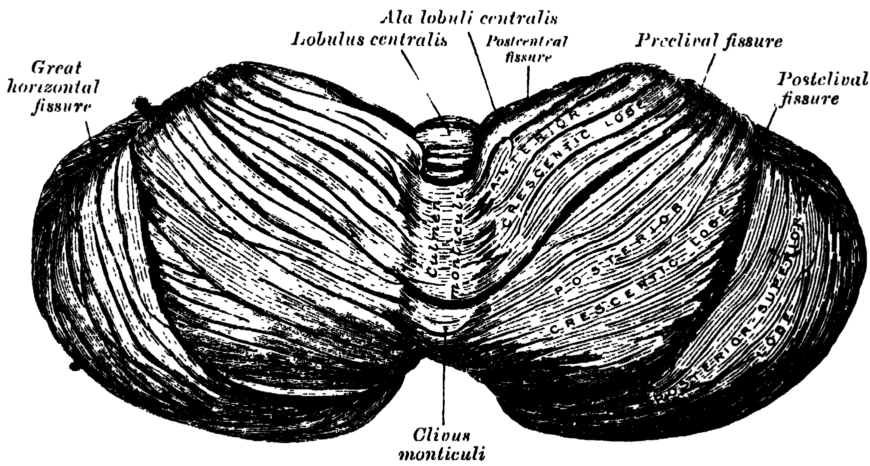
hemispheres. On the upper surface of the cerebellum the vermis is elevated above the level of the hemispheres, but on the under surface it is sunk almost out of sight in the bottom of a deep depression between them; this depression is called the *vallecula cerebelli*, and lodges the medulla oblongata. The part of the vermis which lies on the upper surface of the cerebellum is named the *superior vermis*; that on the lower surface, the *inferior vermis*. Below and behind, the hemispheres are separated by a deep notch, the *posterior cerebellar notch* (incisura cerebelli posterior), and in front by a broader shallower notch, the *anterior cerebellar notch* (incisura cerebelli anterior). The anterior notch lies close to the pons and upper part of the medulla, and its upper edge encircles the lower pair of corpora quadrigemina and the superior peduncles of the cerebellum. The posterior notch contains the upper part of a fold of dura mater, the falx cerebelli.

The cerebellum is characterised by its laminated or foliated appearance; it is marked by deep, somewhat curved fissures, which lie close together, and extend for a considerable distance into its substance, dividing it into a series of layers or leaves. The largest and deepest fissure is named the *great horizontal fissure* (sulcus horizontalis cerebelli). It commences in front at the pons, and passes horizontally round the free margin of the hemisphere to the middle line behind, and divides the cerebellum into an upper and a lower portion. Several secondary but deep fissures separate the cerebellum into lobes, and these are further subdivided by shallower sulci, which separate the individual folia or laminæ from each other. Upon making sections across the laminæ, it will be seen that the folia, though differing in appearance from the convolutions of the cerebrum, are analogous to them, inasmuch as they consist of a central white substance with a covering or cortex of grey matter.

The cerebellum is connected to the cerebrum, pons, and medulla by three pairs of peduncles: a superior pair connect it with the cerebrum; a middle pair with the pons; and an inferior pair with the medulla.

The **upper surface of the cerebellum** (fig. 703) is elevated in the middle line and sloped towards the circumference, the hemispheres being connected together by the superior vermis, which assumes the form of a raised median ridge, most prominent in front, but not sharply defined from the hemispheres. This surface is traversed by four curved fissures, which extend across its whole width and divide it into five lobes. Although each lobe

FIG. 703.—Upper surface of the cerebellum. (Schäfer.)



extends continuously from side to side the portion of the lobe in the vermis has received a different name from that in the hemispheres. The five lobes in the vermis are named, from before backwards: (1) the *lingula*, (2) the *lobulus centralis*, (3) the *culmen monticuli*, (4) the *clivus monticuli*, and (5) the *folium cacuminis*; and the corresponding lobes in each hemisphere are termed: (1) the *frænulum*, (2) the *ala lobuli centralis*, (3) the *anterior crescentic*, (4) the *posterior*

crescentic, and (5) the *postero-superior*. The four fissures are named from before backwards, the *precentral*, the *postcentral*, the *preclival*, and the *postclival*. The arrangement of these lobes and fissures will be understood by a reference to the accompanying scheme, in which they are named in order from before backwards.

Hemisphere	*Superior vermis*	*Hemisphere*
Frænulum.	Lingula.	Frænulum.
	Precentral fissure	
Ala lobuli centralis.	Lobulus centralis.	Ala lobuli centralis.
	Postcentral fissure	
Anterior crescentic lobe.	Culmen monticuli.	Anterior crescentic lobe.
	Preclival fissure	
Posterior crescentic lobe.	Clivus monticuli.	Posterior crescentic lobe.
	Postclival fissure	
Postero-superior lobe.	Folium cacuminis.	Postero-superior lobe.

The **lingula** is a small tongue-shaped process, consisting of four or five folia; it lies in front of the lobulus centralis, and is concealed by it. Anteriorly, it rests on the dorsal surface of the valve of Vieussens, and its white matter is continuous with that of the valve. On either side, the lingula gradually shades off, and is prolonged for only a short distance into the hemispheres, where it forms the **frænulum**. This does not stretch beyond the superior peduncle of the cerebellum, over which it lies.

The **lobulus centralis** is a small square lobe, situated in the anterior notch. It overlaps the lingula, and is in turn partially concealed by the culmen monticuli; laterally, it extends along the upper and anterior part of each hemisphere, where it forms a wing-like prolongation, the **ala lobuli centralis.**

The **culmen monticuli** is much larger than the two lobes just described, and constitutes, with the succeeding lobe, the bulk of the superior vermis. In front, it partially overlaps and obscures the lobulus centralis; and behind, it is separated from the clivus by the *preclival fissure*. It forms the most prominent part of the superior vermis, and is marked on its surface by three or four secondary fissures, which divide it into smaller lobules. Laterally, it is continuous with the **anterior crescentic lobes** of the hemispheres, which are separated from the posterior crescentic lobes by the preclival fissure. The culmen monticuli and the two anterior crescentic lobes form the **lobus culminis.**

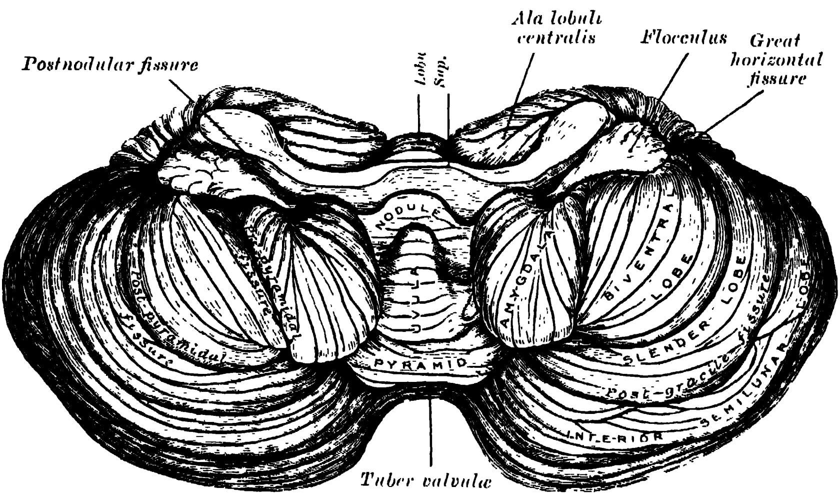
The **clivus monticuli** is of considerable size, and consists of a group of laminæ which are separated in front from the culmen by the preclival fissure, but appear behind to be almost continuous with the folium cacuminis; it will be found, however, on careful examination, to be separated from it by a well-defined fissure, the *postclival fissure*. Laterally, this lobe is continued into the hemispheres as the **posterior crescentic lobes,** which are somewhat semilunar in shape, and form, with the anterior crescentic lobes, the greater part of the upper surface of the hemispheres. The two posterior crescentic lobes and the intervening clivus monticuli constitute the **lobus clivi.**

The **folium cacuminis** is a short, narrow, concealed band at the posterior extremity of the vermis, consisting apparently of a single folium, but in reality marked on its upper and under surfaces by secondary fissures. Laterally, it expands in either hemisphere into a considerable lobe, which is semilunar in shape, and is situated at the postero-superior part of the hemisphere, and bounded below by the *great horizontal fissure*. It is named the **postero-superior lobe,** and occupies the posterior third of the upper surface of the hemisphere, forming its rounded postero-lateral border. The postero-superior lobes and the folium cacuminis form the **lobus cacuminis.**

The **under surface of the cerebellum** (figs. 704, 705) presents, in the middle line, the *inferior vermis*, buried in the vallecula, and separated from the hemisphere on either side by a deep groove, the *sulcus valleculæ*. Here, as on the upper surface, there are deep fissures, dividing it into separate segments or

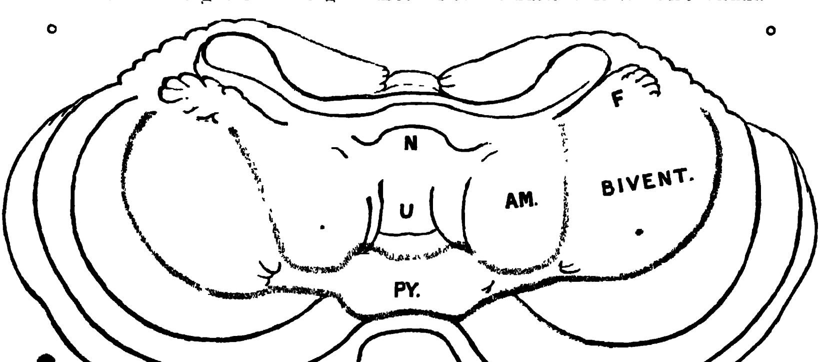
lobes ; but the arrangement is more complicated, and the relation of the segments of the vermis to those of the hemisphere is less clearly marked. This surface is divided into four lobes by three main fissures, which, however, are not so regularly disposed as those on the upper surface. The lobes on the vermis are named from before backwards : (1) the *nodule*, (2) the *uvula*, (3) the *pyramid*, and (4) the *tuber valvulæ* or *tuber posticum*. On the hemispheres

Fig. 704.—Under surface of the cerebellum. (Schäfer.)



the corresponding lobes are : (1) the *flocculus*, (2) the *amygdala* or *tonsil*, (3) the *biventral* or *digastric lobe*, and (4) the *postero-inferior lobe*, which occupies at least two-thirds of the under surface and is subdivided by a secondary fissure, named the *postgracile fissure* ; the anterior of the two subdivisions is named the *slender lobe* (lobus gracilis) ; and the posterior, the *inferior semilunar*

Fig. 705.—Diagram showing fissures on under surface of the cerebellum.



F. Flocculus. N. Nodule. U. Uvula. PY. Pyramid. AM. Amygdala. BIVENT. Biventral lobe.

or *postero-inferior lobe*. The three main fissures are : (1) The *postnodular fissure* which runs transversely across the vermis, separating the nodule in front from the uvula behind. When this fissure reaches the hemispheres, it passes in front of the amygdala, and then crosses between the flocculus in front and the biventral lobe behind, and joins the anterior end of the great horizontal fissure. (2) The *prepyramidal fissure* crosses the vermis between the uvula in

front and the pyramid behind, then curves laterally behind the amygdala, and passes forwards along the outer border of this lobe, between it and the biventral lobe, to join the postnodular fissure. (3) The *postpyramidal fissure* passes across the vermis behind the pyramid and in front of the tuber valvulæ, and, in the hemispheres, courses behind the amygdala and biventral lobes, and then along the outer border of the biventral lobe to the postnodular sulcus. It forms the anterior boundary of the postero-inferior lobe, which, as already stated, is subdivided by the *postgracile fissure*. These fissures and lobes are here arranged, from before backwards, in a schematic form.

Hemisphere	*Inferior vermis*	*Hemisphere*
Flocculus.	Nodule.	Flocculus.
	Postnodular fissure	
Amygdala.	Uvula.	Amygdala.
	Prepyramidal fissure	
Biventral lobe.	Pyramid.	Biventral lobe.
	Postpyramidal fissure	
Lobus gracilis.	Tuber valvulæ.	Lobus gracilis.
Postgracile fissure.		*Postgracile fissure.*
Inferior semilunar lobe.		Inferior semilunar lobe.

The **nodule** and **flocculus.**—The nodule is a distinct prominence, forming the anterior extremity of the inferior vermis. It abuts against the roof of the fourth ventricle, and can only be distinctly seen after the cerebellum has been separated from the medulla and pons. On either side of the nodule is a thin layer of white substance, named the *inferior medullary velum*. It is semilunar in form, its convex border being continuous with the white substance of the cerebellum ; it extends on either side as far as the flocculus, which it connects with the nodule. The flocculus is a prominent, irregular lobule, situated just in front of the biventral lobe, between it and the middle peduncle of the cerebellum. It is subdivided into a few small laminæ, and is connected to the inferior medullary velum by its central white core. The flocculi, together with the inferior medullary velum and nodule, constitute the **lobus noduli.**

The **uvula** and **amygdalæ.**—The uvula forms a considerable portion of the inferior vermis ; it is separated on either side from the amygdala by the *sulcus valleculæ*, at the bottom of which it is connected to the amygdala by a ridge of grey matter, indented on its surface by shallow furrows, and hence called the *furrowed band*. It is marked on its surface by three or four transverse fissures. The amygdalæ, or tonsils, are rounded masses, situated in the lateral hemispheres. Each lies in a deep fossa, termed the *bird's nest* (nidus avis), between the uvula and the biventral lobe. The uvula and tonsils form the **lobus uvulæ.**

The **pyramid** and **biventral lobes** constitute the **lobus pyramidis.** The pyramid is a conical projection, forming the largest prominence of the inferior vermis. It is separated from the hemispheres by the sulcus valleculæ, across which it is connected to the biventral lobe by an indistinct grey band, analogous to the furrowed band already described. The biventral lobe is triangular in shape ; its apex points inwards and backwards, and is joined by the connecting band to the pyramid. The external border is separated from the slender lobe by the postpyramidal fissure. The base is directed forwards, and is on a line with the anterior border of the amygdala, and is separated from the flocculus by the postnodular fissure.

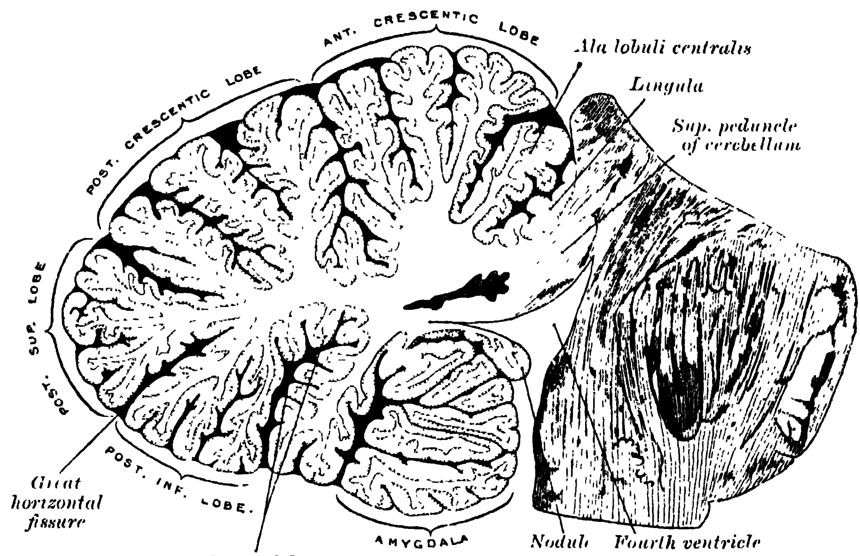
The **tuber valvulæ** and the **postero-inferior lobes** collectively form the **lobus tuberis.** The tuber valvulæ is the most posterior division of the inferior vermis. It is of small size, and laterally spreads out into the large postero-inferior lobes of the hemispheres. These lobes, as stated above, comprise at least two-thirds of the inferior surface of the hemisphere, and are divided into two by the *postgracile fissure*. The anterior part is named the *slender lobe* (lobus gracilis) ; and the posterior, the *inferior semilunar lobe*. Each of them is traversed by a curved fissure ; that in the slender lobe being well marked and termed the *intragracile fissure*.

Internal Structure of the Cerebellum

The cerebellum consists of white and grey matter.

White matter.—If a sagittal section (fig. 706) be made through either hemisphere, the interior will be found to consist of a central stem of white matter, in the interior of which is a grey mass, the *nucleus dentatus*. From the surface of this central stem a series of plates of medullary matter are detached; these are covered with grey matter and form the laminæ. In consequence of the main branches from the central stem dividing and subdividing, the section presents a characteristic appearance, which is named the *arbor vitæ*. If the sagittal section be made through the middle of the vermis, it will be found that the central stem divides into a vertical and a horizontal branch. The *vertical* branch passes upwards to the culmen, where it subdivides freely, one of its ramifications passing forwards and upwards to the central lobe. The *horizontal* branch passes backwards to the folium cacuminis, greatly diminished in size in consequence of having given off large secondary branches: one, from its upper surface, ascends to the clivus; the others descend, and enter the lobes in the inferior vermiform process,

Fig. 706.—Sagittal section of the cerebellum, near the point of junction of the vermis with the hemisphere. (Schäfer.)



viz. the tuber valvulæ, the pyramid, the uvula, and the nodule. It is not necessary to describe in detail the various divisions of the white matter, as they correspond to the lobes on the surface.

The white matter of the cerebellum includes two sets of nerve-fibres: (1) the *peduncular fibres*, continuous with those of the peduncles of the cerebellum; (2) the fibres proper (*fibræ propriæ*) of the cerebellum itself.

The **peduncles.**—From the anterior part of each hemisphere arise three large processes or peduncles—superior, middle, and inferior—by which the cerebellum is connected with the rest of the brain.

The **superior peduncles** emerge from the upper and mesial part of the white substance of the hemispheres and are placed under cover of the upper part of the cerebellum. They are joined to each other across the middle line by the valve of Vieussens, and can be followed upwards as far as the inferior quadrigeminal bodies, under which they disappear. Below, they form the upper lateral boundaries of the fourth ventricle, but as they ascend they converge on the dorsal aspect of the ventricle and thus assist in roofing it in.

The fibres of the superior peduncle are mainly derived from the cells of the nucleus dentatus, and emerge from the hilus of this nucleus; a few arise

from the cells of the smaller grey nuclei in the cerebellar white substance, and others from the cells of the cerebellar cortex. They are continued upwards beneath the corpora quadrigemina, and the fibres of the two peduncles undergo a complete decussation in front of the Sylvian aqueduct. Having crossed the middle line they divide into ascending and descending groups of fibres, the former ending in the red nucleus, the thalamus, and the nucleus of the third nerve, while the descending fibres can be traced as far as the dorsal part of the pons; Cajal believes them to be continued into the anterior column of the spinal cord.

As already stated (page 806), the greater part of the tract of Gowers passes to the cerebellum, which it reaches by way of the superior peduncle.

The **middle peduncles** are the largest, and are formed by the transverse fibres of the pons. They enter the cerebellum between the margins of the great horizontal fissure, and their fibres are grouped into two main bundles: one, consisting of the upper transverse fibres of the pons, spreads out in the infero-lateral part of the hemisphere; the other, comprising the lower transverse fibres of the pons, radiates into the upper part of the hemisphere.

The middle peduncle is composed entirely of centripetal fibres, which arise from the cells of the nuclei pontis of the opposite side and terminate in the cerebellar cortex.

The **inferior peduncles** consist mainly of afferent fibres, and are continuous below with the restiform bodies of the medulla oblongata.* They pass at first upwards and outwards, forming part of the lateral walls of the fourth ventricle, and then bend abruptly backwards to enter the cerebellum between the middle and superior peduncles.

The inferior peduncle contains the following fasciculi: (1) the direct cerebellar tract of the spinal cord, which terminates mainly in the superior vermis; (2) fibres from the nucleus gracilis and nucleus cuneatus of the same and of the opposite sides; (3) fibres from the opposite olivary body; (4) crossed and uncrossed fibres from the reticular formation of the medulla; (5) vestibular fibres, derived partly from the vestibular division of the auditory nerve and partly from the nuclei in which this division terminates—these fibres occupy the inner segment of the peduncle and divide into ascending and descending groups of fibres; the ascending fibres partly end in the roof nucleus of the opposite side of the cerebellum; (6) cerebello-bulbar fibres which come from the opposite roof nucleus and probably from the nucleus dentatus, and are said to end in the nucleus of Deiters and in the formatio reticularis of the medulla oblongata.

The **valve of Vieussens,** or **superior medullary velum,** is a thin, transparent lamina of white matter, which stretches across from one superior peduncle to the other; on the dorsal surface of its lower half the folia of the lingula are prolonged. It forms, together with the superior peduncles, the roof of the upper part of the fourth ventricle, and is continuous with the central white stem of the cerebellum. It is narrow above, where it passes beneath the corpora quadrigemina, and broader below, at its connection with the white substance of the superior vermis. A slightly elevated ridge, the *frænulum veli*, descends upon the upper part of the valve from between the lower corpora quadrigemina, and on either side of this the fourth nerve emerges.

The **inferior medullary velum** is a thin layer of white substance, which is prolonged from the white centre of the medulla above and on either side of the nodule, and assists in forming a part of the roof of the fourth ventricle. Somewhat semilunar in shape, it is continuous with the white substance of the cerebellum by its convex edge, while its thin concave margin is apparently free. In reality, however, it is continuous with the epithelium of the ventricle, which is prolonged downwards from the inferior medullary velum to the ligulæ.

The two medullary vela are in contact with each other along their line of emergence from the white substance of the cerebellum; and this line of contact forms the summit of the roof of the fourth ventricle, which, in a vertical section through the cavity, appears as a pointed angle.

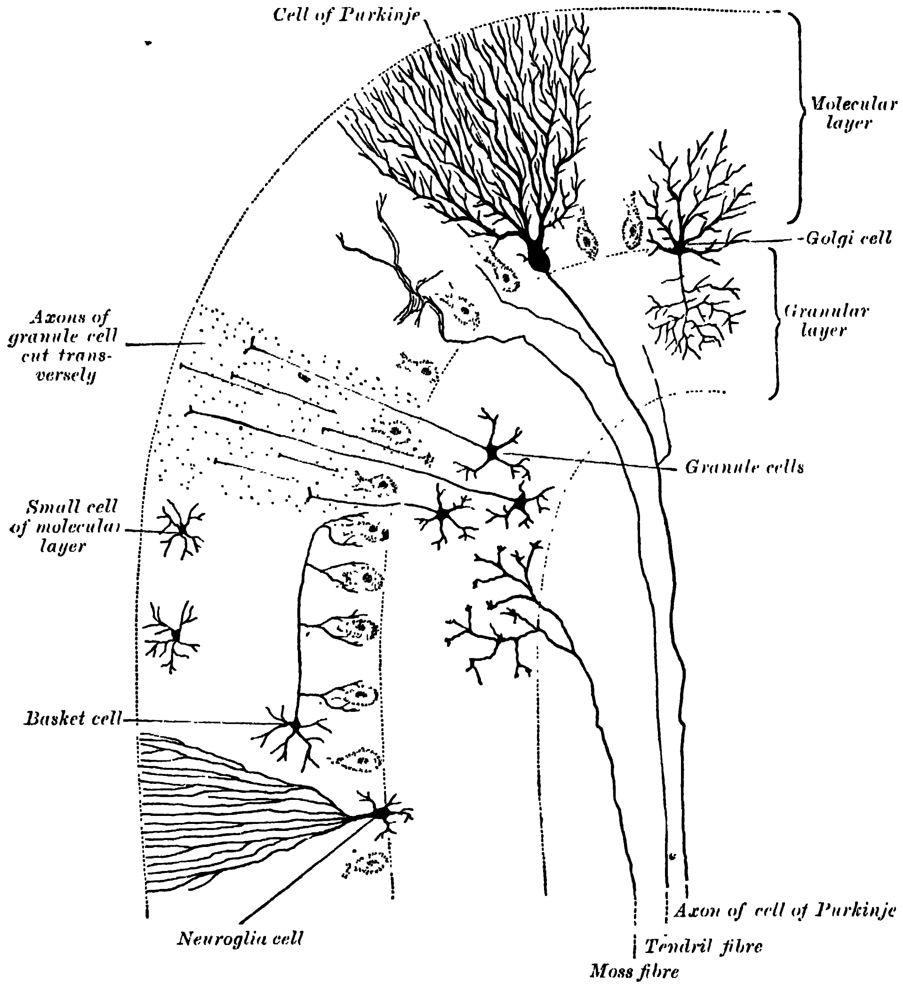
* Strictly speaking, each inferior peduncle consists of an inner and an outer segment, the latter of which is the restiform body.

The **fibræ propriæ** of the cerebellum are of two kinds: (1) *commissural fibres*, which cross the middle line to connect the opposite halves of the cerebellum, some at the anterior part, and others at the posterior part of the vermiform process; (2) *arcuate* or *association fibres*, which connect adjacent laminæ with each other.

Grey matter.—The grey matter of the cerebellum is found in two situations: (1) on the surface, forming the cortex; (2) as independent masses in the interior.

(1) The **grey matter of the cortex** presents a characteristic foliated appearance, due to the series of laminæ which are given off from the central

FIG. 707.—Transverse section of a cerebellar folium. (Diagrammatic, after Cajal and Kölliker.)



white matter; these in their turn give off secondary laminæ, which are covered with grey matter. This arrangement gives to the cut surface of the organ a foliated appearance (fig. 706). Externally, the cortex is covered by pia mater; internally is the medullary centre, consisting mainly of nerve-fibres.

Microscopic appearance of the cortex.—The cortex consists of two distinct layers, viz. an external grey molecular layer, and an internal rust-coloured granular layer. Between the two layers is an incomplete stratum of cells which are characteristic of the cerebellum, viz. the *cells of Purkinje.*

The *external grey* or *molecular layer* (fig. 707) consists of fibres and cells. The nerve-fibres are delicate fibrillæ, and are derived from the following

sources : (*a*) the dendrites and axon-collaterals of Purkinje's cells ; (*b*) fibres from cells in the granular layer ; (*c*) fibres from the central white substance of the cerebellum ; (*d*) fibres derived from cells in the molecular layer itself. In addition to these are other fibres, which have a vertical direction. These are the processes of large neuroglia-cells, situated in the granular layer. They pass outwards to the periphery of the grey matter, where they expand into little conical enlargements which form a sort of limiting membrane beneath the pia mater, analogous to the membrana limitans interna in the retina, formed by the fibres of Müller.

The *cells of the molecular layer* are small, and are arranged in two strata, an outer and an inner. They all possess branched axis-cylinder processes ; those of the inner layer run for some distance horizontally--i.e. parallel with the surface of the folium—giving off collaterals, which pass in a vertical direction towards the cell-bodies of Purkinje's corpuscles, around which they become enlarged, and form a basket-like network. Hence these cells of the inner layer are named *basket-cells.*

The *cells of Purkinje* form a single stratum of large, flask-shaped cells situated at the junction of the molecular and granular layers, their bases resting against the latter ; in fishes and reptiles they are arranged in several layers. The cells are flattened in a direction transverse to the long axis of the folium, and thus appear broad in sections carried across the folium, and fusiform in sections parallel to the long axis of the folium. From the neck of the flask one or more dendrites arise and pass into the molecular layer, where they subdivide and form an extremely rich arborescence, the various subdivisions of the dendrites being covered by lateral spine-like processes. This arborescence is not circular, but, like the cell, is flattened at right angles to the long axis of the folium ; in other words, it does not resemble a round bush, but has been aptly compared by Obersteiner to the branches of a fruit tree trained against a trellis or a wall. Hence, in sections carried across the folium the arborescence is broad and expanded ; whereas in those which are parallel to the long axis of the folium, the arborescence, like the cell itself, is seen in profile, and is limited to a narrow area.

From the bottom of the flask-shaped cell the axon arises ; this passes through the granular layer, and, becoming medullated, is continued as a nerve-fibre in the subjacent white substance. This axon as it passes through the granular layer gives off fine collaterals some of which run back into the molecular layer.

The *internal rust-coloured, granular,* or *nuclear, layer* (fig. 707) is characterised by containing numerous small nerve-cells or granules of a reddish-brown colour, together with many nerve-fibrils. Most of the cells are nearly spherical and provided with short dendrites which spread out in a spider-like manner in the granular layer. Their axons pass outwards into the molecular layer, and, bifurcating at right angles, run horizontally for some distance. In the outer part of the granular layer are some larger cells, of the type termed *Golgi cells.* Their axons undergo frequent division as soon as they leave the nerve-cells, and pass into the granular layer ; while their dendrites ramify chiefly in the molecular layer.

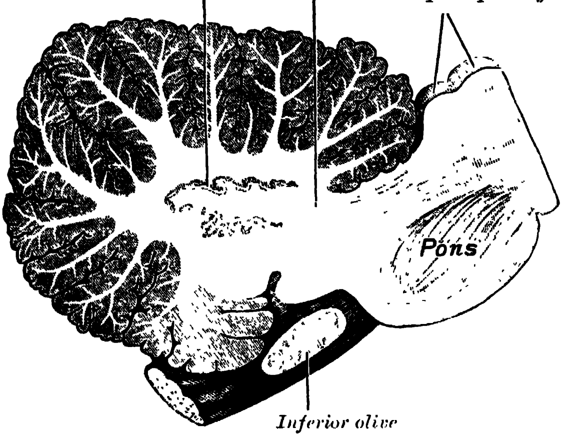
Finally, in the grey matter of the cerebellar cortex, there are fibres which come from the white centre and penetrate the cortex. The cell-origin of these fibres is unknown, though it is believed that it is probably in the grey matter of the spinal cord. Some of these fibres end in the granular layer by dividing into numerous branches, on which are to be seen peculiar moss-like appendages ; hence they have been termed by Ramón y Cajal the *moss-fibres* ; they form an arborescence around the cells of the granular layer. Other fibres derived from the medullary centre can be traced into the molecular layer, where their branches cling around the dendrites of Purkinje's cells, and hence they have been named the *clinging* or *tendril fibres.*

(2) The **independent centres of grey matter** in the cerebellum are four in number on either side : one is of large size, and is known as the nucleus dentatus ; the other three, much smaller, are situated near the middle of the cerebellum, and are known as the nucleus emboliformis, nucleus globosus, and nucleus fastigii.

The *nucleus dentatus* (fig. 708) is situated a little to the inner side of the centre of the stem of the white matter of the hemisphere. It consists of an irregularly folded lamina, of a greyish-yellow colour, containing white fibres, and presenting on its antero-internal aspect an opening, the hilus, from which most of the fibres of the superior cerebellar peduncle emerge.

The *nucleus emboliformis* lies immediately to the inner side of the corpus dentatum, and partly covering its hilus. The *nucleus globosus* is an elongated mass, directed antero-posteriorly, and placed to the inner side of the preceding. The *nucleus fastigii*, or roof nucleus of Stilling, is somewhat larger than the other

FIG. 708.—Sagittal section through right cerebellar hemisphere. The right olivary body has also been cut sagittally.



two, and is situated close to the middle line at the anterior end of the superior vermiform process, and immediately over the roof of the fourth ventricle, from which it is separated by a thin layer of white matter.

Weight of the cerebellum.—Its average weight in the male is about 5 oz. 4 drs. It attains its maximum between the twenty-fifth and fortieth years; its increase after the fourteenth year being relatively greater in the female than in the male. The proportion between the cerebellum and cerebrum is, in the male, as 1 to 8·2, and in the female as 1 to 8. In the infant the cerebellum is proportionately much smaller than in the adult, the relation between it and the cerebrum being, according to Cruveilhier, 1 to 20.

Applied Anatomy.—The general functions of the cerebellum in the human economy appear to be the co-ordination of movements and equilibration. The exact functions of its different parts are still quite uncertain, owing to the contradictory nature of the evidence furnished by (1) ablation experiments upon animals, and (2) clinical observations in man of the effects produced by abcesses or tumours affecting different portions of the organ. According to W. A. Turner, 'The following localising symptoms would therefore indicate the presence of a tumour implicating the right cerebellar hemisphere and middle peduncle: deafness in the right ear, unassociated with middle ear complications; an unsteady and uncertain gait, with a tendency to fall more particularly to the right side; coarse nystagmoid oscillations on looking to the right; movements resembling those of disseminated sclerosis on volitional effort of the right arm; an awkward uncertain action of the right leg; a slight increase of the right knee-jerk; and, perhaps, slight blunting of sensibility over the right cornea and side of the face.'

THE FOURTH VENTRICLE

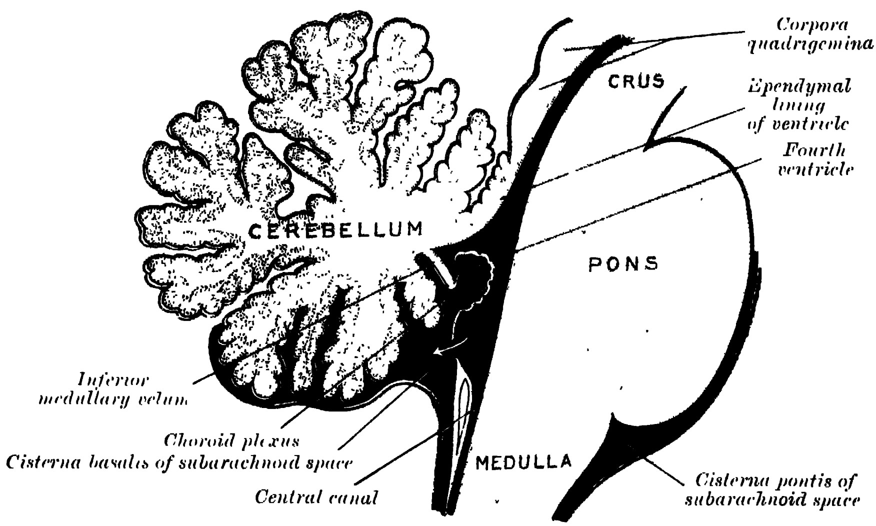
The **fourth ventricle** (ventriculus quartus), or cavity of the hind-brain, is situated in front of the cerebellum and behind the pons Varolii and upper half of the medulla oblongata. It is lined by ciliated epithelium, and is continuous below

with the central canal of the medulla oblongata ;* above, it communicates, by means of a passage termed the aqueduct of Sylvius, with the cavity of the third ventricle. It presents four angles, and possesses a roof or dorsal wall, a floor or ventral wall, and lateral boundaries.

Angles.—The *superior angle* is on a level with the upper border of the pons Varolii, and is continuous with the lower end of the aqueduct of Sylvius. The *inferior angle* is on a level with the lower end of the olivary body, and opens into the central canal of the medulla oblongata. Each *lateral angle* corresponds with the point of meeting of the three cerebellar peduncles. A little below the lateral angles, on a level with the striæ acusticæ, the ventricular cavity is prolonged outwards in the form of two narrow passages, one on either side. These are named the *lateral recesses*, and are situated between the restiform bodies and the flocculi, reaching as far as the attachments of the glosso-pharyngeal and vagi nerves.

Lateral boundaries.—The lower part of each lateral boundary is constituted by the clava, the fasciculus cuneatus, and the restiform body ; the upper part by the superior cerebellar peduncle.

FIG. 709.—Scheme of roof of fourth ventricle.



The arrow is in the foramen of Majendie.

Roof or dorsal wall (fig. 709).—The upper portion of the roof is formed by the superior cerebellar peduncles and the valve of Vieussens ; the lower portion, by the inferior medullary velum, the epithelial lining of the ventricle covered by the tela chorioidea inferior, the ligulæ and the obex.

The *superior peduncles*, on emerging from the central white substance of the cerebellum, pass upwards and forwards, forming at first the lateral boundaries of the upper part of the cavity ; but on approaching the inferior quadrigeminal bodies, they converge, and their mesial portions overlap the cavity and form part of its roof,

The *superior medullary velum* (velum medullare anterius) (page 831) fills in the angular interval between the superior peduncles, and is continuous behind with the central white substance of the cerebellum ; it is covered on its dorsal aspect by the lingula of the superior vermis.

The *inferior medullary velum* (velum medullare posterius) (page 831) is continued downwards and forwards from the central white substance of the cerebellum in front of the nodule and amygdalæ, and ends inferiorly in a thin,

* J. T. Wilson (*Journal of Anatomy and Physiology*, vol. xl.) has pointed out that the central canal of the medulla, immediately below its entrance into the fourth ventricle, retains the cleft-like form presented by the fœtal spinal canal, and that it is marked by dorso- and ventro-lateral sulci.

concave, somewhat ragged margin. Below this margin the roof is devoid of nervous matter except in the immediate vicinity of the lower lateral boundaries of the ventricle, where two narrow white bands, the *ligulæ*, appear; these bands meet over the inferior angle of the ventricle in a thin triangular lamina, the *obex*. The non-nervous part of the roof is formed by the *epithelial lining of the ventricle*, which is prolonged downwards as a thin membrane (*membrana tectoria*), from the deep surface of the inferior medullary velum to the corresponding surface of the obex and ligulæ, and thence on to the floor of the ventricular cavity. It is covered and strengthened by a portion of the pia mater, which is named the *tela chorioidea ventriculi quarti*.

The *ligulæ* are two narrow bands of white matter, one on either side, which complete the lower part of the roof of the ventricle. Each consists of an inner vertical and an outer horizontal part. The vertical part is continuous below the obex, and is adherent by its outer border to the clava; the horizontal portion extends transversely outwards across the restiform body, below the striæ acusticæ, and roofs in the lower and posterior part of the lateral recess. It is attached by its lower margin to the restiform body, and partly encloses the choroid plexus, which, however, projects beyond it like a cluster of grapes; and hence this part of the ligula has been termed the *cornucopia* (Bochdalek). The *obex* is a thin, triangular, grey lamina, which roofs in the lower angle of the ventricle and is attached by its lateral margins to the clavæ.* The *tela chorioidea ventriculi quarti* is the name applied to the triangular fold of pia mater which is carried upwards between the cerebellum and the medulla oblongata. It consists of two layers, which are continuous with each other in front, and are more or less adherent throughout. The posterior layer covers the antero-inferior surface of the cerebellum, while the anterior is applied to the structures which form the lower part of the roof of the ventricle, and is continuous inferiorly with the pia mater on the restiform bodies and closed part of the medulla.

Choroid plexuses.—These consist of two highly vascular inflexions of the tela chorioidea inferior, which invaginate the lower part of the roof of the ventricle. Each consists of a vertical and a horizontal portion: the former lies close to the middle line, and the latter passes into the lateral recess and projects beyond its apex; they are everywhere covered by the epithelial lining of the ventricle. The vertical parts of the plexuses are distinct from each other, but the horizontal portions are joined in the middle line; and hence the entire structure presents the form of the letter T, the vertical limb of which, however, is double.

Openings in the roof.—In the roof of the fourth ventricle there are three openings in the pia mater and subjacent epithelium: one of these, the *foramen of Majendie*, is situated in the middle line immediately above the inferior angle of the ventricle; the other two (*foramina of Luschka*, or *foramina of Key and Retzius*) are found at the extremities of the lateral recesses. By means of these three foramina the cavity of the ventricle communicates with the subarachnoid space, and the cerebro-spinal fluid can pass from the ventricle into this space, or *vice versa*.

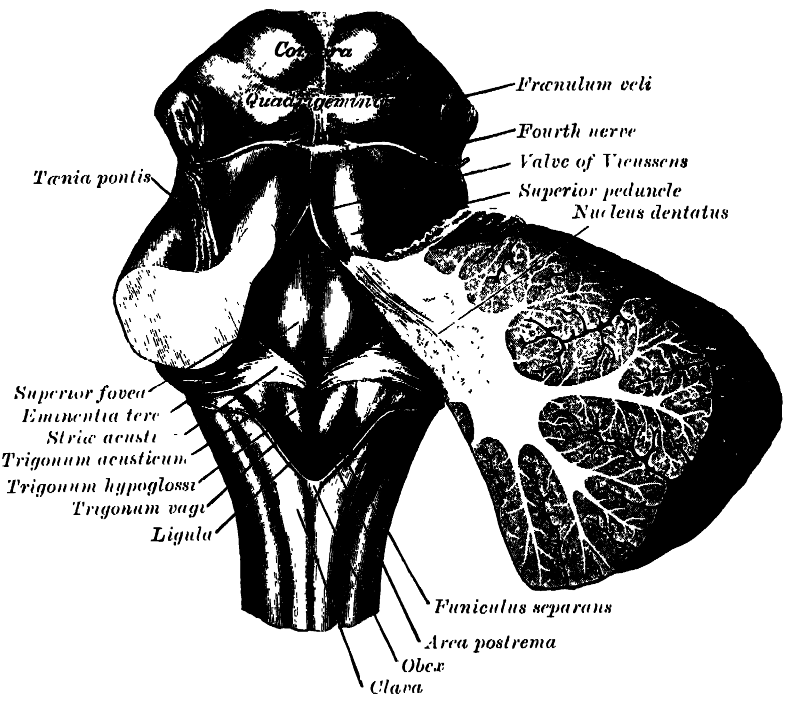
Floor or ventral wall (fig. 710).—This is rhomboidal in shape, its upper portion being formed by the dorsal surface of the pons Varolii, and its lower by the corresponding surface of the open part of the medulla oblongata. It is covered by a layer of grey matter continuous with the grey matter of the spinal cord; superficial to this is a thin lamina of neuroglia, which constitutes the ependyma of the ventricle and supports a layer of ciliated epithelium. It is traversed by a median sulcus, which divides it into symmetrical halves, and it is crossed at the level of the lateral recesses by a number of white strands, named the *striæ acusticæ*. These form a portion of the cochlear division of the auditory nerve, and vary greatly in different brains as to their direction and prominence; they sweep round the outer aspect of the restiform body, extend inwards on the floor of the ventricle, and disappear by passing into the median

* J. T. Wilson, *op. cit.*, recognises two forms of obex: (*a*) the *true obex*, constituted by a medullary thickening of the roof plate, and (*b*) a *false or membranous obex* where the medullary thickening fails to take place, and where the roof plate is represented only by the ependymal layer clothing the ventral surface of a pial reduplication which forms the main substance of

sulcus. They divide the floor into two triangular areas, an upper and a lower, which correspond, approximately, to the portions of the floor which are formed by the back of the pons and medulla respectively.

Below the striæ acusticæ, at a short distance from the median sulcus, on either side, is a small triangular depression, the *inferior fovea*, the apex of which is directed upwards, while its sides are prolonged downwards as divergent furrows. The inner of these furrows is carried towards the lower angle of the ventricle, the outer towards its lateral wall; and in this manner three small triangular areas are marked off on either side of the middle line. That which lies between the diverging furrows of the fovea is darker in colour than the other two, and is named the *ala cinerea* or *trigonum vagi*; it corresponds with the position of the sensory nuclei of the vagus and glosso-pharyngeal nerves. The base of the trigonum vagi is crossed by a narrow translucent elevation named the *funiculus separans*, between which and the clava is a small tongue-shaped area, the *area postrema*. On section, it is seen that the funiculus separans is formed by a strip of thickened ependyma, and that the area postrema is

Fig. 710.—Floor of fourth ventricle.



occupied by a loose highly vascular myelospongium, and contains neurons of a moderate size. The area which lies between the inner limb of the fovea and the median sulcus is termed the *trigonum hypoglossi*; its base, directed upwards, is continuous with an elevation, the *eminentia teres*, which lies above the striæ acusticæ; its apex forms with that of the opposite side a pointed elevation, the *calamus scriptorius*. When examined under water with a lens, the trigonum vagi is seen to consist of a mesial and a lateral area separated from one another by a series of oblique furrows; the mesial area corresponds with the ventricular part of the nucleus of the hypoglossal nerve, the lateral with a small-celled nucleus, the *nucleus intercalatus*. The third area, that on the outer side of the fovea inferior, is named the *trigonum acusticum*, and corresponds with one of the chief nuclei of the auditory nerve. Its base is directed upwards, and is continuous with a larger eminence, termed the *eminentia* or *area acusiica*, which is crossed by the striæ acusticæ.

In each half of that part of the floor of the ventricle which lies above the striæ acusticæ, a small depression, the *superior fovea*, is seen. Between it and

the median sulcus is an elongated eminence, the *eminentia teres*, which overlies the nucleus of the sixth nerve, and is, in part at least, produced by the ascending portion of the root of the seventh nerve. This eminence becomes less distinct above, while below it is continuous with the trigonum hypoglossi. Outside the superior fovea is the prominence of the *area acustica* (already referred to); and above it is a bluish, depressed spot, the *locus cœruleus*, which owes its colour to an underlying patch of deeply pigmented nerve-cells, termed the *substantia ferruginosa*, in which a part of the sensory root of the fifth nerve terminates.

THE MID-BRAIN

The **mid-brain, or mesencephalon** (fig. 711), is the short, constricted portion which connects the pons Varolii and cerebellum with the thalamencephalon and cerebral hemispheres. It is directed upwards and forwards, and consists of: (1) a ventro-lateral portion, composed of a pair of cylindrical bodies, named the *crura cerebri*; (2) a dorsal portion, consisting of four rounded eminences, named the *corpora quadrigemina*; and (3) an intervening passage or tunnel, the *aqueduct of Sylvius*, which represents the original cavity of the mid-brain and connects the third with the fourth ventricle.

The **crura cerebri** (pedunculi cerebri) are two cylindrical masses situated at the base of the brain, and largely hidden by the temporal lobes of the cerebrum, which must be drawn aside or removed in order to expose them. They emerge from the upper surface of the pons Varolii, one on either side of the middle line, and, diverging as they pass upwards and forwards, disappear into the substance of the cerebral hemispheres. The depressed area between the crura is termed the *locus perforatus posticus* or *fossa interpeduncularis*, and consists of a layer of greyish matter (substantia perforata posterior) which is pierced by numerous small apertures for the transmission of blood-vessels. Its lower part lies on the ventral aspect of the mesial portions of the tegmenta, and contains a nucleus named the *ganglion interpedunculare* (page 840); its upper part assists in forming the floor of the third ventricle. The ventral surface of each crus is crossed from within outwards by the superior cerebellar and posterior cerebral arteries; its lateral surface is in relation to the uncinate convolution of the cerebral hemisphere

and is crossed from behind forwards by the fourth nerve. Close to its point of disappearance into the cerebral hemisphere, the optic tract winds forwards around its ventro-lateral surface. The inner surface of the crus forms the lateral boundary of the posterior part of a space known as the interpeduncular space, and is marked by a longitudinal furrow, the *oculo-motor sulcus*, from which the roots of the third or oculo-motor nerve emerge. On the outer surface of each crus there is a second longitudinal furrow, termed the *sulcus lateralis*, which is prolonged downwards between the superior and middle cerebellar peduncles. The fibres of the lateral fillet come to the surface in

this sulcus, and pass backwards and upwards, to disappear under the lower quadrigeminal body.

Structure of the crura cerebri (figs. 713, 714).—On transverse section, each crus is seen to consist of a dorsal and a ventral part, separated by a deeply pigmented lamina of grey matter, termed the *substantia nigra*. The dorsal part is named the *tegmentum*; the ventral, the *crusta* or *pes*; the two crustæ are separated from each other, but the tegmenta are joined in the mesial plane by a forward prolongation of the raphe of the pons Varolii. Laterally, the tegmenta are free, and are constituted by the fibres of the lateral fillet; dorsally, they blend with the corpora quadrigemina.

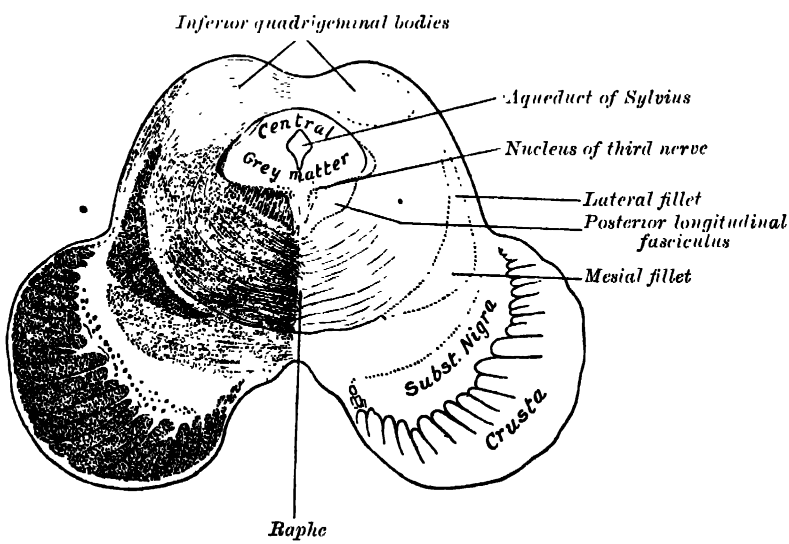
The **crusta**, or **pes** (basis pedunculi) is semilunar on transverse section, and consists almost entirely of longitudinal bundles of efferent fibres, which arise from the cells of the cerebral cortex and are grouped into three principal sets, viz. pyramidal, geniculate, and cortico-pontine (fig. 712). The *pyramidal* fibres occupy the middle three-fifths of the crusta, and are continued downwards through the pons into the pyramid of the medulla. The *geniculate* fibres—so named because they are situated in the knee-shaped bend of the internal capsule—occupy the inner fifth of the crusta, and terminate, after decussating with the corresponding fibres of the other side, in the motor nuclei of the cranial nerves. The *cortico-pontine* fibres terminate below in the nuclei pontis, and consist of anterior and posterior

FIG. 713.—Transverse section of mid-brain at level of inferior quadrigeminal bodies.

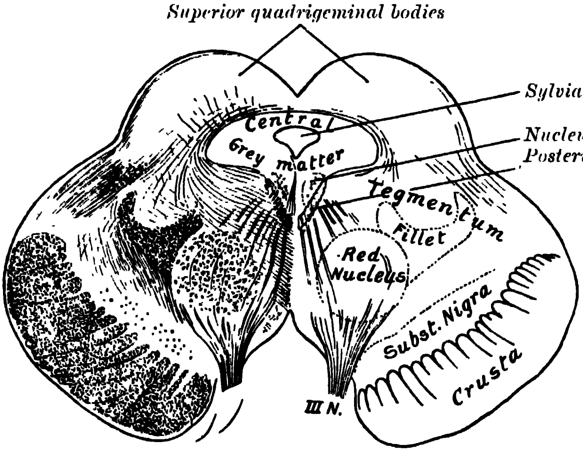


groups. The fibres of the posterior group arise in the temporal and occipital lobes, and occupy the outer fifth of the crusta; while those of the anterior group take origin in the frontal lobe, and are disseminated among the pyramidal and geniculate fibres. On the dorsal aspect of the cortico-pontine fibres a strand of the mesial fillet passes up in the crusta.*

The **substantia nigra** is a layer of grey matter containing numerous deeply pigmented, multipolar nerve-cells. Like the crusta, it is semilunar on transverse section, its concavity being directed towards the tegmentum; from its convex aspect, prolongations extend downwards between the fibres of the crusta. Thicker internally than externally, it reaches from the oculo-motor sulcus to the lateral sulcus, and extends from the upper surface of the pons to the subthalamic region; its inner part is traversed by the fibres of the third nerve as these stream forwards to reach the oculo-motor sulcus. The connections of the substantia nigra have not been definitely established.

The **tegmentum** is continuous below with the reticular formation of the pons, and, like it, consists of longitudinal and transverse fibres, together with a considerable amount of grey matter. The principal grey masses of the

FIG. 714.—Transverse section of mid-brain at level of superior quadrigeminal bodies.



tegmentum are the red nucleus and the ganglion interpedunculare; of its fibres the chief longitudinal tracts are the superior cerebellar peduncle, the posterior longitudinal fasciculus, and the fillet.

Grey matter.—The *red nucleus* (nucleus ruber) is situated in the anterior part of the tegmentum, and is continued upwards into the posterior part of the subthalamic region. In sections at the level of the upper quadrigeminal body it appears as a circular mass which is traversed by the fibres of the third nerve. Most of the fibres of the superior cerebellar peduncle terminate in it (page 831). The axons of its larger cells cross the middle line and are continued downwards into the lateral column of the spinal cord as the rubrospinal tract or tract of Monakow; those of its smaller cells end mainly in the thalamus.

The *ganglion interpedunculare* is a median collection of nerve cells situated in the ventral part of the tegmentum. The fibres of the fasciculus retroflexus of Meynert, which have their origin in the cells of the ganglion habenulæ (page 849), end in it.

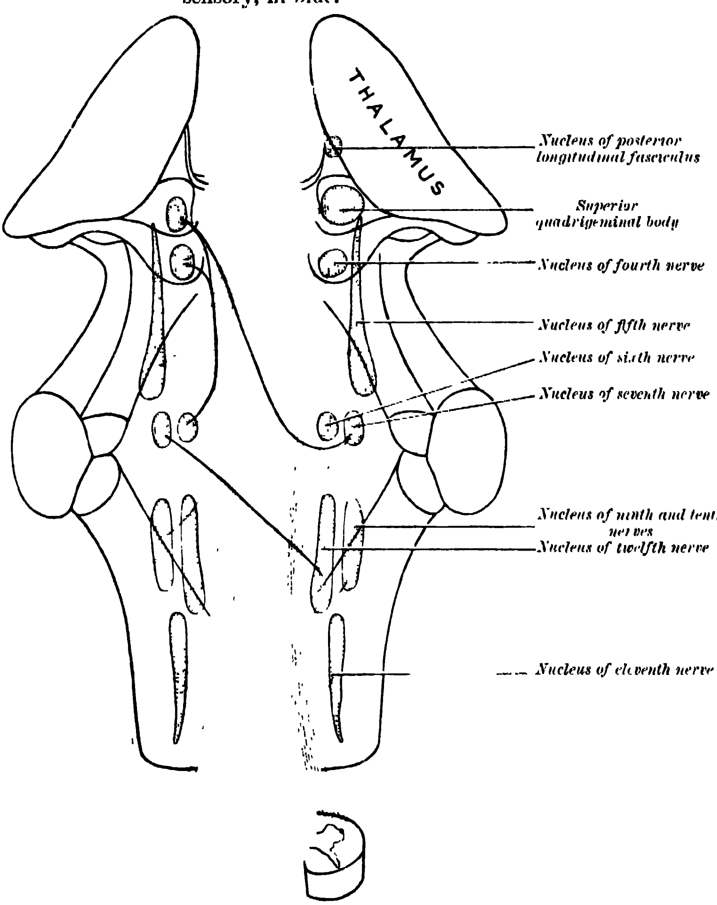
Besides the two nuclei mentioned, there are small collections of cells which form the dorsal and ventral nuclei and the central nucleus or nucleus of the raphe.

* A band of fibres, the *tractus peduncularis transversus*, is sometimes seen emerging from in front of the upper quadrigeminal body; it passes round the ventral aspect of the crus about midway between the pons and the optic tract, and dips into the oculomotor sulcus. This band is a constant structure in many mammals, but is only present in about thirty per cent. of human brains. Since it undergoes atrophy after enucleation of the eyeballs, it may be considered as forming a path for visual sensations.

White matter.—(1) The origin and course of the *superior cerebellar peduncle* have already been described (page 830).

(2) The *dorsal* or *posterior longitudinal fasciculus* (fig. 715) is continuous below with the antero-lateral ground-bundle of the spinal cord; and has been traced by Edinger as far as a nucleus, the *nucleus of the posterior longitudinal fasciculus*, situated in the hypothalamus, immediately in front of the aqueduct of Sylvius. In the medulla oblongata and pons, it runs close to the middle line, near the floor of the fourth ventricle; in the mid-brain, it is situated on the ventral aspect of the Sylvian aqueduct, below the nuclei of the third and fourth nerves. Its connections are imperfectly known, but it consists largely of ascending and descending intersegmental or association fibres, which connect the various nuclei of the mid- and hind-brains to each other. Many of the descending

FIG. 715.—Scheme of the posterior longitudinal fasciculus; motor fibres in red, sensory, in blue.

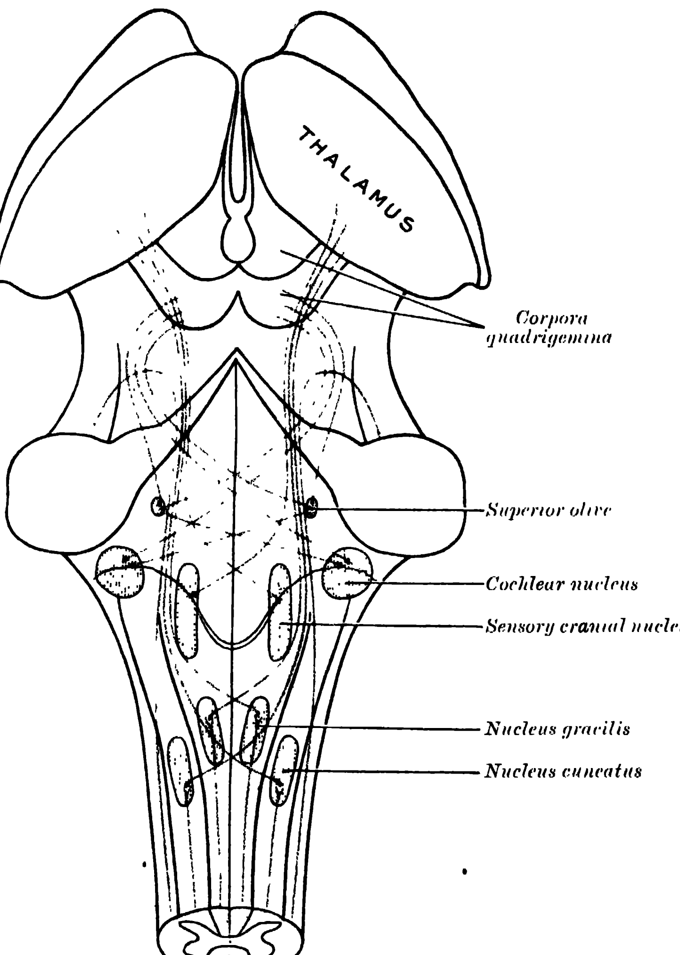


fibres arise in the superior quadrigeminal body, and, after decussating in the middle line, terminate in the motor nuclei of the pons and medulla. The ascending fibres arise from the cells of the grey matter of the upper part of the cord, and from the nuclei in the medulla and pons, and pass, without undergoing decussation, to the higher nuclei. Fibres are also carried through the posterior longitudinal fasciculus from the nucleus of the sixth nerve into the third nerve of the opposite side, and through this nerve to the Internal rectus of the eyeball. Again, fibres are said to be prolonged through this fasciculus from the nucleus of the third nerve into the seventh nerve, and are distributed to the Orbicularis palpebrarum, the Corrugator supercilii, and the Occipito-frontalis.*

* A. Bruce and J. H. Harvey Pirrie, 'On the Origin of the Facial Nerve,' *Review of Neurology and Psychiatry*, vol. vi. No. 12, December 1908, produce weighty evidence against the view that the facial nerve derives fibres from the nucleus of the third nerve.

(3) *The fillet* or *lemniscus* (fig. 716).—The fibres of the fillet have been seen to take origin in the gracile and cuneate nuclei of the medulla oblongata, and to cross to the opposite side in the sensory decussation (page 816). They then pass upwards through the medulla, in which they are situated behind the pyramidal fibres and between the olivary bodies. Here they are joined by the fibres of Gowers' ascending tract, these having already undergone decussation in the spinal cord. As the fillet ascends, it receives additional fibres from the terminal nuclei of the sensory nerves of the opposite side. In the pons, it assumes a flattened, ribbon-like appearance, and is placed on the dorsal aspect of the trapezium. In the mid-brain, its outer part is folded backwards and

FIG. 716.—Scheme showing the course of the fibres of the fillet; mesial fillet in blue, lateral fillet in red.



forms nearly a right angle with its mesial portion; and hence it is customary to speak of the fillet as consisting of lateral and mesial parts.

The *lateral fillet* (lemniscus lateralis) has been seen to come to the surface of the mid-brain along its lateral sulcus, and to disappear under the inferior quadrigeminal body. It consists of fibres which are derived from the terminal nuclei of the cochlear division of the auditory nerve, together with others which arise within the superior olive and the trapezoid nucleus. Most of these fibres are crossed, but some are uncrossed. Many of them pass to the inferior quadrigeminal body of the same or opposite side; but others are prolonged to the thalamus, and thence through the posterior part of the internal capsule to the middle and superior temporal convolutions.

The *mesial fillet* (lemniscus medialis) comprises that portion of the fillet which commences in the gracile and cuneate nuclei of the opposite side, and which is joined by Gowers' tract and by fibres from the terminal nuclei of the sensory nerves of the opposite side, excepting the cochlear division of the auditory. In the crus cerebri, a few of its fibres pass upwards in the outer part of the pes or crusta, on the dorsal aspect of the cortico-pontine fibres, and reach the lenticular nucleus and the island of Reil. The greater part of the mesial fillet, on the other hand, is prolonged through the tegmentum, and most of its fibres end in the thalamus; probably some are continued directly through the posterior part of the internal capsule to the cerebral cortex. From the cells of the thalamus a relay of fibres is prolonged to the cerebral cortex.

Besides these three tracts, there are the *tecto-spinal tract* from the upper quadrigeminal body and the *rubro-spinal tract* from the red nucleus; these tracts cross the middle line and are continued downwards into the spinal cord.

The **corpora quadrigemina** are four rounded eminences which form the dorsal part of the mid-brain. They are situated above and in front of the valve of Vieussens and superior peduncles of the cerebellum, and below and behind the third ventricle and posterior commissure. They are covered by the splenium of the corpus callosum, and are partly overlapped on either side by the inner angle, or pulvinar, of the posterior end of the thalamus; on their lateral aspect, under cover of the pulvinar, is an oval eminence, named the *internal geniculate body*. The corpora quadrigemina are arranged in pairs (upper and lower), and are separated from one another by a crucial sulcus. The longitudinal part of this sulcus expands superiorly to form a slight depression which supports the *pineal body*, a cone-like structure which projects backwards from the thalamencephalon and partly obscures the upper quadrigeminal bodies. From the lower end of the longitudinal sulcus, a white band, termed the *frænulum veli*, is prolonged downwards to the valve of Vieussens; on either side of this band the fourth cranial nerve emerges, and passes forwards on the lateral aspect of the crus to reach the base of the brain. The *upper pair* (colliculi superiores) are larger and darker in colour than the lower, and are oval in shape. The *lower pair* (colliculi inferiores) are hemispherical, and somewhat more prominent than the upper. The upper quadrigeminal bodies are associated with the sense of sight, the lower with that of hearing. From the lateral aspect of each of the four bodies, a white band, termed the *brachium*, is prolonged upwards and forwards. The *superior brachium* (brachium quadrigeminum superius) extends outwards from the upper quadrigeminal body, and, passing between the pulvinar and internal geniculate body, is partly continued into an eminence called the external geniculate body, and partly into the outer portion of the optic tract. The *inferior brachium* (brachium quadrigeminum inferius) passes forwards and upwards from the lower quadrigeminal body, and disappears under cover of the internal geniculate body.

In close relationship with the corpora quadrigemina are the *superior peduncles of the cerebellum*, which emerge from the upper and mesial part of the cerebellar hemispheres. They run upwards and forwards, and, passing under the corpora quadrigemina, enter the tegmenta as already described (page 830).

Structure of the corpora quadrigemina.—The *lower* quadrigeminal body consists of a compact nucleus of grey matter containing large and small multipolar nerve-cells, and more or less completely surrounded by white fibres derived from the lateral fillet. Most of these fibres end in the grey nucleus of the same side, but some cross the middle line and terminate in that of the opposite side. From the cells of the grey nucleus, fibres are prolonged through the inferior brachium into the tegmentum of the crus cerebri, and are carried to the optic thalamus and the cortex of the temporal lobe; other fibres cross the middle line and end in the opposite quadrigeminal body.

The *upper* quadrigeminal body is covered by a thin stratum of white fibres, termed the *stratum zonale*, the majority of whose fibres are derived from the optic tract. Beneath this is the *stratum cinereum*, a layer of grey matter which resembles a cap: it is semilunar in shape, thicker in the centre than at the margins, and consists of numerous multipolar nerve-cells, for the most part of small size, imbedded in a fine network of nerve-fibres. Still deeper is the *stratum opticum*, which contains large multipolar nerve-cells, separated by

numerous fine nerve-fibres. Finally, there is the *stratum lemnisci*, which consists of fibres derived partly from the fillet and partly from the cells of the stratum opticum; interspersed among these fibres are many large multipolar nerve-cells. The two last-named strata are sometimes termed the *grey-white layers*, from the fact that they consist of both grey and white matter. Of the afferent fibres which reach the superior quadrigeminal body, some are derived from the fillet, but the majority have their origin in the retina and are conveyed to it through the superior brachium; all of them terminate by arborising around the cells of the grey matter. Of the fibres which arise from the cells of the grey matter, some cross the middle line to the opposite quadrigeminal body; many ascend through the superior brachium, and finally reach the cortex of the occipital lobe of the cerebrum; while others, after undergoing decussation (the *fountain decussation of Meynert*) form the tecto-spinal tract which descends through the formatio reticularis of the mid-brain, pons, and medulla into the spinal cord, where it is found partly in the anterior column and partly intermingled with the fibres of the rubro-spinal tract.

The corpora quadrigemina are larger in the lower animals than in man. In fishes, reptiles, and birds, they are hollow, and only two in number (corpora bigemina); they represent the superior quadrigeminals of mammals, and are frequently termed the optic lobes, because of their intimate connection with the optic tracts.

The **aqueduct of Sylvius** (aquæductus cerebri) is a narrow canal, about fifteen millimetres in length, situated between the corpora quadrigemina and tegmenta, and connecting the third with the fourth ventricle. Its shape, as seen in transverse sections, varies at different levels, being T-shaped below, triangular above, and oval in the middle. The central part is slightly dilated, and was named by Retzius the *ventricle of the mid-brain*. It is lined by ciliated columnar epithelium, and is surrounded by a layer of grey matter named the *central grey matter* (stratum griseum centrale) of the aqueduct: this is continuous below with the grey substance in the floor of the fourth ventricle, and above with that of the third ventricle. Dorsally, it is partly separated from the grey matter of the quadrigeminal bodies by the fibres of the lemniscus; ventral to it are the posterior longitudinal fasciculus, and the formatio reticularis of the tegmentum. Scattered throughout its grey matter are numerous nerve-cells of various sizes, interlaced by a network of fine fibres. Besides these scattered cells it contains three groups which constitute the nuclei of the third and fourth nerves, and the nucleus of the Sylvian or mesencephalic root of the fifth nerve. The *nucleus of the fifth nerve* extends along the entire length of the aqueduct, and occupies the outer part of the grey substance, while those of the third and fourth are situated in its ventral part. The *nucleus of the third nerve* measures about ten millimetres in length, and lies under the upper quadrigeminal body, beyond which, however, it extends for a short distance into the grey matter of the third ventricle. The *nucleus of the fourth nerve* is small and nearly circular, and is on a level with a plane carried transversely through the upper part of the lower quadrigeminal body.

THE FORE-BRAIN

The **fore-brain** consists of: (1) the *diencephalon* or *inter-brain*, which corresponds in a large measure to the third ventricle and the structures which bound it; and (2) the *telencephalon*, which comprises the largest part of the brain, viz. the cerebral hemispheres; these hemispheres are intimately connected with each other across the middle line, and each contains a large cavity, named the lateral ventricle. The lateral ventricles communicate through the foramen of Monro with the third ventricle, but are separated from each other by a mesial septum; this contains a slit-like cavity, the so-called fifth ventricle, which, however, has no communication with the other brain ventricles.

The Diencephalon

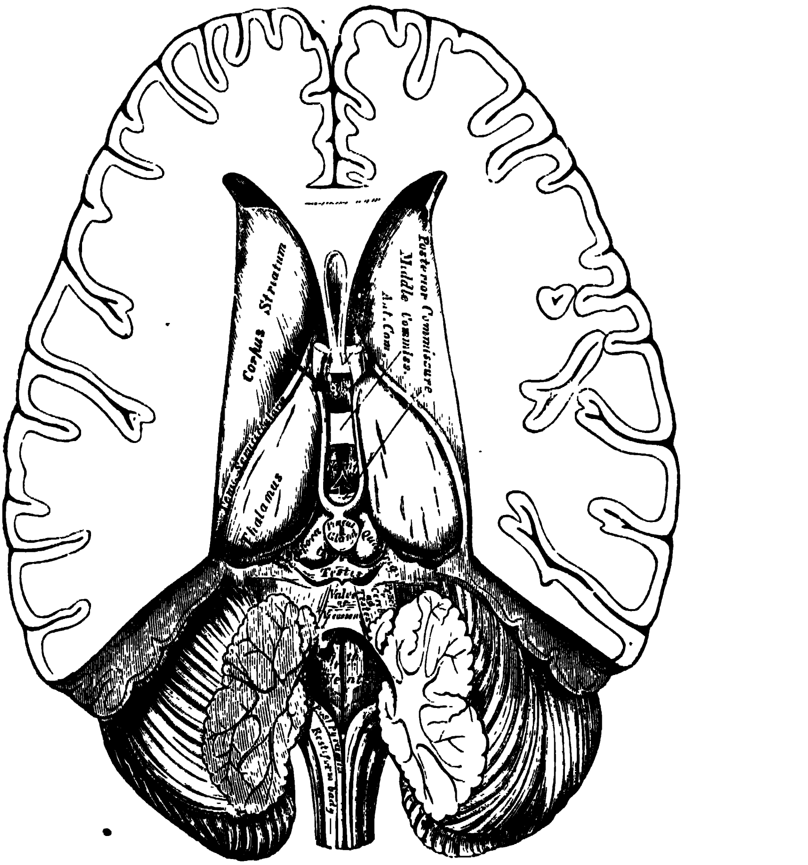
The **diencephalon** or **inter-brain** is connected above and in front with the cerebral hemispheres; behind with the mid-brain. Its upper surface

is concealed by the corpus callosum, and is covered by a fold of pia mater, named the velum interpositum; inferiorly it reaches to the base of the brain.

The diencephalon comprises: (1) the thalamencephalon: (2) the pars mamillaria hypothalami; and (3) the posterior part of the third ventricle. For descriptive purposes, however, it is more convenient to consider the whole of the third ventricle and its boundaries together: this necessitates the inclusion, under this heading, of the pars optica hypothalami and the corresponding part of the third ventricle—structures which properly belong to the telencephalon.

The **thalamencephalon** consists of: (1) the thalamus: (2) the metathalamus or corpora geniculata; and (3) the epithalamus, which comprises the trigonum habenulæ, the pineal body, and the posterior commissure.

FIG. 717.—The third and fourth ventricles.



The lower arrow has been placed in the aqueduct of Sylvius; the upper points to the foramen of Monro.

The **thalami** or **optic thalami** (figs. 717, 718) are two large ovoid masses, situated one on either side of the third ventricle and reaching for some distance behind that cavity. Each measures about an inch and a half in length, and presents two extremities, an anterior and posterior, and four surfaces, superior, inferior, internal, and external.

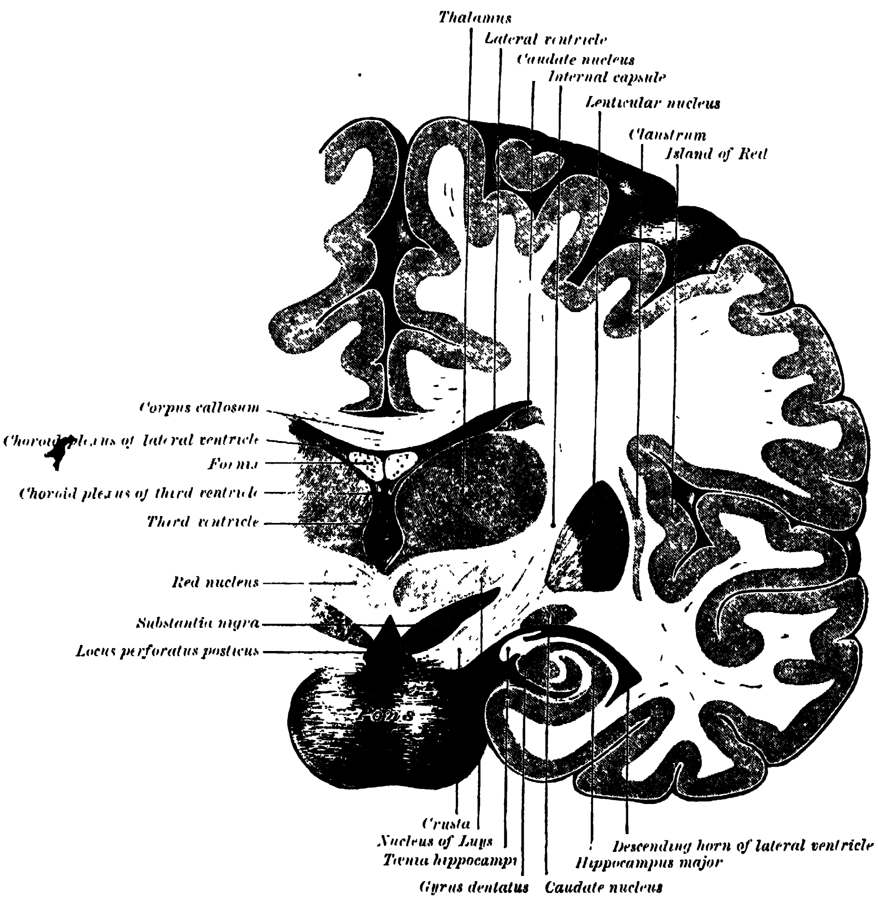
The *anterior extremity* is narrow, directed forwards and inwards, and lies close to the middle line, where it forms the posterior boundary of the foramen of Monro.

The *posterior extremity* is expanded, directed backwards and outwards, and overlaps the superior quadrigeminal body. Internally, it presents a well-marked angular prominence, the *posterior tubercle* or *pulvinar*, which

is continued externally into an oval swelling, the *external geniculate body*, while beneath the pulvinar, but separated by the superior brachium, is a second oval swelling, the *internal geniculate body*.

The *superior surface* is free, slightly convex, and covered by a layer of white matter, termed the *stratum zonale*. It is separated externally from the caudate nucleus by a white band named the *tænia semicircularis*, and by the *vein of the corpus striatum*. It is divided into an inner and an outer portion by an oblique shallow furrow which runs from behind forwards and inwards and corresponds with the outer margin of the fornix. The part on the outer side of the furrow forms a portion of the floor of the lateral ventricle, and is covered by the epithelial lining of this cavity. The part on the inner side is covered by the velum interpositum, and excluded from the lateral and

FIG. 718.—Coronal section of brain immediately in front of pons.



third ventricles, and is therefore destitute of an epithelial covering. In front, it is separated from the internal surface by a salient margin in which are contained the fibres of the stria pinealis, and along which the epithelial lining of the third ventricle is reflected on to the under surface of the velum interpositum. Behind, it is limited internally by a groove, the *sulcus habenulæ*, which intervenes between it and a small triangular area, termed the *trigonum habenulæ*.

The *inferior surface* rests upon and is continuous with the upward prolongation of the tegmentum (*subthalamic tegmental region*), in front of which it is related to the *substantia innominata of Meynert*.

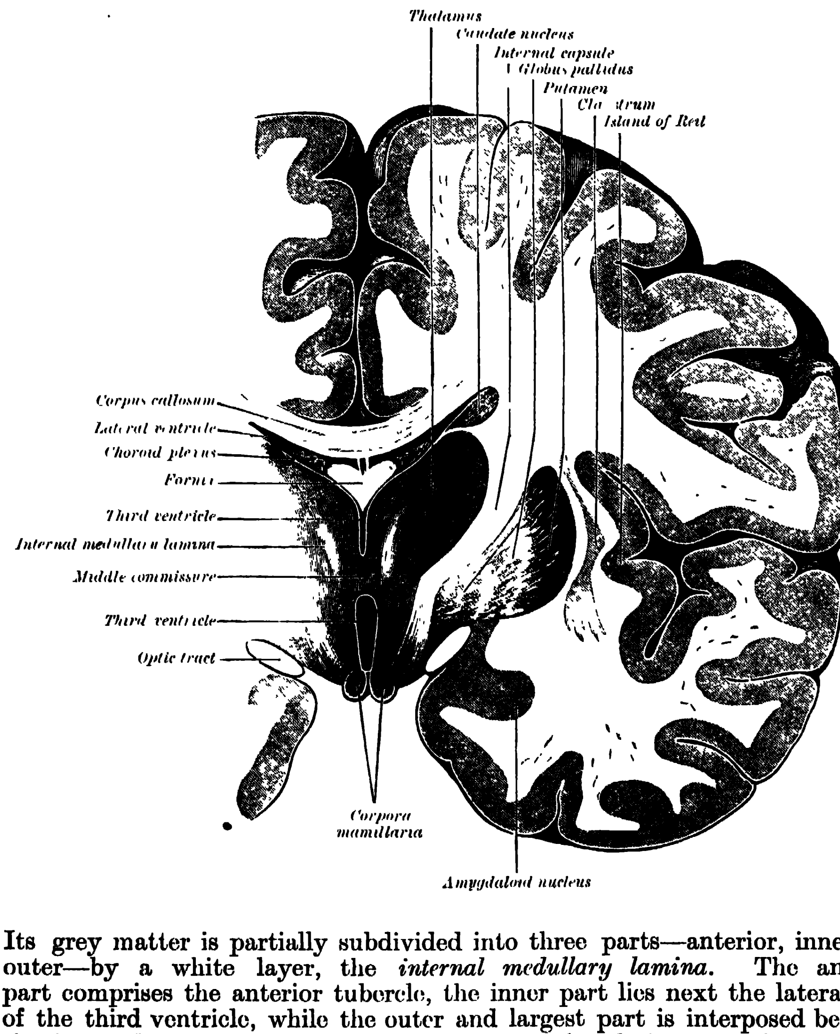
The *internal surface* constitutes the upper part of the lateral wall of the third ventricle, and is connected to the corresponding surface of the opposite

thalamus by a flattened grey band, the *middle* or *grey commissure.* This commissure averages about one-third of an inch in its antero-posterior diameter: it sometimes consists of two parts and occasionally is absent. It contains nerve-cells and nerve-fibres: a few of the latter may cross the middle line, but most of them pass towards the middle line and then curve outwards on the same side.

The *external surface* is in contact with a thick band of white matter which forms the posterior limb of the internal capsule and separates the thalamus from the lenticular nucleus of the corpus striatum.

Structure.—The thalamus consists chiefly of grey matter, but its upper surface is covered by a layer of white matter, named the *stratum zonale*, and its outer surface by a similar layer termed the *external medullary lamina.*

FIG. 719.—Coronal section of brain through middle commissure.

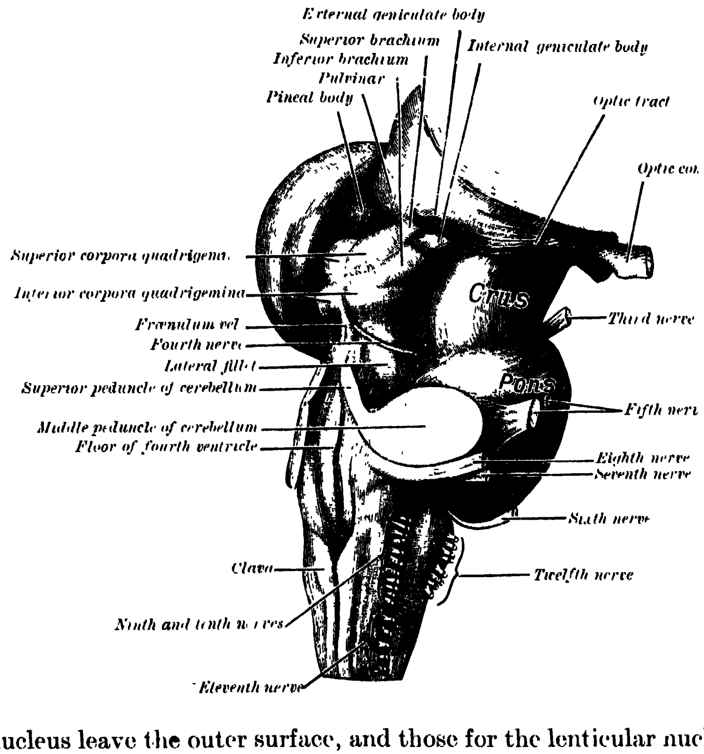


Its grey matter is partially subdivided into three parts—anterior, inner and outer—by a white layer, the *internal medullary lamina.* The anterior part comprises the anterior tubercle, the inner part lies next the lateral wall of the third ventricle, while the outer and largest part is interposed between the internal and external medullary laminæ and includes the pulvinar. The outer part is traversed by numerous fibres which radiate from the thalamus into the internal capsule, and pass through the latter to the cerebral cortex. These three parts are built up of numerous nuclei, the connections of many of which are imperfectly known.

Connections.—The thalamus may be regarded as a large ganglionic mass in which the ascending tracts of the tegmentum and a considerable proportion of the fibres of the optic tract end, and from the cells of which

numerous fibres (thalamo-cortical) take origin, and radiate to almost every part of the cerebral cortex. The fillet, together with the other longitudinal strands of the tegmentum, enters its ventral part: the bundle of Vicq d'Azyr, from the corpus albicans, ends in its anterior tubercle, while many of the fibres of the optic tract terminate in its posterior extremity. The thalamus also receives numerous fibres (cortico-thalamic) from the cells of the cerebral cortex. The fibres which arise from the cells of the thalamus form four principal groups or stalks: (*a*) those of the *anterior stalk* pass through the anterior limb of the internal capsule to the frontal lobe; (*b*) the fibres of the *posterior stalk* or *optic radiations* arise in the pulvinar and are conveyed through the extreme posterior part of the internal capsule to the occipital lobe; (*c*) the fibres of the *inferior stalk* leave the under and mesial surfaces of the thalamus, and pass outwards beneath the lenticular nucleus to end in the temporal lobe and island of Reil; (*d*) those of the *parietal stalk* pass from the outer nucleus of the thalamus to the parietal lobe. Fibres also extend from the thalamus into the corpus striatum—those destined for the caudate

Fig. 720.—Postero-lateral view of the hind- and mid-brains.



nucleus leave the outer surface, and those for the lenticular nucleus, the inferior surface of the thalamus.

The **metathalamus** (fig. 720) comprises the corpora geniculata, which are two in number—an internal and an external—on each side and have already been referred to in connection with the posterior extremity of the thalamus.

The *internal geniculate body* (corpus geniculatum mediale) lies under cover of the pulvinar of the thalamus and on the lateral aspect of the corpora quadrigemina. Oval in shape, with its long axis directed forwards and outwards, it is lighter in colour and smaller in size than the external. The inferior brachium from the lower quadrigeminal body disappears under cover of it, while from its outer extremity a strand of fibres passes to join the optic tract. Entering it are many acoustic fibres from the lateral fillet. The internal geniculate bodies are connected with one another by the commissure of Gudden, which passes through the posterior part of the optic commissure.

The *external geniculate body* (corpus geniculatum laterale) forms an oval elevation on the outer part of the posterior extremity of the thalamus, and

is connected internally with the upper quadrigeminal body by the superior brachium. It is of a dark colour, and presents a laminated arrangement consisting of alternate layers of grey and white matter. It receives numerous fibres from the optic tract, while other fibres of this tract pass over or through it into the pulvinar. Its cells are large and pigmented; their axons pass to the visual area in the occipital part of the cerebral cortex.

The upper quadrigeminal body, the pulvinar and the external geniculate body receive many fibres from the optic tracts, and are therefore intimately connected with sight, constituting what are termed the *lower visual centres.* Extirpation of the eyes in newly born animals entails an arrest of the development of these centres, but has no effect on the internal geniculate or lower quadrigeminal bodies. Moreover, the latter are well-developed in the mole, an animal in which the upper quadrigeminal body is rudimentary.

The **epithalamus** comprises the trigonum habenulæ, the pineal body, and the posterior commissure.

The *trigonum habenulæ* is a small depressed triangular area situated in front of the upper quadrigeminal body and on the lateral aspect of the posterior part of the stria pinealis. It contains a group of nerve-cells termed the *ganglion habenulæ.* Fibres enter it from the stria pinealis, and others, forming what is termed the *superior commissure* (commissura habenularum), pass across the middle line to the corresponding ganglion of the opposite side. Most of its fibres are, however, directed downwards and form a bundle, the *fasciculus retroflexus* of Meynert, which passes on the mesial side of the red nucleus, and, after decussating with the corresponding fasciculus of the opposite side, ends in the ganglion interpedunculare.

The *pineal body* (corpus pineale) is a small, conical, reddish-grey body which lies in the depression between the upper quadrigeminal bodies. It is placed beneath the splenium of the corpus callosum, but is separated from this by the velum interpositum, the lower layer of which envelops it. It measures about one-third of an inch in length, and its base, directed forwards, is attached by a stalk or peduncle of white matter. The *stalk* of the pineal body divides anteriorly into two laminæ, a dorsal and a ventral, separated from one another by the recessus pinealis of the third ventricle. The ventral lamina is continuous with the posterior commissure; the dorsal lamina is continuous with the commissura habenularum and divides into two strands, named the striæ medullares, which run forwards, one on either side, along the junction of the mesial and upper surfaces of the thalamus to blend in front with the anterior pillars of the fornix.

Structure.—The pineal body is destitute of nervous matter, and consists of follicles lined by epithelium and enveloped by connective tissue. These follicles contain a variable quantity of gritty material named *brain sand,* composed of phosphate and carbonate of calcium, phosphate of magnesia and ammonia, and a little animal matter.

The pineal body is generally believed to be the homologue of the pineal eye of lizards. In these animals it is attached by an elongated stalk and projects through an aperture in the roof of the cranium. Its extremity lies immediately under the epidermis, and, on microscopic examination, presents in a rudimentary fashion structures similar to those found in the eyeball. Recent observations tend to the conclusion that the pineal body arises as a paired structure, probably serially homologous with the paired eyes.

The *posterior commissure* (commissura posterior) is a rounded band of white fibres which stretches across the middle line on the dorsal aspect of the upper end of the Sylvian aqueduct. Its fibres acquire their medullary sheaths early, but their connections have not been definitely determined. Most of them have their origin in a nucleus, the *nucleus of the posterior commissure* or *nucleus of Darkschewitsch,* which lies in the central grey matter of the upper end of the Sylvian aqueduct, in front of the nucleus of the third nerve. Some are probably derived from the posterior part of the thalamus and the superior quadrigeminal body, while others are believed to be continued downwards into the posterior longitudinal bundle.

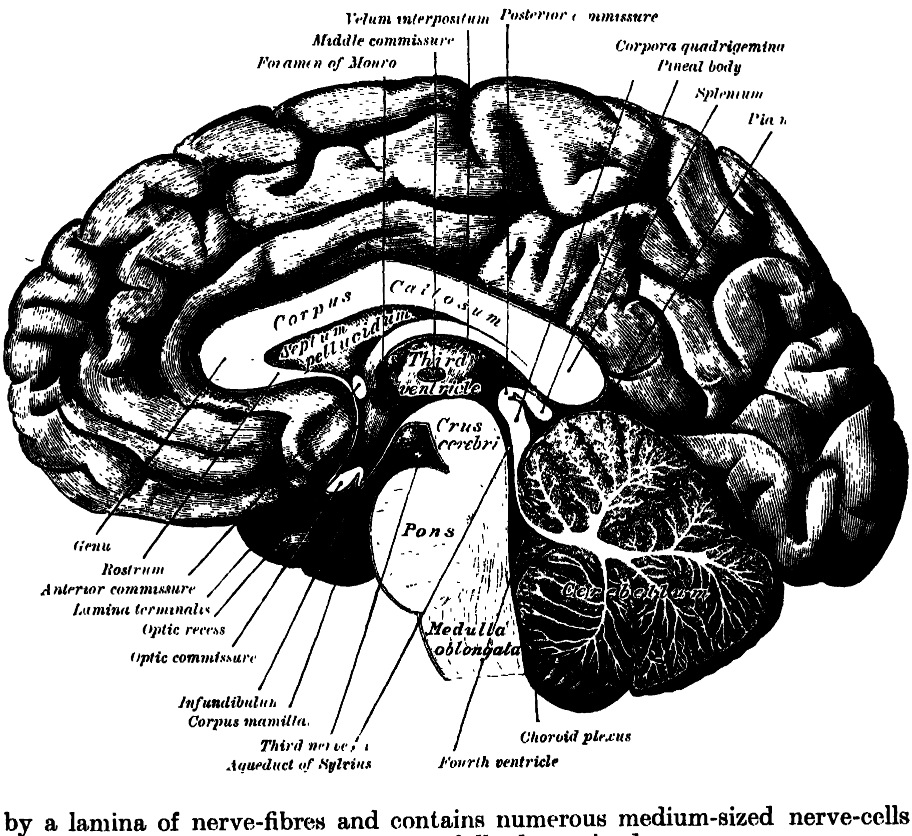
The **hypothalamus** (fig. 721) includes the subthalamic tegmental region and the structures which form the greater part of the floor of the third

ventricle, viz. the corpora mamillaria, tuber cinereum, infundibulum, pituitary body, and optic commissure.

The *subthalamic tegmental region* consists of the upward continuation of the tegmentum, which lies on the ventro-lateral aspect of the thalamus and separates it from the fibres of the internal capsule. The red nucleus and the substantia nigra are prolonged into its lower part; in front it is continuous with the substantia innominata of Meynert, internally with the grey matter of the floor of the third ventricle.

It consists from above downwards of three strata: (1) *stratum dorsale*, directly applied to the under surface of the thalamus and consisting of fine longitudinal fibres; (2) *zona incerta*, a continuation forwards of the formatio reticularis of the tegmentum; and (3) the *corpus subthalamicum* or *nucleus of Luys*, a brownish mass presenting a lenticular shape on transverse section, and situated on the dorsal aspect of the fibres of the crusta; it is encapsuled

FIG. 721.—Mesial sagittal section of brain. The relations of the pia mater are indicated by the red colour.



by a lamina of nerve-fibres and contains numerous medium-sized nerve-cells the connections of which are as yet not fully determined.

The *corpora mamillaria* are two round white masses, each about the size of a small pea, which lie side by side below the grey matter of the floor of the third ventricle in front of the locus perforatus posticus. They consist of white matter externally and of grey matter internally, the cells of the latter forming two nuclei, a *mesial* of smaller and a *lateral* of larger cells. The white matter is mainly formed by the fibres of the anterior pillars of the fornix, which descend to the base of the brain and end partly in the corpora mamillaria. From the cells of the grey matter of each mamillary body two fasciculi arise; one, the bundle of Vicq d'Azyr, passes upwards into the anterior nucleus of the thalamus; the other is directed downwards into the tegmentum. Afferent fibres are believed to reach the corpus mamillare from the mesial fillet and from the tegmentum.

The *tuber cinereum* is a hollow eminence of grey matter situated between the corpora mamillaria behind, and the optic commissure in front. Laterally it is continuous with the grey matter of the anterior perforated spaces and anteriorly with a thin lamina, the *lamina terminalis*. From the under surface of the tuber cinereum a hollow conical process, the *infundibulum*, projects downwards and forwards and is attached to the posterior lobe of the pituitary body.

In the lateral part of the tuber cinereum is a nucleus of nerve-cells, the *basal optic nucleus of Meynert*, while close to the cavity of the third ventricle are three additional nuclei.

Between the tuber cinereum and the corpora mamillaria a small elevation, with a corresponding depression in the third ventricle, is sometimes seen. Retzius has named it the *eminentia saccularis*, and regards it as the representative of the saccus vasculosus found in this situation in some of the lower vertebrates.

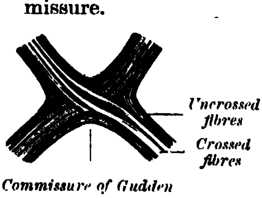
Fig. 722.—The pituitary body, in position. Shown in sagittal section. (Testut.)

Anterior cerebral artery. 9. Basilar artery. 10. Posterior cerebral artery. 11. Corpus albicans. 12. Crus cerebri. 13. Pons Varolii.

The *pituitary body* (hypophysis) (fig. 722) is a reddish-grey, somewhat oval mass, measuring about half an inch in its transverse, and about one-third of an inch in its antero-posterior diameter. It is attached to the extremity of the infundibulum, and is situated in the pituitary fossa of the sphenoid bone, where it is retained by a circular fold of dura mater, the *diaphragma sellæ*. This fold almost completely roofs in the pituitary fossa, leaving only a small central aperture through which the infundibulum passes.

The pituitary body consists of an anterior and a posterior lobe, which differ from one another in their mode of development and in their structure. The *anterior lobe* is the larger, and is somewhat kidney-shaped, the concavity being directed backwards and embracing the posterior lobe. It is developed from a diverticulum of the ectoderm of the primitive buccal cavity or stomatodæum (see page 155). It is highly vascular, and consists essentially of epithelial cells arranged in cord-like trabeculæ or alveoli, the latter sometimes containing a colloid material similar to that found in the alveoli of the thyroid body. The *posterior lobe* is developed as a downgrowth from the floor of the embryonic brain, and during early fœtal life contains a cavity continuous with that of the third ventricle. This cavity undergoes obliteration and, in the adult, the lobe consists of a reticulum of connective tissue with branched cells, some of which contain pigment. In man this lobe contains no nervous elements, but in certain of the lower vertebrates (e.g. fishes) nervous structures are present, and the lobe is of large size.

Fig. 723.—Course of the fibres in the optic commissure.



Optic commissure.—The optic commissure consists of a flattened, somewhat quadrilateral band of fibres, which is situated at the junction of the floor and anterior wall of the third ventricle. Most of its fibres have their origin in the retina, and reach it through the optic nerves, which are continuous with its antero-lateral angles. In the commissure, they undergo a partial decussation (fig. 723): those fibres which come from the nasal or inner half of the retina decussate and enter the optic tract of the opposite side, while the fibres from the temporal or outer half of the retina do not undergo decussation, but pass back

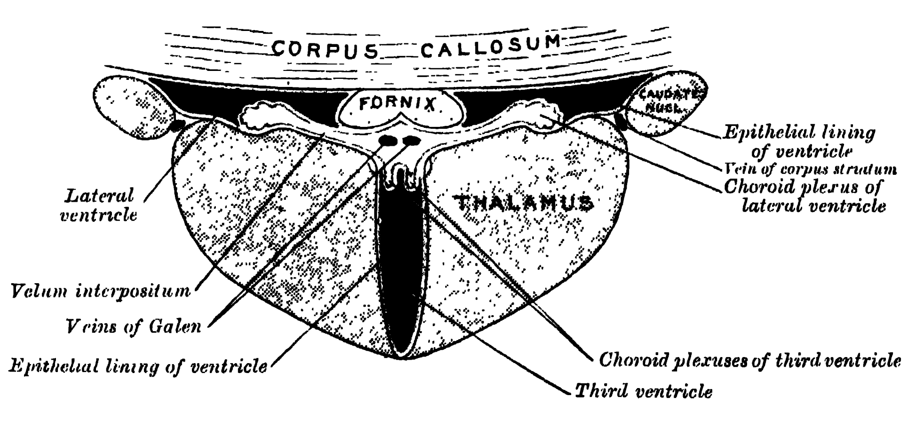
into the optic tract of the same side. Occupying the posterior part of the commissure, however, is a strand of fibres which is not derived from the optic nerves; this constitutes the *commissure of Gudden*, and has already been referred to as forming a connecting link between the internal geniculate bodies.

Optic tracts.—The optic tracts are continued backwards and outwards from the postero-lateral angles of the optic commissure. Each passes between the anterior perforated space and the tuber cinereum, and, winding round the ventro-lateral aspect of the crus cerebri, divides into a mesial and a lateral root. The former comprises the fibres of Gudden's commissure. The lateral root consists mainly of afferent fibres which arise in the retina and undergo partial decussation in the optic commissure, as described; but it also contains a few fine efferent fibres which have their origins in the brain and their terminations in the retina. When traced backwards, the fibres of the lateral root are found to end in the external geniculate body and pulvinar of the optic thalamus, and in the upper quadrigeminal body; and these three structures constitute the *lower visual centres*. Fibres arise from the nerve-cells in these centres, and pass through the hindmost part of the internal capsule, under the name of the *optic radiations*, to the cortex of the occipital lobe of the cerebrum, where the *higher visual centre* is situated. Some of the fibres of the optic radiations take an opposite course, arising from the cells of the occipital cortex and passing to the lower visual centres. Some fibres are detached from the optic tract, and pass through the crus cerebri to the nucleus of the third nerve. These may be regarded as the afferent branches for the Sphincter pupillæ and Ciliary muscles. Other fibres have been described as reaching the cerebellum through its superior peduncles; while others, again, are lost in the pons Varolii.

The Third Ventricle

The **third ventricle** (figs. 717, 721) consists of a median cleft between the two thalami. Behind, it communicates with the fourth ventricle through the aqueduct of Sylvius, and in front with the lateral ventricles through the foramen of Monro. Somewhat triangular in shape, with the apex directed backwards, it presents a roof, a floor, an anterior and a posterior boundary and a pair of lateral walls.

Fig. 724.—Coronal section of lateral and third ventricles. (Diagrammatic.)



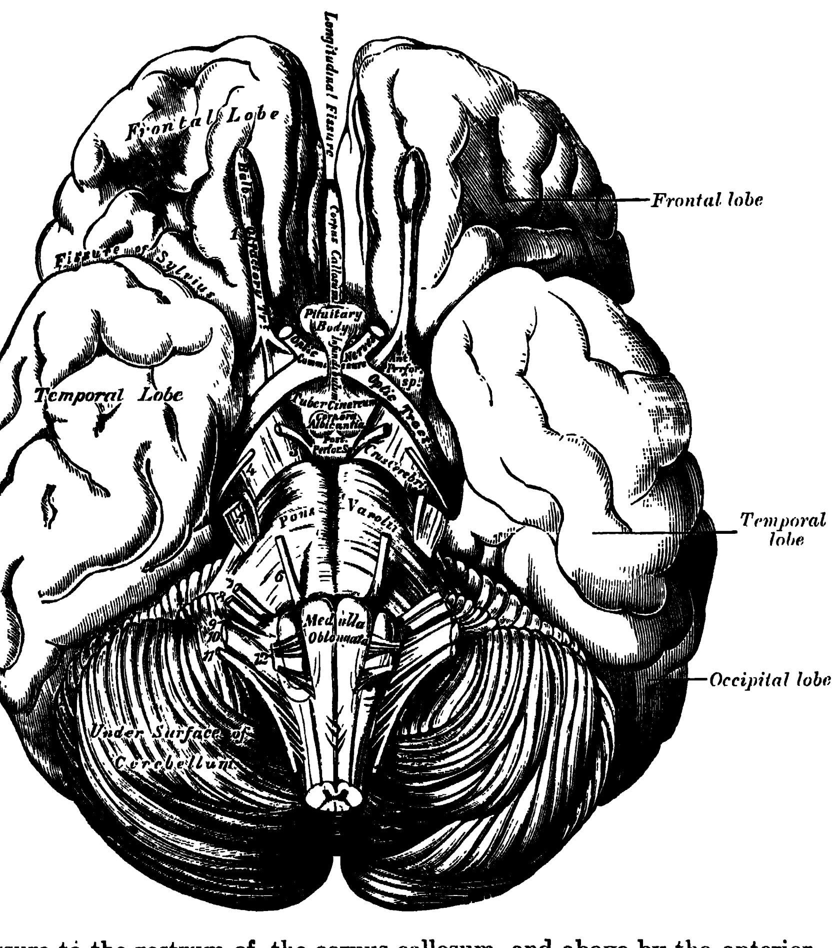
The *roof* (fig. 724) is formed by a layer of epithelium, which stretches between the upper edges of the lateral walls of the cavity and is continuous with the epithelial lining of the ventricle. It is covered by and adherent to a fold of pia mater, named the *velum interpositum*, from the under surface of which a pair of vascular fringed processes, the *choroid plexuses of the third ventricle*, project downwards, one on either side of the middle line, and invaginate the

epithelial roof into the ventricular cavity. When the velum interpositum is reflected, the epithelial roof is torn from its lateral attachments and removed with it, and the cavity of the ventricle is exposed.

The *floor* slopes downwards and forwards and is formed mainly by the structures which constitute the hypothalamus: from before backwards these are, the optic commissure, the tuber cinereum and infundibulum, and the corpora mamillaria. Behind the last, the floor is formed by the locus perforatus posticus and the tegmenta of the crura cerebri. The ventricle is prolonged downwards as a funnel-shaped recess, the *recessus infundibuli*, into the infundibulum, and to the apex of the latter the pituitary body is attached.

The *anterior boundary* is constituted below by the *lamina terminalis*, a thin layer of grey matter which stretches from the upper surface of the optic

FIG. 725.—Base of brain.



commissure to the rostrum of the corpus callosum, and above by the anterior pillars of the fornix and the anterior commissure. At the junction of the floor and anterior wall, immediately above the optic commissure, the ventricle presents a small angular recess or diverticulum, the *optic* or *supra-optic recess*. Between the anterior pillars of the fornix and above the anterior commissure is a second recess termed the *vulva*. At the junction of the roof and anterior wall of the ventricle, and situated between the thalami behind and the anterior pillars of the fornix in front, is the *foramen of Monro* (foramen interventriculare) through which the third communicates with the lateral ventricles.

The *posterior boundary* is constituted by the pineal body, the posterior commissure and the aqueduct of Sylvius. A small recess, the *recessus pinealis*,

projects into the stalk of the pineal body, whilst in front of and above the pineal body is a second recess, the *recessus suprapinealis*, consisting of a diverticulum of the epithelium which forms the ventricular roof.

Each *lateral wall* consists of an upper portion formed by the inner surface of the anterior two-thirds of the thalamus and a lower consisting of an upward continuation of the grey matter of the ventricular floor. These two parts correspond to the alar and basal laminæ respectively of the lateral wall of the fore-brain vesicle and are separated from each other by a furrow, the *sulcus of Monro*, which extends from the foramen of Monro to the aqueduct of Sylvius (see page 122). The lateral wall is limited above by a delicate band of white fibres, the *stria pinealis*, which runs forwards along the junction of the mesial and upper surfaces of the thalamus to join the corresponding anterior pillar of the fornix. The anterior pillars of the fornix curve downwards in front of the foramen of Monro, and then run in the lateral walls of the ventricle, where, at first, they form distinct prominences, but are subsequently lost to sight. The lateral walls are joined to each other by a band of grey matter, the *middle or grey commissure* (massa intermedia), which passes across the cavity of the ventricle. This commissure varies much in size; it is sometimes duplicated and occasionally is absent.

Interpeduncular space (fig. 725).—This is a somewhat lozenge-shaped area of the base of the brain, limited in front by the optic commissure, behind by the antero-superior surface of the pons, antero-laterally by the converging optic tracts and postero-laterally by the diverging crura cerebri. The structures contained in it are, from behind forwards, the locus perforatus posticus, corpora mamillaria, tuber cinereum, infundibulum and pituitary body, all of which have already been described.

THE TELENCEPHALON

The **telencephalon** includes: (1) the cerebral hemispheres with their cavities, the lateral ventricles; and (2) the pars optica hypothalami and the anterior portion of the third ventricle, which have already been described under the diencephalon. As stated in the chapter on Embryology (page 124), each cerebral hemisphere may be divided into three fundamental parts, viz. the rhinencephalon, the corpus striatum and the neopallium. The rhinencephalon, associated with the sense of smell, is the oldest part of the telencephalon, and forms almost the whole of the hemisphere in some of the lower animals (e.g. fishes, amphibians, and reptiles). In man, on the other hand, it is rudimentary, whereas the neopallium undergoes great development and forms by far the larger part of the hemisphere.

THE CEREBRAL HEMISPHERES

The **cerebral hemispheres** constitute the largest part of the encephalon, and, when viewed together from above, assume the form of a large ovoid mass which is broader behind than in front, the greatest transverse diameter corresponding with a line connecting the two parietal eminences. They are separated mesially by a deep cleft, named the *great longitudinal fissure*, and each possesses a central cavity, named the lateral ventricle.

The great longitudinal fissure (fissura longitudinalis cerebri) separates the cerebral hemispheres, and contains a sickle-shaped process of dura mater, the falx cerebri. In front and behind, the fissure extends from the upper to the under surfaces of the hemispheres and completely severs them, but its middle portion only separates them for about one-half of their vertical extent; for at this part they are connected across the middle line by a great central white commissure, the *corpus callosum*.

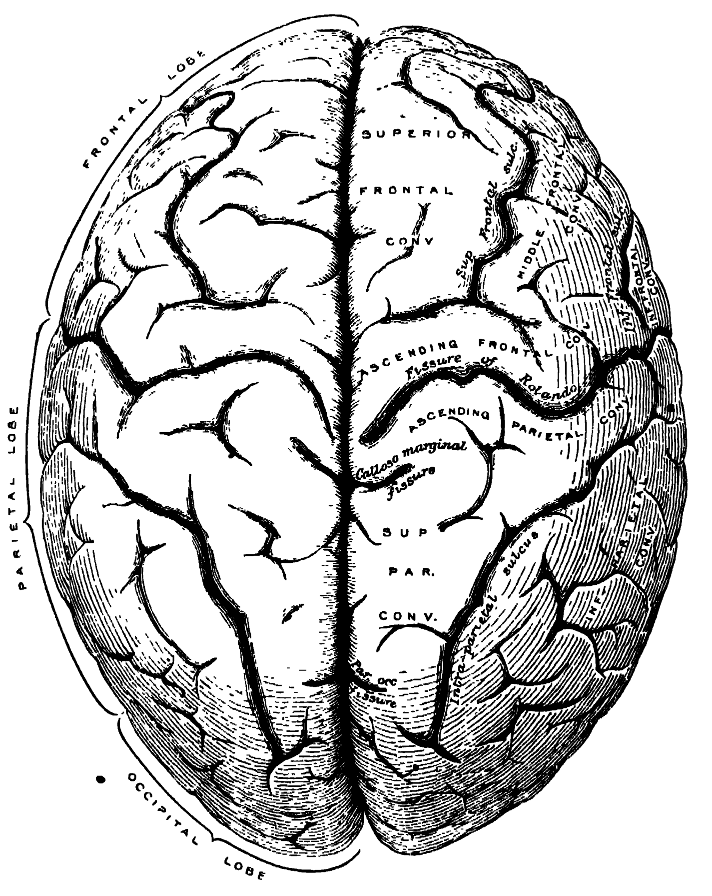
In a median sagittal section (fig. 721) the cut corpus callosum presents the appearance of a broad, arched band. Its thick posterior end, termed the *splenium*, overlaps the mid-brain, but is separated from it by the velum interpositum and the pineal body. Its anterior curved end, termed the *genu*, gradually tapers into a thinner portion, the *rostrum*, which is continued downwards and backwards in front of the anterior commissure to join the lamina terminalis. Arching backwards from immediately behind the anterior

commissure to the under surface of the splenium is a second white band named the *fornix*: between this and the corpus callosum are the laminæ of the septum pellucidum, enclosing between them the cavity of the so-called fifth ventricle.

SURFACES OF THE CEREBRAL HEMISPHERES

Each hemisphere presents three surfaces: an outer, a mesial, and a lower. The *outer surface* is convex in adaptation to the concavity of the corresponding half of the vault of the cranium. The *mesial surface* is flat and vertical, and is separated from that of the opposite hemisphere by the great longitudinal fissure and the falx cerebri. The *lower surface* is of an irregular form, and may be divided into three areas: anterior, middle, and posterior. The anterior area, formed by the orbital surface of the frontal lobe, is concave, and rests on the roof of the orbit and nose; the middle area is convex, and

FIG. 726.—Convolutions and sulci on the upper surface of the cerebral hemispheres.



consists of the under surface of the temporal lobe: it is adapted to the corresponding half of the middle cranial fossa. The posterior area is concave, directed inwards as well as downwards, and is named the *tentorial surface*, since it rests upon the tentorium cerebelli, which intervenes between it and the upper surface of the cerebellum.

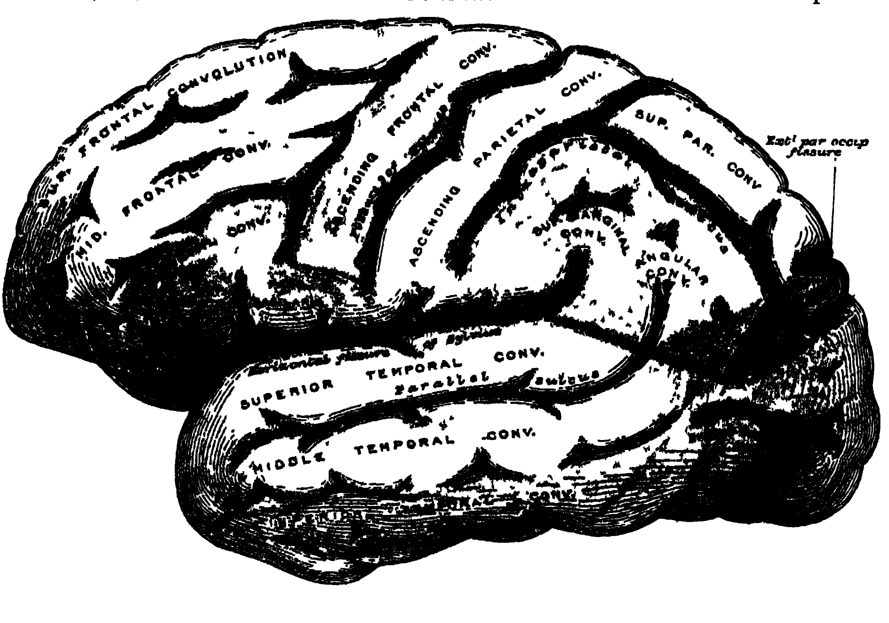
These three surfaces are separated from each other by the following borders: (a) *supero-mesial*, between the outer and mesial surfaces; (b) *infero-lateral*, between the outer and inferior surfaces; the anterior part of this border separating the outer from the orbital surface, is known as the *superciliary border*; (c) *internal occipital*, separating the mesial and tentorial surfaces; and (d) *internal orbital*, separating the orbital from the mesial surface. The

anterior extremity of the hemisphere is named the *frontal pole*; the posterior, the *occipital pole*; and the anterior end of the temporal lobe, the *temporal pole*. About two inches in front of the occipital pole on the infero-lateral border is an indentation or notch, named the *pre-occipital notch*.

The surfaces of the hemispheres are moulded into a number of irregular eminences, named *convolutions* or *gyri*, and these are separated by clefts or furrows, termed *fissures* or *sulci*. The fissures are of two kinds, *complete* and *incomplete*. The former appear early in fœtal life, are few in number, and are produced by infoldings of the entire thickness of the brain-wall, and give rise to corresponding elevations in the interior of the ventricle. They comprise the hippocampal or dentate fissure, and parts of the calcarine and collateral fissures. The incomplete fissures are very numerous, and only indent the central white substance, without producing any corresponding elevations in the ventricular cavity.

The convolutions and their intervening fissures are fairly constant in their arrangement; at the same time they vary within certain limits, not only in different individuals, but on the two hemispheres of the same brain. The convoluted condition of the surface permits of a great increase of the grey

FIG. 727.—Convolutions and sulci on the external surface of the cerebral hemisphere.



matter without the sacrifice of much additional space. The number and extent of the convolutions, as well as the depth of the intervening sulci, appear to bear a direct relation to the intellectual powers of the individual.

Certain of the fissures are utilised for the purpose of dividing the hemisphere into lobes, and are therefore termed *interlobular*; included under this category are the fissure of Sylvius, the fissure of Rolando, the parieto-occipital, calcarine, calloso-marginal, and collateral fissures, and the sulcus circularis of Reil.

The **fissure of Sylvius** (fissura cerebri lateralis) (fig. 727) constitutes a well-marked cleft on the under and outer surfaces of the hemisphere, and consists of a short stem which divides into three limbs. The *stem* is situated on the base of the brain, and commences at the outer angle of the anterior perforated spot, in a depression named the vallecula Sylvii. From this point it extends outwards between the anterior part of the temporal lobe and the orbital surface of the frontal lobe, and reaches the outer surface of the hemisphere. Here it divides into three limbs: an anterior, an ascending, and a posterior. The *anterior limb* (ramus anterior horizontalis) passes forwards for nearly an inch into the inferior frontal convolution, while the *ascending limb* (ramus anterior

ascendens) extends upwards into the same convolution for about an equal distance. The *posterior limb* (ramus posterior) is the longest; it is carried backwards and slightly upwards for about three inches, and terminates by an upward inflexion in the parietal lobe.

The **fissure of Rolando** (sulcus centralis) (figs. 726, 727) is situated about the middle of the outer surface of the hemisphere, and commences in or near the great longitudinal fissure, a little behind its mid-point. It runs sinuously downwards and forwards, and terminates a little above the posterior limb of the fissure of Sylvius, and about an inch behind the ascending limb of the same fissure. It describes two chief curves: an upper or *superior genu* with its concavity directed forwards, and a lower or *inferior genu* with its concavity directed backwards. The fissure of Rolando forms an angle opening forwards, of about seventy degrees with the mesial plane.

The **parieto-occipital fissure** (fissura parietooccipitalis) (fig. 729).—Only a small part of this fissure is seen on the outer surface of the hemisphere, its chief part being situated on the mesial surface. That on the outer surface is usually named the external, and that on the mesial aspect the internal parieto-occipital fissure.

The *external* parieto-occipital fissure is situated about two inches from the posterior extremity or occipital pole of the hemisphere, and extends on to the outer surface for about half an inch.

The *internal* parieto-occipital fissure runs downwards and forwards as a deep cleft on the mesial surface of the hemisphere, and joins the calcarine fissure below and behind the posterior end of the corpus callosum. On separating the lips of this fissure, it will be seen in most cases to contain a submerged convolution.

The **calcarine fissure** (fissura calcarina) (fig. 729) is situated on the mesial surface of the hemisphere. It begins near the occipital pole in a bifid extremity, and runs almost horizontally forward to a point a little below the splenium of the corpus callosum: it is joined at an acute angle by the internal parieto-occipital fissure.

The **calloso-marginal fissure** (sulcus cinguli) (fig. 729) is situated on the mesial surface of the hemisphere; it commences below the anterior end of the corpus callosum and runs upwards and forwards nearly parallel to the rostrum of this body and, curving in front of the genu, is continued backwards above the corpus callosum, and finally ascends to the upper margin of the hemisphere a short distance behind the upper extremity of the fissure of Rolando. It separates the marginal convolution from the callosal convolution.

The **collateral fissure** (fissura collateralis) (fig. 729) is situated on the tentorial surface of the hemisphere, and extends from near the occipital to within a short distance of the temporal pole. Behind, it lies below and to the outer side of the calcarine fissure, from which it is separated by the gyrus lingualis; in front, it is situated between the hippocampal convolution and the anterior part of the temporo-occipital convolution.

The **sulcus circularis of Reil** (fig. 731) is situated on the lower and lateral surfaces of the hemisphere: it surrounds the island of Reil and separates it from the frontal, parietal and temporal lobes.

Lobes of the hemispheres.—By means of these fissures, assisted by certain arbitrary lines, each hemisphere is divided into the following lobes: the *frontal*, the *parietal*, the *temporal*, the *occipital*, the *limbic*, and the *insula*, or *island of Reil*. The first four of these lobes are named after the bones of the skull with which they are chiefly in relation, but it must be borne in mind that their limits do not correspond accurately with the margins of these bones.

Frontal lobe (lobus frontalis).—On the outer surface of the hemisphere this lobe extends from the frontal pole to the fissure of Rolando, the latter separating it from the parietal lobe. Below, it is limited by the posterior limb of the fissure of Sylvius, which intervenes between it and the temporal lobe. On the mesial surface, it is separated from the limbic lobe by the calloso-marginal fissure; and on the under surface, it is bounded behind by the posterior limb of the Sylvian fissure.

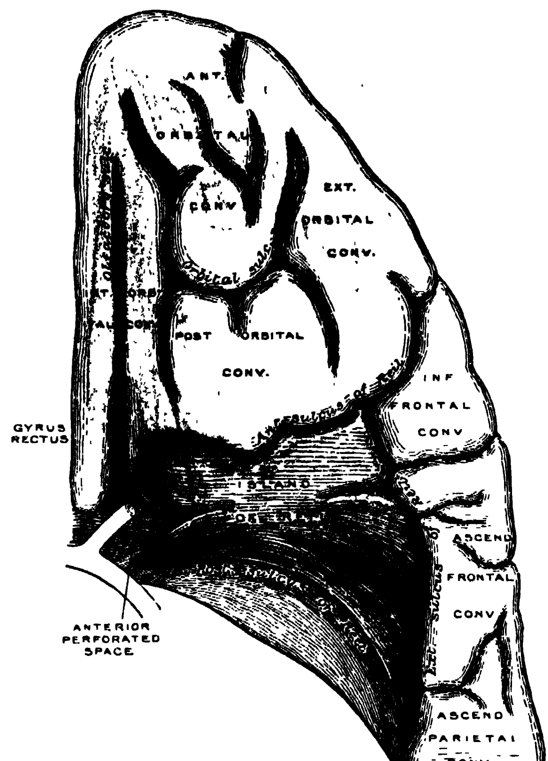
The *outer surface* of the frontal lobe (fig. 727) is traversed by three sulci which divide it into four convolutions: the sulci are named the precentral, and the superior and inferior frontal, while the convolutions are the precentral, and

the superior, middle, and inferior frontal. The *precentral sulcus* runs parallel to the fissure of Rolando, and is usually divided into an upper and a lower part. It forms the anterior limit of a convolution, which lies between it and the fissure of Rolando, and which is called the *precentral convolution.* From it two sulci, the *superior* and *inferior frontal*, run forwards and downwards, and divide the remainder of the outer surface of the lobe into three parallel convolutions, named, respectively, the *superior*, *middle*, and *inferior frontal convolutions.*

The *precentral convolution* (gyrus centralis anterior) is a simple convolution, bounded in front by the precentral sulcus, behind by the fissure of Rolando, and extending from the supero-mesial border of the hemisphere to the posterior limb of the fissure of Sylvius.

The *superior frontal convolution* (gyrus frontalis superior) is situated between the margin of the longitudinal fissure and the superior frontal sulcus.

FIG. 728.—Convolutions and sulci on the under surface of the frontal lobe.



It is continuous on the inner aspect of the hemisphere with the marginal convolution, and on the orbital surface with the internal orbital convolution. It is usually more or less completely subdivided into an upper and a lower part by an antero-posterior sulcus, the *sulcus paramesialis*, which, however, is frequently interrupted by bridging convolutions.

The *middle frontal convolution* (gyrus frontalis medius) is situated between the superior and inferior frontal sulci, and is continuous with the anterior orbital convolution on the lower surface of the hemisphere. It is frequently subdivided into two by a horizontal sulcus which terminates anteriorly in a wide bifurcation, the *sulcus frontalis medius* of Eberstaller.

The *inferior frontal convolution* (gyrus frontalis inferior) is situated below the inferior frontal sulcus, and extends forwards from the lower part of the precentral sulcus; it is continuous with the external and posterior orbital convolutions on the under surface of the lobe. It is subdivided by the anterior

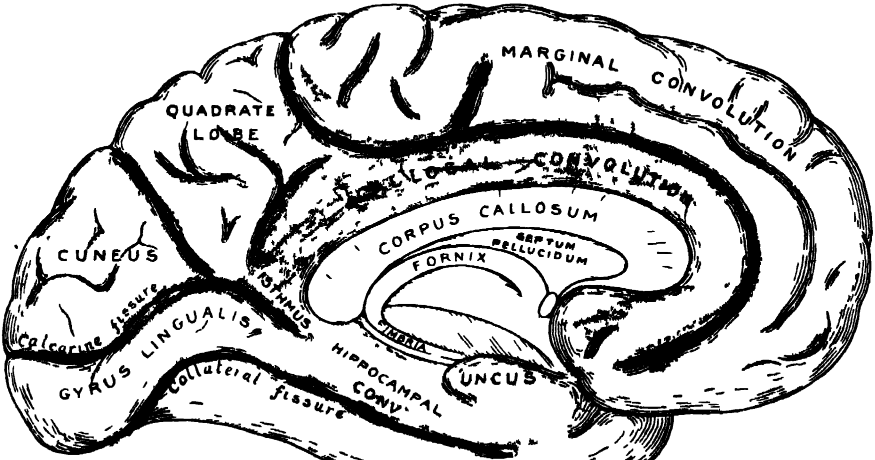
and ascending limbs of the fissure of Sylvius into three parts, viz.: (1) the *pars orbitalis*, below the anterior limb of the fissure; (2) the *pars triangularis* ('cap' of Broca), between the two limbs; and (3) the *pars basilaris*, behind the ascending limb.

The left inferior frontal convolution is, as a rule, more highly developed than the right, and is named the *convolution of Broca*, from the fact that in 1861 Broca discovered that it was the centre for speech.

The *under* or *orbital surface* of the frontal lobe is concave, and rests on the orbital plate of the frontal bone (fig. 728). It is divided into four convolutions (gyri orbitales) by a well-marked H-shaped sulcus, the *sulcus orbitalis*. These are named, from their position, the *internal*, *anterior*, *external*, and *posterior orbital convolutions*. The internal orbital convolution presents a well-marked antero posterior groove or sulcus, the *sulcus olfactorius*, for the olfactory tract; the portion internal to this is named the *gyrus rectus*, and is continuous with the marginal gyrus on the mesial surface.

The *mesial* or *internal surface* of the frontal lobe is occupied by a single curved convolution, which from its situation is termed the *marginal gyrus* (fig. 729). It commences in front of the anterior perforated space, runs along the margin of the longitudinal fissure on the mesial surface of the orbital

FIG. 729.—Mesial surface of left cerebral hemisphere.



lobe, where it is continuous with the internal orbital convolution; it then ascends, and runs backwards to the point where the calloso-marginal fissure turns upwards to reach the superior border of the hemisphere. The posterior part of this convolution is sometimes marked off by a vertical fissure, and is distinguished as the *paracentral lobule* (lobulus paracentralis), because it is continuous with those convolutions which lie immediately in front of and behind the central fissure or fissure of Rolando.

Parietal lobe. The parietal lobe (lobus parietalis) forms a part of both the outer and mesial surfaces of the hemisphere. It is separated from the frontal lobe by the fissure of Rolando, but its boundaries below and behind are not so definite. Posteriorly, it is limited by the external parieto-occipital fissure, and by a line carried across the hemisphere from the outer end of this fissure towards the preoccipital notch. Below, it is separated from the temporal lobe by the posterior limb of the fissure of Sylvius, and by a line carried backwards from the horizontal part of this fissure to meet the line passing downwards to the pre-occipital notch.

The *outer surface* of the parietal lobe (fig. 727) is cleft by a well-marked furrow, the *intraparietal sulcus* of Turner, which consists of an oblique and a horizontal portion. The oblique part is named the *sulcus postcentralis*, and commences below, about midway between the lower end of the fissure of Rolando and the

upturned end of the fissure of Sylvius. It runs upwards and backwards, parallel to the fissure of Rolando, and is sometimes divided into an *upper* and a *lower* ramus. It forms the posterior limit of the postcentral convolution.

From about the middle of the postcentral sulcus, or from the upper end of its inferior ramus, the *horizontal portion* of the intraparietal sulcus is carried backwards and slightly upwards on the parietal lobe, and is prolonged, under the name of the *ramus occipitalis*, on to the occipital lobe; here it divides into two parts, which form nearly a right angle with the main stem and constitute the *sulcus occipitalis transversus*. The part of the parietal lobe above the horizontal ramus is named the superior parietal convolution; the part below, the inferior parietal convolution.

The *postcentral convolution* (gyrus centralis posterior) extends from the great longitudinal fissure above to the horizontal limb of the fissure of Sylvius below. It lies parallel with the ascending frontal or precentral convolution, with which it is connected below, and also, sometimes, above, the fissure of Rolando.

The *superior parietal convolution* (lobulus parietalis superior) is bounded in front by the upper part of the postcentral sulcus which lies between it and the postcentral convolution, but it is usually connected with this latter above the upper extremity of the sulcus; behind, it is bounded by the external parieto-occipital fissure, outside the termination of which it is joined to the occipital lobe by a narrow convolution, the *arcus parieto-occipitalis*; below, it is separated from the inferior parietal convolution by the horizontal portion of the intraparietal sulcus; and above, it is continuous on the inner surface of the hemisphere with the precuneus or quadrate lobe.

The *inferior parietal convolution* lies below the horizontal ramus, and behind the lower part of the post-central sulcus. It is divided from before backwards into three convolutions. One, the *supramarginal*, arches over the upturned end of the fissure of Sylvius; it is continuous in front with the post-central convolution, and behind with the superior temporal convolution. The second, the *angular*, arches over the posterior end of the superior temporal or parallel sulcus, behind which it is continuous with the middle temporal convolution. The third, the *postparietal*, curves round the end of the second temporal sulcus, and is continuous with the third temporal convolution.

The *internal* or *mesial surface* of the parietal lobe (fig. 729) is continuous with the external surface, over the supero-mesial border of the hemisphere. It is bounded behind by the internal parieto-occipital fissure; in front, by the upturned end of the calloso-marginal fissure; and below, it is separated from the limbic lobe by the *sulcus subparietalis*. It is of small size, and consists of a square-shaped convolution, which is termed the *quadrate lobe* or *precuneus*.

Occipital lobe.—The occipital lobe (lobus occipitalis) is small and pyramidal in shape; it presents three surfaces: an outer, a mesial, and a tentorial.

The *outer surface* is limited in front by the external parieto-occipital fissure, and by a line carried from the outer end of this fissure to the pre-occipital notch. This surface is traversed by the transverse occipital and the lateral occipital sulci. The *sulcus occipitalis transversus* is continuous with the posterior end of the ramus occipitalis of the intraparietal sulcus, and runs across the upper part of the lobe, a short distance behind the external parieto-occipital fissure. The *sulcus occipitalis lateralis* extends from behind forwards, and divides the outer surface of the occipital lobe into an *upper* and a *lower* convolution, which are continuous in front with the parietal and temporal lobes.*

The *mesial surface* of the occipital lobe is bounded in front by the internal parieto-occipital fissure, and is traversed by the calcarine fissure, which subdivides it into the cuneus and the lingual lobule. The *calcarine fissure* (fissura calcarina) commences near the occipital pole in a bifid extremity; it runs almost horizontally forwards, and ends in the substance of the limbic lobe, a little below the posterior extremity of the corpus callosum. It is joined at an acute angle by the *internal parieto-occipital fissure*, and the wedge-shaped area between the two fissures is named the *cuneus*. The anterior portion of the calcarine fissure gives rise to the prominence of the *hippocampus minor*, or *calcar avis*, in the interior of the lateral ventricle. The *lingual lobule* (gyrus

* Elliot Smith has named the lateral occipital sulcus the *sulcus lunatus*; he regards it as the representative, in the human brain, of the 'Affenspalte' of the brain of the ape.

lingualis) lies between the calcarine fissure and the posterior part of the collateral fissure, and extends, therefore, on to the tentorial surface. Behind, it reaches the occipital pole; in front, it is continued on to the tentorial surface of the temporal lobe, and joins the hippocampal convolution.

The *tentorial surface* of the occipital lobe is limited in front by an imaginary line carried inwards from the pre-occipital notch, and consists of the posterior part of the *occipito-temporal convolution* and the lower part of the *lingual lobule*, which are separated from each other by the posterior segment of the *collateral fissure.*

Temporal lobe.—The temporal lobe (lobus temporalis) presents upper, lower, and tentorial surfaces.

The *upper surface* form the lower limit of the fissure of Sylvius, and overlaps the island of Reil. On opening out the fissure of Sylvius, three or four gyri will be seen springing from the depth of the hinder end of the fissure, and running obliquely forwards and outwards on the posterior part of the upper surface of the first temporal convolution; these are named the *gyri temporales transversi* or *gyri of Heschl* (fig. 730).

FIG. 730.—Section of brain showing upper surface of temporal lobe.

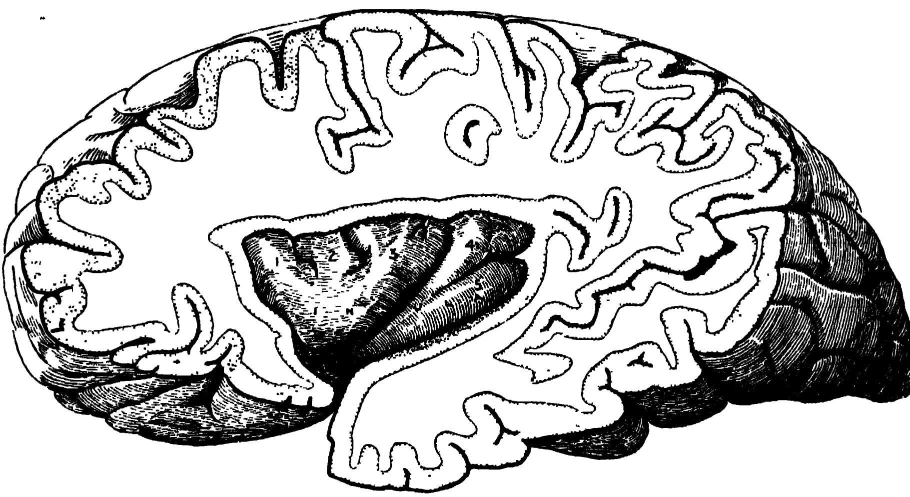
The *outer surface* (fig. 727) is bounded above by the posterior limb of the fissure of Sylvius, and by the imaginary line continued backwards from it; below, it is limited by the infero-lateral border of the hemisphere. It is divided into superior, middle, and inferior convolutions by two sulci, which are termed the first and second temporal sulci. The *first temporal sulcus* (sulcus temporalis superior) runs from before backwards through the temporal lobe, some little distance below, but parallel with, the posterior limb of the fissure of Sylvius; and hence it is often termed the *parallel sulcus.* The *second temporal sulcus* (sulcus temporalis medius) takes the same direction as the first, but is situated at a lower level, and is usually subdivided into two or more parts. The *superior temporal convolution* (gyrus temporalis superior) lies between the posterior limb of the fissure of Sylvius and the parallel sulcus, and is continuous behind with the supra-marginal and angular convolutions. The *middle temporal convolution* (gyrus temporalis medius) is placed between the first and second temporal sulci, and is joined posteriorly with the angular and postparietal convolutions. The *inferior temporal convolution* (gyrus temporalis inferior) is placed below the second temporal sulcus, and is connected behind with the lower occipital convolution; it also extends round the infero-lateral border

on to the tentorial surface, where it is limited by the occipito-temporal sulcus about to be described.

The *tentorial surface* is concave, looks downwards and inwards, and is directly continuous posteriorly with the tentorial surface of the occipital lobe. It is traversed by the *occipito-temporal sulcus* (sulcus temporalis inferior) which extends from near the occipital pole behind, to within a short distance of the temporal pole in front, but is frequently subdivided by bridging gyri. To the outer side of this fissure is the narrow tentorial part of the third temporal convolution, and to its inner side the *occipito-temporal convolution*, which extends from the occipital to the temporal pole. This convolution is limited internally by the collateral fissure, which separates it from the lingual lobule behind and from the hippocampal convolution of the limbic lobe in front.

The insula, or island of Reil (fig. 731), lies deeply in the Sylvian fissure, and can only be seen when the lips of that fissure are widely separated, since it is overlapped and hidden by the convolutions which bound the fissure. These convolutions are termed the *opercula of the insula* ; they are separated from each other by the three limbs of the Sylvian fissure, and named the orbital, frontal, fronto-parietal, and temporal opercula. The *orbital operculum* lies below the anterior limb of the fissure, the *frontal* between the anterior and ascending

Fig. 731.—The island of Reil. Left side. The overlapping parts of the hemisphere have been removed.



1, 2, 3. Gyri breves. 4, 5. Gyrus longus, bifurcated at its upper extremity. Between the gyri breves and the gyrus longus is seen the sulcus centralis.

limbs, the *fronto-parietal* between the ascending limb and the upturned end of the posterior limb, and the *temporal* below the posterior limb. The frontal operculum is of small size when the anterior and ascending limbs of the fissure of Sylvius arise from a common stem which lies between the orbital and fronto-parietal opercula. The island of Reil is surrounded by a deep *limiting sulcus* (sulcus circularis) which separates it from the frontal, parietal, and temporal lobes. When the opercula have been removed it presents the form of a triangular eminence, the apex of which is directed downwards and inwards towards the anterior perforated space. It is divided into a *precentral* and a *postcentral* lobe by the *sulcus centralis*, which runs backwards and upwards from the apex of the insula. The precentral lobe is further subdivided by shallow sulci into three or four short convolutions, the *gyri breves insulæ*, while the postcentral lobe is named the *gyrus longus insulæ*, and is often bifurcated at its upper extremity. The grey matter of the insula is continuous with that of the different opercula, while its deep surface corresponds with the lenticular nucleus of the corpus striatum.

Limbic lobe (fig. 729).—The term limbic lobe (*grande lobe limbique*) was introduced by Broca in 1878, and under it he included the callosal and hippocampal convolutions, which together arch round the corpus callosum and

the dentate or hippocampal fissure. These he separated on the morphological ground that they are well developed in animals possessing a keen sense of smell (osmatic animals), such as the dog and fox. They were thus regarded as a part of the rhinencephalon, but it is now recognised that they belong to the neopallium; the callosal convolution is therefore sometimes described as a part of the frontal lobe and the hippocampal convolution as a part of the temporal lobe.

The *callosal convolution* (gyrus cinguli) is an arch-shaped convolution, lying in close relation to the superficial surface of the corpus callosum, from which it is separated by a slit-like fissure, the *callosal fissure*. It commences below the rostrum of the corpus callosum, curves round in front of the genu, extends along the upper surface of the body, and finally turns downwards behind the splenium, where it is connected by a narrow *isthmus* with the gyrus hippocampi. It is separated from the marginal convolution by the calloso-marginal sulcus, and from the quadrate lobe by the subparietal sulcus.

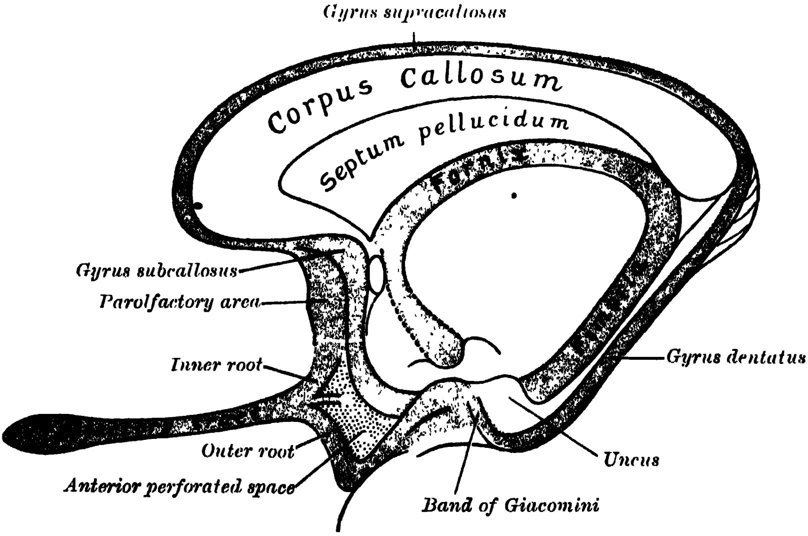
The *hippocampal convolution* (gyrus hippocampi) is bounded above by the hippocampal or dentate fissure, and below by the anterior part of the collateral fissure. Behind, it is continuous superiorly, through the isthmus, with the callosal convolution, and inferiorly with the lingual lobule. Running in the substance of the callosal and hippocampal convolutions, and connecting them together, is a tract of arched fibres, named the *cingulum*. The anterior extremity of the hippocampal convolution is recurved in the form of a hook, named the *uncus*, which is separated from the apex of the temporal lobe by a slight fissure, the *incisura temporalis*. Although superficially continuous with the hippocampal convolution the uncus forms morphologically a part of the rhinencephalon.

The **dentate** or **hippocampal fissure** commences immediately behind the posterior extremity of the corpus callosum, and runs forwards between the hippocampal and dentate convolutions to terminate in the uncus. It is a complete fissure (see page 856), and gives rise to the prominence of the hippocampus major in the descending horn of the lateral ventricle.

Rhinencephalon (fig. 732)

The **rhinencephalon** comprises the olfactory lobe, the uncus, the sub-callosal, supracallosal, and dentate gyri, the septum pellucidum, the fornix, and the hippocampus major.

Fig. 732.—Scheme of rhinencephalon.



1. The **olfactory lobe** is situated on the under surface of the frontal lobe. In many vertebrates it constitutes a well-marked portion of the hemisphere

and encloses an extension of the anterior horn of the lateral ventricle; but in man and some other mammals it is rudimentary. It consists of the olfactory bulb, the olfactory tract, the trigonum olfactorium, the area of Broca, and the anterior perforated space.

(*a*) The *olfactory bulb* (bulbus olfactorius) is an oval, reddish-grey mass which rests on the cribriform plate of the ethmoid and forms the anterior expanded extremity of the olfactory tract. Its under surface receives the olfactory nerves, which pass upwards through the cribriform plate from the olfactory region of the nose. Its minute structure is described on page 883.

(*b*) The *olfactory tract* (tractus olfactorius) is a narrow white band, triangular on transverse section, the apex being directed upwards. It lies in the olfactory sulcus on the under surface of the frontal lobe, and when traced backwards is seen to divide into two roots, an outer and an inner. The *outer root* is directed across the lateral part of the anterior perforated space and then bends abruptly inwards towards the uncus of the gyrus hippocampi. The *inner root* turns inwards behind Broca's area and ends in the subcallosal gyrus; in some cases a small *middle root* is seen running backwards to the anterior perforated space.

(*c*) The *trigonum olfactorium* is a small triangular area in front of the anterior perforated space. Its apex, directed forwards, occupies the posterior part of the olfactory sulcus, and is brought into view by turning backwards the olfactory tract.

(*d*) The *area of Broca* (parolfactory area) is a small triangular field on the mesial surface of the hemisphere in front of the gyrus subcallosus; it is continuous below with the trigonum olfactorium, and above and in front with the callosal convolution.

(*e*) The *anterior perforated space* is an irregularly quadrilateral area in front of the optic tract and behind the trigonum olfactorium, from which it is separated by the *fissura prima*; internally it is continuous with the lamina terminalis; externally it is bounded by the outer root of the olfactory tract. Its grey matter is continuous above with that of the corpus striatum, and is perforated anteriorly by numerous small blood-vessels. Its posterior part assumes the form of a whitish band, the *diagonal band of Broca*, continued in front into the gyrus subcallosus and behind into the temporal lobe.

2. The **uncus** has already been described (page 863) as the recurved, hook-like portion of the hippocampal convolution.

3. The **subcallosal, supracallosal,** and **dentate gyri** form a rudimentary arch-shaped lamina of grey matter which establishes a circuitous connection between the diagonal band of Broca and the uncus.

(*a*) The *subcallosal gyrus* or peduncle of the corpus callosum is a narrow lamina on the mesial surface of the hemisphere in front of the lamina terminalis, behind the area of Broca, and below the rostrum of the corpus callosum. It is continuous around the genu of the corpus callosum with the gyrus supracallosus and below with the diagonal band of Broca.

(*b*) The *supracallosal gyrus* or *indusium griseum* consists of a thin, atrophic layer of grey matter in contact with the upper surface of the corpus callosum and continuous laterally with the grey matter of the callosal convolution. It contains two longitudinally directed strands of fibres termed respectively the *mesial longitudinal striæ* or *striæ Lancisi* and the *lateral longitudinal striæ* or *tæniæ tectæ*. The supracallosal gyrus is prolonged round the splenium of the corpus callosum as a delicate lamina, the *fasciola cinerea*, which is continuous in front with the dentate gyrus.

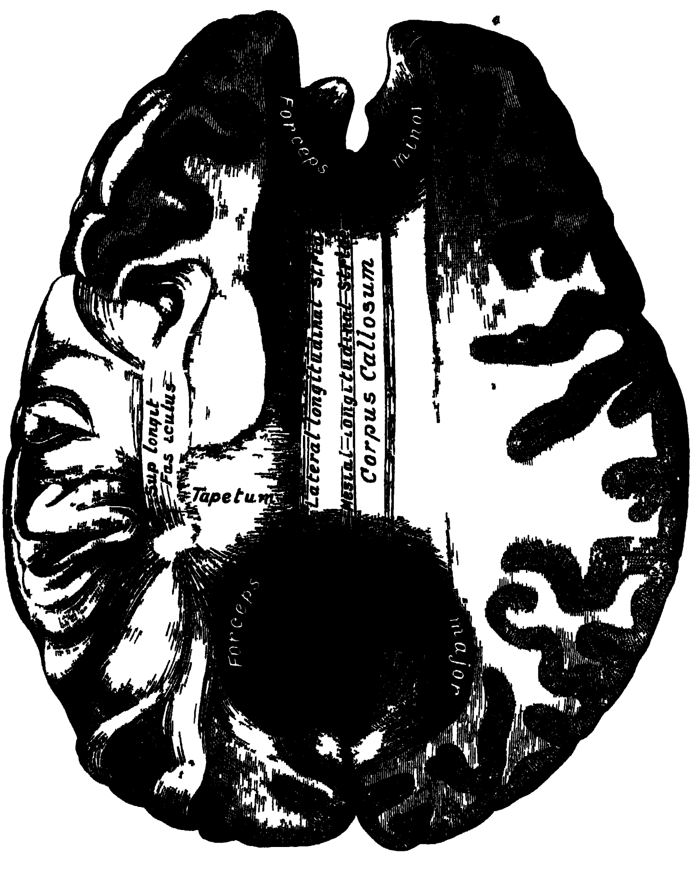
(*c*) The *dentate gyrus* is a narrow band which extends downwards and forwards above the hippocampal convolution, from which it is separated by the hippocampal or dentate fissure. Its free margin is notched and overlapped by the fimbria—the *fimbrio-dentate fissure* intervening. Anteriorly the dentate gyrus is continued into the notch produced by the recurving of the uncus, where it forms a sharp bend and is then continued as a delicate band, the *band of Giacomini*, over the uncus, on the outer surface of which it is lost.

The remaining parts of the rhinencephalon, viz. the septum pellucidum, fornix, and hippocampus major, will be described in connection with the lateral ventricle.

Interior of the Cerebral Hemispheres

If the upper part of either hemisphere be removed with a knife, at a level about half an inch above the corpus callosum, the internal white matter will be exposed. It is an oval-shaped centre of white substance surrounded by a narrow convoluted margin of grey matter of almost uniform thickness The white central mass has been called the *centrum ovale minus*. Its surface is studded with numerous minute red dots (*puncta vasculosa*), produced by the escape of blood from divided blood-vessels, in inflammation or great congestion of the brain these are very numerous, and of a dark colour If the remaining portions of the hemispheres be slightly drawn apart a broad band of white substance will be observed, connecting them at the bottom of the longitudinal fissure; this is the *corpus callosum* The margins of the hemispheres which

Fig. 733.—Corpus callosum from above



overlap it are called the *labia cerebri*. Each labium is part of the callosal convolution already described, and the slit-like interval between it and the upper surface of the corpus callosum is termed the *callosal fissure* (fig 729). If the hemispheres be sliced off to a level with the upper surface of the corpus callosum, the white substance of that structure will be seen connecting the two hemispheres. The large expanse of medullary matter now exposed, surrounded by the convoluted margin of grey substance, is called the *centrum ovale majus*.

The **corpus callosum** (fig. 733) is the great transverse commissure which unites the cerebral hemispheres and roofs in the lateral ventricles A good conception of its position and size is obtained by examining a mesial section of the brain (fig. 721), when it is seen to form an arched structure about four

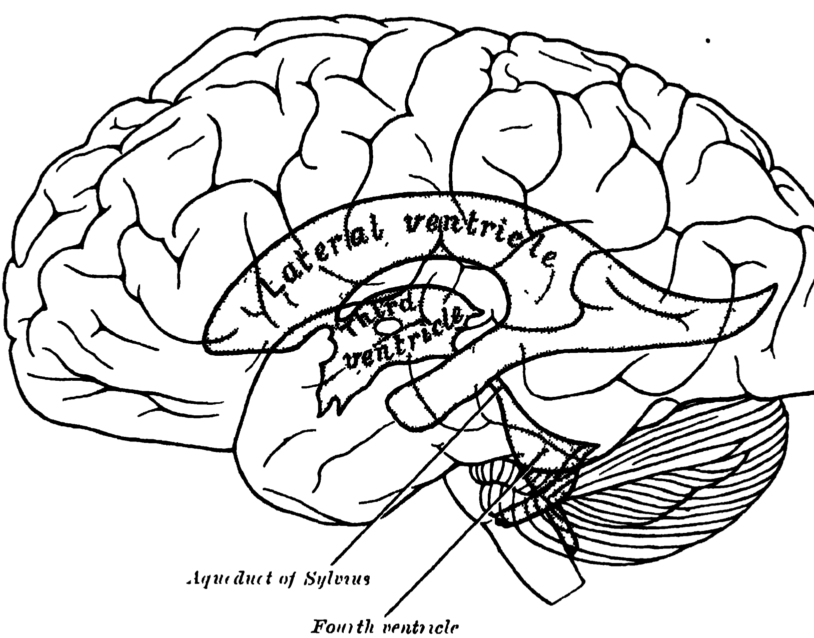
inches in length. Its anterior extremity reaches to within about an inch and a half of the frontal pole, and its posterior extremity about two and a half inches from the occipital pole of the hemisphere.

The *anterior extremity* is named the *genu*, and is bent downwards and backwards in front of the septum pellucidum; diminishing rapidly in thickness, it is prolonged backwards, under the name of the *rostrum*, which is connected below with the lamina terminalis. The anterior cerebral arteries are in contact with the under aspect of the rostrum; they then arch over the front of the genu, and are carried backwards above the body of the corpus callosum.

The *posterior extremity* is termed the *splenium*, and constitutes the thickest part of the corpus callosum. It overlaps the velum interpositum and the mid-brain, and terminates in a thick, convex, free border. When a mesial section of the splenium is examined, it is seen that the posterior end of the corpus callosum is acutely bent forwards, the upper and lower parts being applied to each other.

The *upper surface* is convex from before backwards, and is nearly an inch in width. Its mesial part forms the bottom of the great longitudinal fissure,

FIG. 734.—Scheme showing relations of the ventricles to the surface of the brain.



and is in contact posteriorly with the lower border of the falx cerebri. Laterally it is overlapped by the callosal convolution, but is separated from it by the slit-like callosal fissure. It is traversed by numerous ridges and furrows, and is covered by a thin layer of grey matter, the gyrus supracallosus, which exhibits on either side of the middle line the mesial and lateral longitudinal striæ, already described (page 864).

The *lower surface* is concave, and forms on either side of the middle line the roof of the lateral ventricle. Mesially, this surface is attached in front to the septum pellucidum; behind this it is fused with the upper surface of the body of the fornix, while the splenium is in contact with the velum interpositum.

On either side, the fibres of the corpus callosum radiate in the white substance and pass to the various parts of the cerebral cortex. The part of the corpus callosum which curves forwards from the genu into the frontal lobes is called the *forceps minor*. The part which curves backwards from the splenium into the occipital lobes is known as the *forceps major*. Between these two parts is the main body of the fibres which constitute the *tapetum* or *mat*;

[illegible]ally on either side into the temporal lobe, and covers in the [illegible] ventricle.

The lateral ventricles (ventriculi laterales) (fig. 736).—The lateral ventricles, two in number, right and left, are irregular cavities situated in the lower and inner parts of the cerebral hemispheres, one on either side of the middle line. They are separated from each other by a mesial vertical partition, the *septum pellucidum*, but communicate with the third ventricle and indirectly with each other through the *foramen of Monro.* They are lined by a thin, diaphanous membrane, the *ependyma*, which is covered by ciliated epithelium, and moistened by cerebro-spinal fluid, which, even in health, may be secreted in considerable amount. Each lateral ventricle consists of a *central cavity* or *body*, and three prolongations from it, termed *cornua*. The *anterior* cornu curves forwards and outwards into the frontal lobe; the *posterior* backwards and inwards into the occipital lobe; and the *middle* descends into the temporal lobe.

FIG. 735.—Drawing of a cast of the ventricular cavities viewed from above. (Testut.)

The body (pars centralis) (fig. 736) of the lateral ventricle extends from the foramen of Monro to the splenium of the corpus callosum. It is an irregularly curved cavity, triangular in shape on transverse section, and presents a roof, a floor, and an inner wall. Its roof is formed by the under surface of the corpus callosum; its floor is formed by the following parts, enumerated in their order of position, from before backwards: the *caudate nucleus of the corpus striatum*, the *tænia semicircularis* and the *vein of the corpus striatum*, the outer portion of the upper surface of the *thalamus*, the *choroid plexus*, and the lateral part of the *fornix*; its inner wall is the posterior part of the septum pellucidum, which separates it from the opposite ventricle, and connects the under surface of the corpus callosum with the fornix.

The anterior cornu (cornu anterius) passes forwards and outwards, with a slight inclination downwards, from the foramen of Monro into the frontal lobe, curving round the anterior extremity of the caudate nucleus. It is bounded above by the corpus callosum, and below by the upper surface of the reflected portion of this, the rostrum. It is bounded internally by the anterior portion of the septum pellucidum, and externally by the head of the caudate nucleus of the corpus striatum. Its apex reaches the posterior surface of the genu of the corpus callosum (fig. 741).

The **posterior cornu** (cornu posterius) (figs. 736, 737) passes into the occipital lobe, its direction being backwards and outwards, and then inwards; its concavity is therefore directed inwards. Its roof is formed by the fibres of the corpus callosum passing to the temporal and occipital lobes. On its inner wall is seen a longitudinal eminence, which is an involution of the ventricular wall produced by the calcarine fissure; this is called the *hippocampus minor*, or *calcar avis*. Just above this the forceps major of the corpus callosum, sweeping round to enter the occipital lobe, causes another projection, which is known as the *bulb of the posterior cornu*. The hippocampus minor and bulb of the posterior cornu are extremely variable in their degree of development; in some cases they are ill-defined, in others unusually prominent.

The **middle or descending cornu** (cornu inferius) (fig. 738), the largest of the three, traverses the temporal lobe of the brain, forming in its course a

FIG. 736.—Lateral ventricles of the brain.

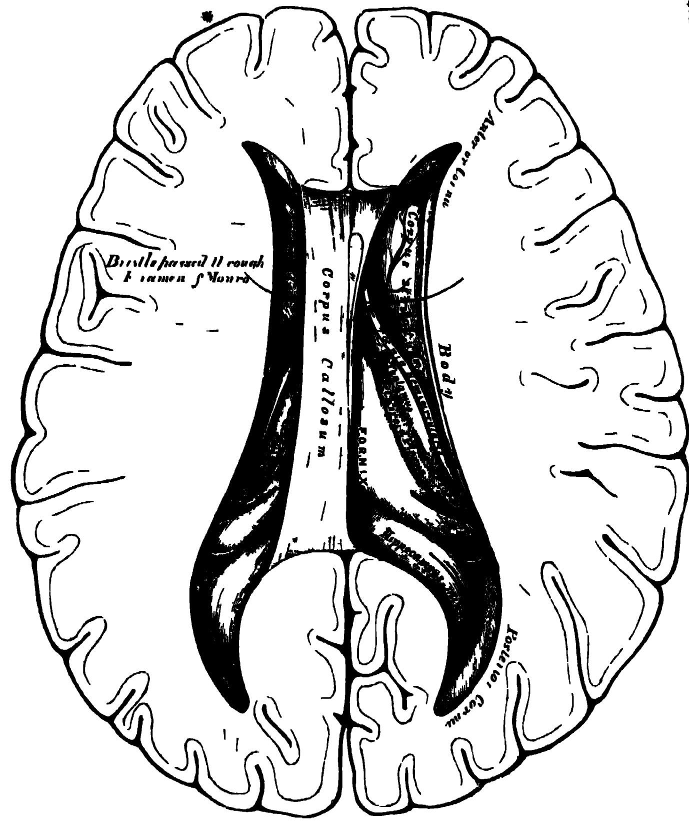

FIG. 737.—Coronal section through posterior cornu of lateral ventricle

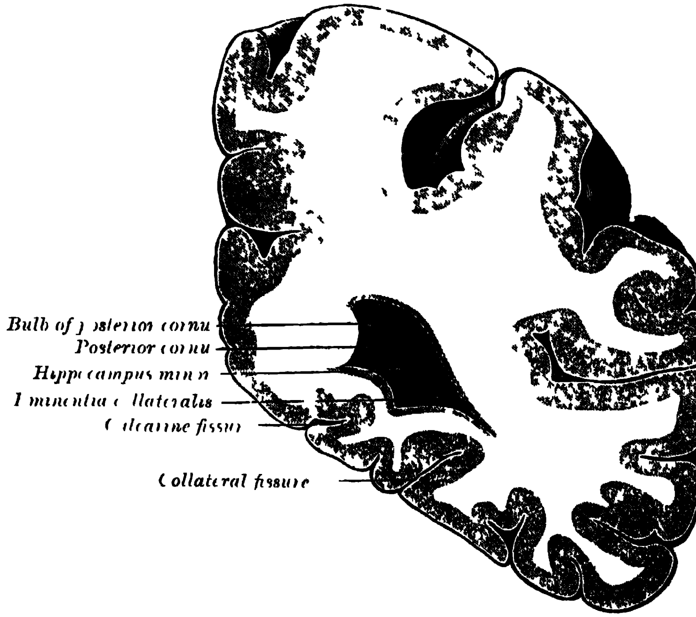
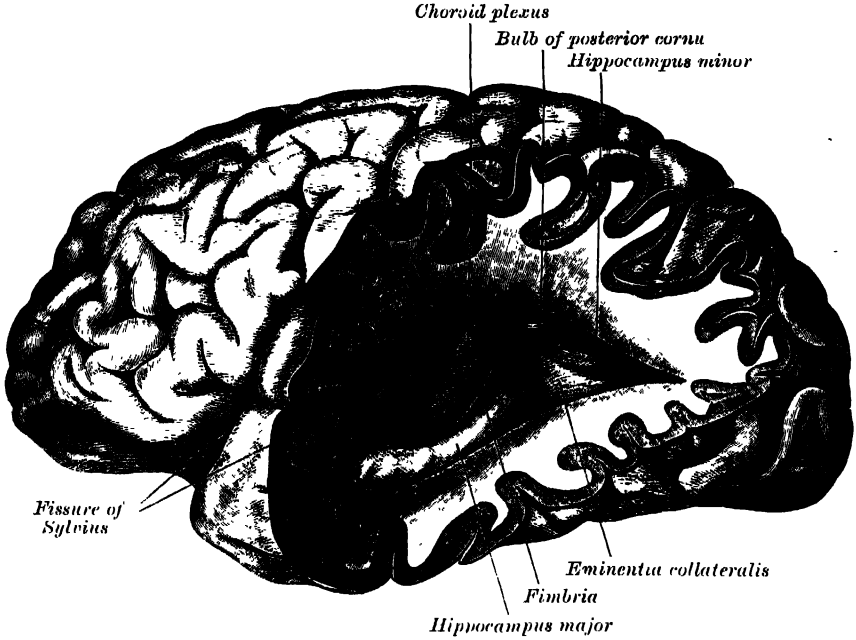


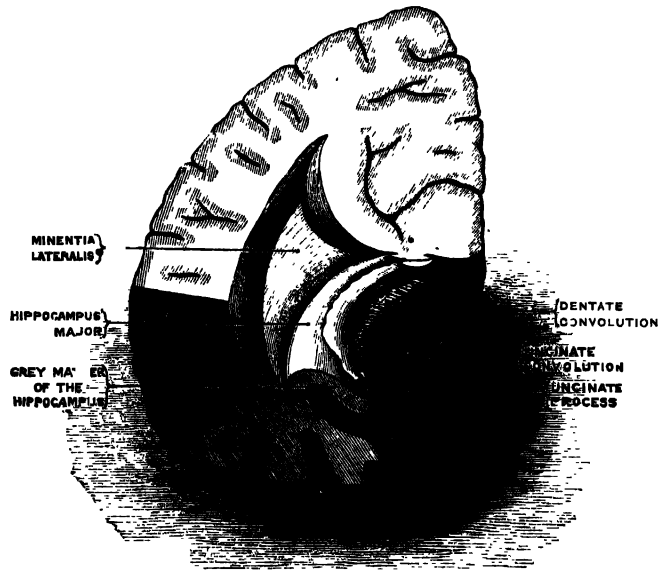
remarkable curve round the back of the thalamus. It passes at first backwards, outwards, and downwards, and then curves forwards, and inwards, to within

FIG. 738.—Posterior and descending cornua of left lateral ventricle exposed from the side.



an inch of the apex of the temporal lobe, its direction being fairly well indicated on the surface of the brain by that of the parallel sulcus. Its roof

FIG. 739.—Transverse section of the descending cornu of the lateral ventricle. (From a drawing by F. A. Barton.)

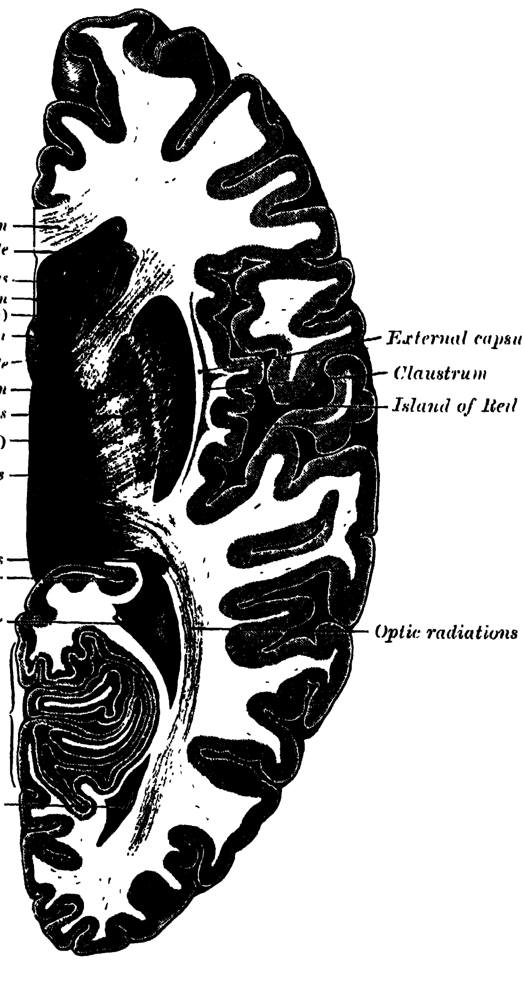


is formed chiefly by the under surface of the tapetum of the corpus callosum, but the tail of the nucleus caudatus, and the tænia semicircularis also extend

forwards in the roof of the descending horn to its extremity, where they end in a mass of grey matter, the *nucleus amygdalæ*. Its floor presents the following parts: the *hippocampus major*, the *fimbria* or *tænia hippocampi*, the *eminentia collateralis*, and the *choroid plexus*. When the choroid plexus is removed, a cleft-like opening is formed along the mesial wall of the descending cornu. This cleft constitutes the lower part of the *choroidal fissure*, and through it the ventricular cavity opens on to the surface of the hemisphere.

The **hippocampus major, or cornu Ammonis** (figs. 738, 739), is a curved eminence, about two inches long, which extends throughout the entire length of the floor of the descending horn. Its lower extremity is enlarged, and presents two or three rounded elevations with intervening depressions (digitationes

FIG. 740.—Horizontal section of right cerebral hemisphere.



hippocampi) which give it a paw-like appearance, and hence it is named the *pes hippocampi*. If a transverse section be made through the hippocampus major, it will be seen that this eminence is produced by the folding of the wall of the hemisphere to form the dentate or hippocampal fissure. The main mass of the hippocampus major consists of grey matter; but on its ventricular surface is a thin layer of white matter, known as the *alveus*, which is continuous with the fimbria of the fornix and is covered by the ependyma of the ventricle. Macarthy has shown * that if the alveus and superficial strata of grey matter be reflected from the surface of the hippocampus by an incision carried along

* *Journal of Anatomy and Physiology*, vol. xxxiii.

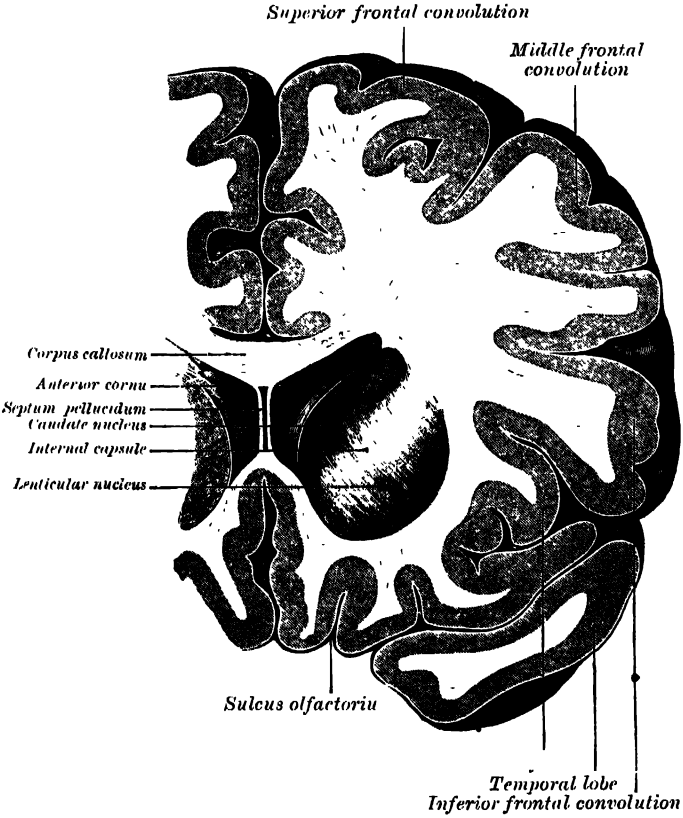
its convexity, the 'core' of the hippocampus, as he terms it, presents, in many cases, a corrugated or crimped appearance.

The **eminentia collateralis** is an elongated eminence lying to the outer side of and parallel with the hippocampus major. It corresponds with the middle part of the collateral fissure, and its size depends on the depth and direction of that furrow. It is continuous behind with a flattened triangular area which is situated between the posterior and descending cornua, and named the *trigonum collaterale*.

The fimbria is a continuation of the posterior pillar of the fornix, and will be discussed with that body; while a description of the choroid plexus will be found on page 877.

The **corpus striatum** (figs. 740, 741, 742) has received its name from the striped appearance which a section of its anterior part presents, in consequence of diverging white fibres being mixed with the grey matter which forms the greater part of its substance. A part of this body is imbedded in the white

FIG. 741.—Coronal section through anterior cornua of lateral ventricles.



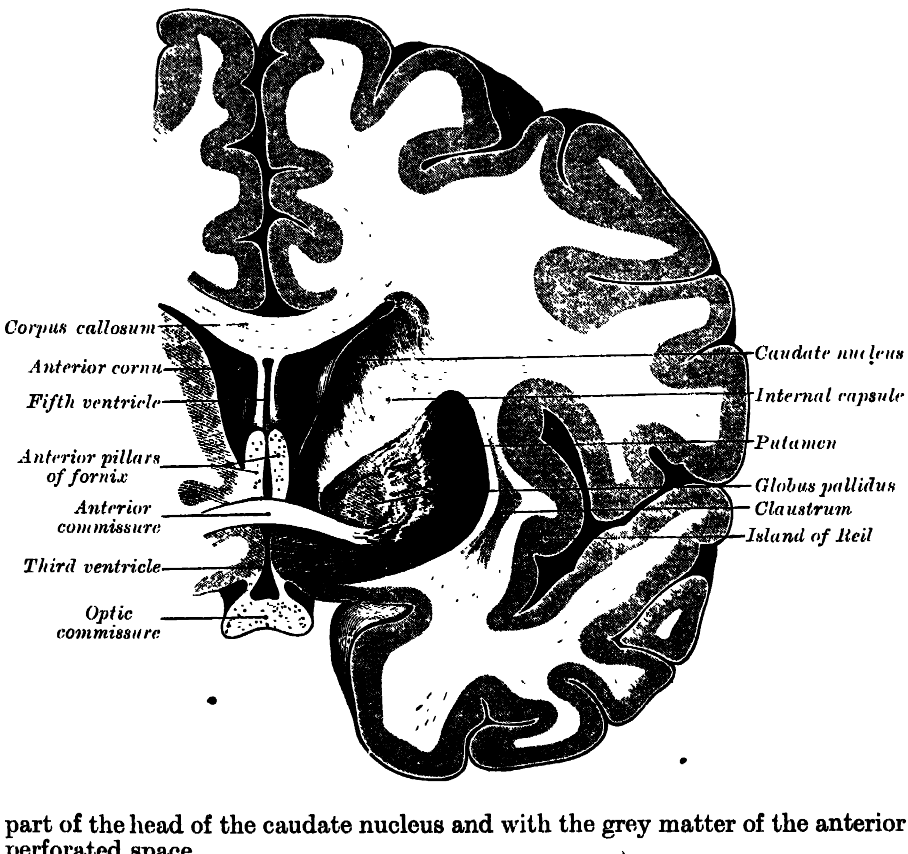
substance of the hemisphere, and is therefore external to the ventricle. It is termed the *extra-ventricular portion*, or the *nucleus lenticularis*; a part, however, is visible in the ventricle, and is named the *intraventricular portion*, or the *nucleus caudatus*.

The **nucleus caudatus** is a pear-shaped, highly arched mass of grey matter; its broad extremity, or *head* (caput nuclei caudati), is directed forwards into the fore-part of the body and anterior cornu of the lateral ventricle, and is continuous with the grey matter of the anterior perforated space and with the anterior end of the lenticular nucleus; its narrow end, or *tail* (cauda nuclei caudati) is directed outwards and backwards on the outer side of the thalamus, from which it is separated by the tænia semicircularis and the vein of the corpus striatum. It is then continued downwards

into the roof of the descending cornu, where it terminates in the *nucleus amygdalæ*, at the apex of the temporal lobe. It is covered by the lining of the ventricle, and crossed by some veins of considerable size. It is separated from the extra-ventricular portion, in the greater part of its extent, by a lamina of white matter, which is called the *internal capsule*, but the two portions of the corpus striatum are united in front (fig. 741).

The **nucleus lenticularis** (nucleus lentiformis), or extra-ventricular portion of the corpus striatum, is placed outside the caudate nucleus and thalamus, and is seen only in sections of the hemisphere. When divided horizontally, it exhibits, to some extent, the appearance of a biconvex lens, while a vertical transverse section of its central part presents a somewhat triangular outline. It does not extend as far forwards or backwards as the nucleus caudatus. It is bounded externally by a lamina of white matter called the *external capsule*, on the outer surface of which is a thin layer of grey matter termed the *claustrum*. Its anterior extremity is continuous with the lower

FIG. 742.—Coronal section of brain through anterior commissure.



part of the head of the caudate nucleus and with the grey matter of the anterior perforated space.

Upon making a transverse vertical section through the middle of the nucleus lenticularis it is seen to be divided by two white laminæ, the *medullary laminæ*, into three zones. The outermost and largest zone is of a reddish colour, and is known as the *putamen*, while the two inner are paler and of a yellowish tint, and together constitute the *globus pallidus*. All three zones are marked by fine radiating white fibres, which are most distinct in the putamen.

The grey matter of the corpus striatum is traversed by nerve-fibres, some of which are believed to originate in it. The cells are multipolar, both large and small; those of the lenticular nucleus contain yellow pigment. The caudate and lenticular nuclei are not only directly continuous with each other anteriorly, but are connected to each other by numerous fibres. The corpus striatum is also connected: (1) to the cerebral cortex, by what are termed

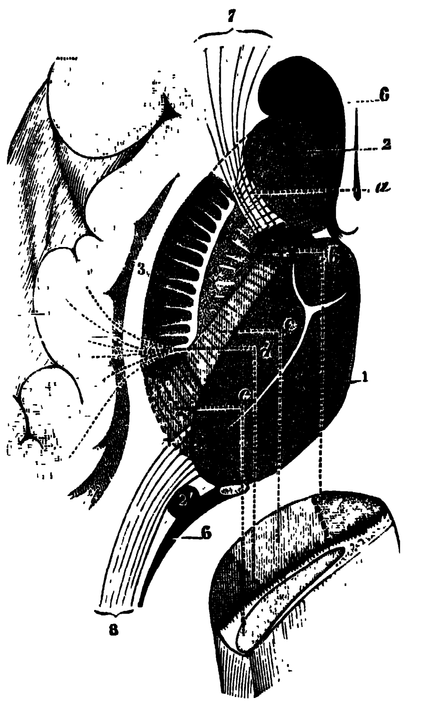
the *cortico-striate* fibres ; (2) to the thalamus, by fibres which pass through the internal capsule, and by a strand named the *ansa lenticularis* ; (3) to the crus cerebri, by fibres which leave the lower aspect of the caudate and lenticular nuclei.

The **claustrum** is a thin layer of grey matter, situated on the outer surface of the external capsule. On transverse section it is seen to be triangular, with its apex directed upwards and its base downwards. Its inner surface, which is contiguous to the external capsule, is smooth, but its outer surface presents ridges and furrows which correspond with the convolutions and sulci of the island of Reil, with which it is in close relationship. The claustrum is regarded as a detached portion of the grey matter of the island of Reil, from which it is separated by a layer of white fibres, the *capsula extrema* or *band of Baillarger*. Its cells are small and spindle-shaped, and contain yellow pigment ; they are similar to those found in the deepest layer of the cortex.

The **nucleus amygdalæ** is an ovoid mass of grey matter, situated in the roof of the descending horn, at its lower extremity. It is merely a localised thickening of the grey cortex, continuous with that of the uncus ; in front it is continuous with the putamen, behind with the tænia semicircularis and the tail of the caudate nucleus.

The **internal capsule** is a flattened band of white fibres, which lies between the lenticular nucleus on the outer side and the caudate nucleus and thalamus on the inner side. In horizontal section (figs. 740, 743) it is seen to be somewhat abruptly curved, with its convexity inwards ; the prominence of the curve is called the *genu*, and projects between the caudate nucleus and the thalamus. The portion in front of the genu is termed the *anterior limb* (pars frontalis), and separates the lenticular from the caudate nucleus ; the portion behind the genu is the *posterior limb* (pars occipitalis), and separates the lenticular nucleus from the thalamus.

FIG. 743.—Horizontal section of the internal capsule. (Schematic.) (Testut.) Below the horizontal section, there is shown a transverse section of the corresponding crus cerebri.



1. Thalamus. 2, 2′. Caudate nucleus. 3. Lenticular nucleus. 4. Claustrum. 5. Island of Reil. 6. Lateral ventricle. 7. Anterior stalk of optic thalamus. 8. Optic radiations. *a*. Anterior segment of internal capsule. *b*. Geniculate bundle (in green). *c*. Pyramidal fibres (in red). *d*. Posterior cortico-pontine fibres. *e*. Fillet.

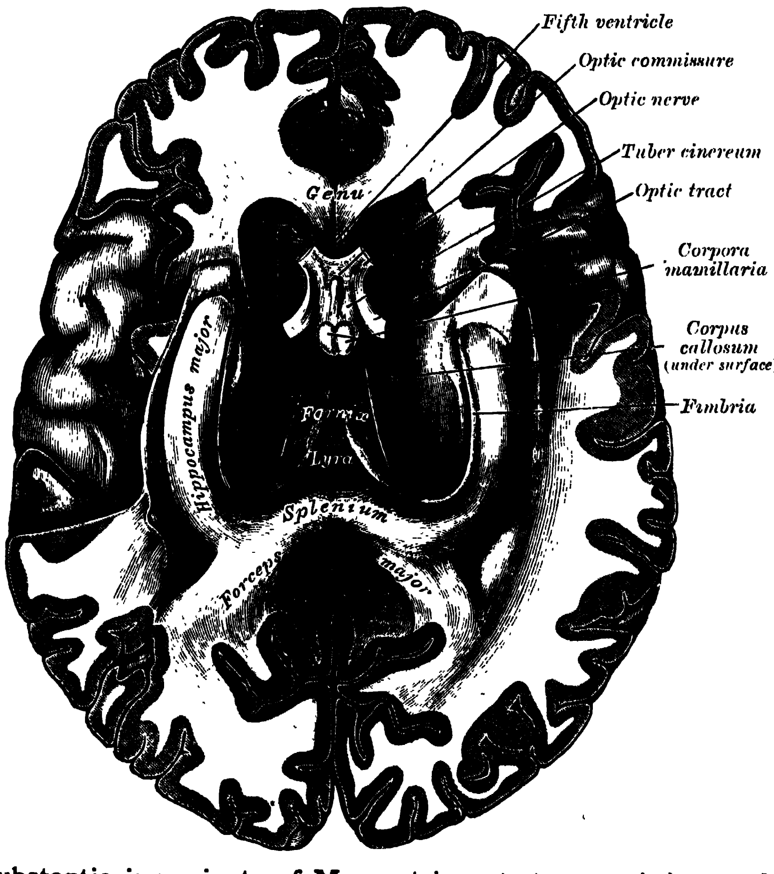
The anterior limb of the internal capsule contains: (1) fibres which pass from the thalamus to the frontal lobe (cortico-thalamic) ; (2) fibres connecting the lenticular and caudate nuclei (lenticulo-caudate) ; (3) fibres connecting the cortex with the corpus striatum (cortico-striate) ; and (4) fibres passing from the frontal lobe to the nuclei pontis (cortico-pontine). The fibres which occupy the region of the genu are named the *geniculate fibres* ; they originate in the motor part of the cerebral cortex, and, after passing downwards in the inner fifth of the crusta, undergo decussation and end in the motor nuclei of the cranial nerves of the opposite side. The anterior two-thirds of the posterior limb contains the *pyramidal fibres*, which arise in the motor area of the cortex and, passing downwards through the middle three-fifths of the crusta, are continued into the pyramids of the medulla. The posterior third of the posterior limb contains : (1) sensory fibres, which are largely derived from the thalamus, but some of which may be continued

upwards from the mesial fillet; (2) the fibres of optic radiation, which pass from the lower visual centres to the cortex of the occipital lobe; (3) auditory fibres, from the lateral fillet to the temporal lobe; and (4) cortico-pontine fibres, which pass from the occipital and temporal lobes to the nuclei pontis.

The fibres of the internal capsule radiate widely as they pass to and from the various parts of the cerebral cortex, forming the *corona radiata* and intermingling with the fibres of the corpus callosum.

The **external capsule** is a lamina of white matter, situated on the outer side of the lenticular nucleus, between it and the claustrum, and continuous with the internal capsule below and behind the lenticular nucleus. It probably contains fibres derived from the thalamus, the anterior white commissure, and the subthalamic region.

Fig. 744.—The fornix and corpus callosum from below. (From a specimen in the Department of Human Anatomy of the University of Oxford.)



The **substantia innominata of Meynert** is a stratum consisting partly of grey and partly of white matter, which lies below the anterior part of the thalamus and lenticular nucleus. It consists of three layers, superior, middle, and inferior. The *superior* layer is named the *ansa lenticularis*, and its fibres, derived from the medullary lamina of the lenticular nucleus, pass inwards to end in the thalamus and subthalamic region, while others are said to terminate in the tegmentum and red nucleus. The *middle* layer consists of nerve-cells and nerve-fibres: fibres enter it from the parietal lobe through the external capsule, while others are said to connect it with the posterior longitudinal fasciculus. The *lower* layer forms the main part of the inferior stalk of the thalamus, and connects this body with the temporal lobe and the island of Reil.

The **tænia semicircularis** is a narrow, whitish band of medullary substance situated in the depression between the caudate nucleus and the

thalamus. Anteriorly, its fibres are partly continued into the anterior pillar of the fornix; some, however, pass over the anterior commissure to the grey matter between the caudate nucleus and septum pellucidum, while others are said to penetrate the caudate nucleus. Posteriorly, it is continued into the roof of the middle or descending horn of the lateral ventricle, at the extremity of which it enters the *nucleus amygdalæ*. Superficial to it is a large vein, the *vena corporis striati*, which receives numerous tributaries from the corpus striatum and thalamus; it runs forwards to the foramen of Monro and joins with the vein of the choroid plexus to form the corresponding *vena Galeni*. On the surface of the vein of the corpus striatum is a narrow band of white fibres, named the *lamina cornea*.

The **fornix** (figs. 721, 744) is a longitudinal, arch-shaped lamella of white matter, situated below the corpus callosum, with which it is continuous behind, but from which it is separated in front by the septum pellucidum. It may be described as consisting of two symmetrical bands, one for either hemisphere. The two portions are not united to each other in front and behind, but their central parts are joined together in the middle line. The anterior parts are called the *anterior pillars* (*columnæ fornicis*); the intermediate united portions constitute the *body of the fornix*; and the posterior parts are termed the *posterior pillars* (*crura fornicis*).

The *body of the fornix* is triangular, narrow in front, and broad behind. The mesial part of its upper surface is connected to the septum pellucidum in front and to the corpus callosum behind. The lateral portion of this surface forms part of the floor of the lateral ventricle, and is covered by the ventricular epithelium. Its outer edge overlaps the choroid plexuses, and is continuous with the epithelial covering of these structures. The under surface rests upon the velum interpositum, which separates it from the epithelial roof of the third ventricle, and from the inner portions of the upper surfaces of the thalami. When viewed from below the lateral portions of the body of the fornix are seen to be joined by a thin triangular lamina, named the *psalterium* or *lyra*. This lamina contains some transverse fibres which connect the two hippocampi across the middle line and constitute the *hippocampal* commissure. Between the psalterium and the corpus callosum a horizontal cleft, the so-called *ventricle of the fornix* or *ventricle of Verga*, is sometimes found.

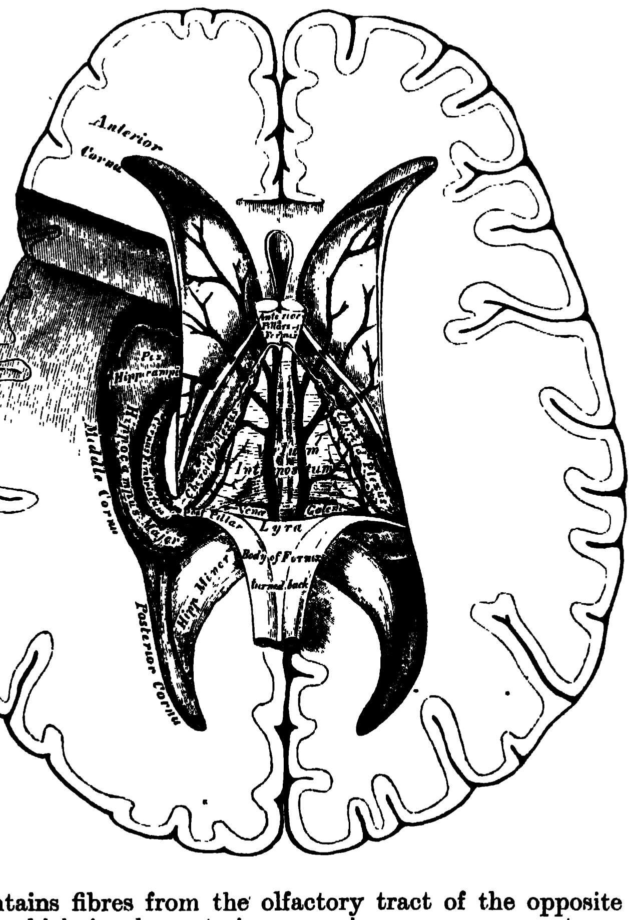
The *anterior pillars* arch downwards in front of the foramen of Monro and behind the anterior commissure, and each descends through the grey matter in the lateral wall of the third ventricle to the base of the brain, where it terminates in the corpus albicans. From the cells of the corpus albicans a fasciculus of fibres, termed the *bundle of Vicq d'Azyr*, takes origin and is prolonged into the anterior nucleus of the thalamus. The anterior pillar of the fornix and the bundle of Vicq d'Azyr together form a loop resembling the figure 8, but the continuity of the loop is broken in the corpus albicans. The anterior pillar of the fornix is joined by the stria pinealis and by the superficial fibres of the tænia semicircularis, and is also said to receive fibres from the septum pellucidum. Zuckerkandl describes an *olfactory fasciculus* which becomes detached from the main portion of the anterior pillar of the fornix, and passes downwards in front of the anterior commissure to the base of the brain, where it divides into two bundles, one joining the inner root of the olfactory tract; the other joins the subcallosal gyrus, and through it reaches the hippocampal convolution.

The *posterior pillars* are prolonged backwards from the body of the fornix. They are flattened bands, and at their commencement are intimately connected by their upper surfaces with the under aspect of the corpus callosum. Diverging from one another, each curves round the posterior extremity of the thalamus, and passes downwards and forwards into the descending horn of the lateral ventricle. Here it lies along the concavity of the hippocampus major, on the surface of which some of its fibres are spread out to form the *alveus*, while the remainder are continued as a narrow white band, the *fimbria* or *tænia hippocampi*, which is prolonged into the uncus of the gyrus hippocampi. Its inner edge overlaps the dentate convolution (page 864), from which it is separated by the *fimbrio-dentate fissure*; from its outer margin, which is thin and ragged, the ventricular epithelium is reflected over the choroid plexus as the latter projects into the choroidal fissure.

Foramen of Monro.—Between the anterior pillars of the fornix and the anterior extremities of the thalami, an oval aperture is seen on either side: this is the foramen of Monro and through it the lateral ventricle communicates with the third ventricle. Behind the epithelial lining of the foramen the choroid plexuses of the lateral ventricles are joined across the middle line.

The **anterior commissure** (commissura anterior) is a bundle of white fibres, which connects the two cerebral hemispheres across the middle line, and is placed in front of the anterior pillars of the fornix. On sagittal section it is seen to be oval in shape, its long diameter being vertical in direction and measuring about one-fifth of an inch. Its fibres can be traced outwards and backwards on each side beneath the corpus striatum into the substance of the temporal lobe. It serves in this way to connect the two temporal lobes,

FIG. 745.—The fornix, velum interpositum, and middle or descending cornu of the lateral ventricle.



but it also contains fibres from the olfactory tract of the opposite side, the decussation of which in the anterior commissure may serve to explain the condition of crossed anosmia, i.e. a loss of smell in one side of the nose resulting from a lesion in the temporal lobe of the opposite side.

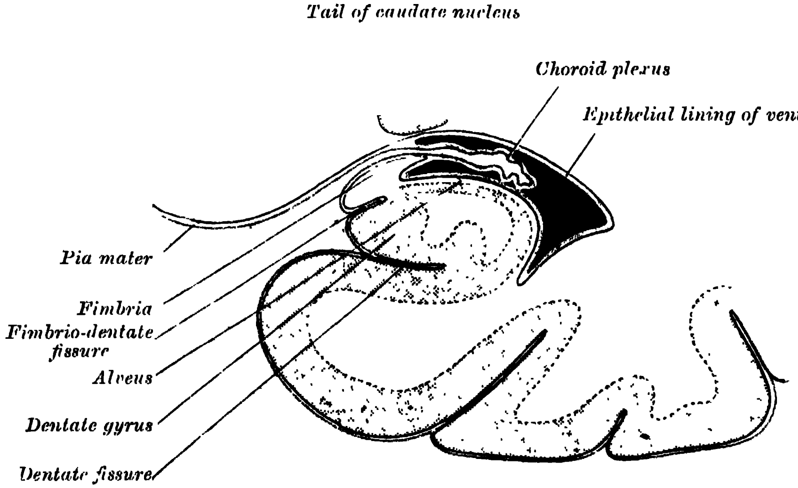
The **septum pellucidum** (*septum lucidum*) is a thin, vertically placed partition. It consists of two distinct laminæ, separated in part of their extent by a narrow chink or interval, the so-called *fifth ventricle.* The outer surface of each lamina is directed towards the body and anterior cornu of the lateral ventricle, and is covered by the ependyma of that cavity, while its mesial surface bounds the cavity of the fifth ventricle. It is a thin, semi-transparent septum, attached, above, to the under surface of the corpus callosum; below, to the anterior part of the fornix behind, and the reflected portion of the corpus callosum in front. It is triangular in form, broad in front and narrow

behind; its inferior angle corresponds with the upper part of the anterior commissure.

The *cavum septi pellucidi* or so-called *fifth ventricle* is generally regarded as part of the great longitudinal fissure, which has become shut off by the union of the hemispheres in the formation of the corpus callosum above and the fornix below. Each half of the septum is therefore formed by the median wall of the hemisphere, and consists of a mesial layer of grey matter, derived from the grey matter of the cortex, and an external layer of white substance continuous with the white matter of the cerebral hemispheres. The fifth ventricle differs from the other ventricles of the brain, inasmuch as it is not developed from the cavity of the cerebral vesicles, is not lined by ciliated epithelium, and does not communicate with the general ventricular cavity.

The **choroid plexus of the lateral ventricle** (plexus chorioideus ventriculi lateralis) (fig. 745) is a highly vascular fringe-like process of pia mater, which appears as if it were contained within the ventricular cavity. The plexus, however, is not actually within the cavity, as it is everywhere covered by a layer of epithelium continuous with the epithelial lining of the ventricle, which therefore shuts it out of the ventricular cavity. It extends from the foramen of Monro, where it is joined with the plexus of the opposite ventricle, to the extremity of the descending horn. The part in relation to the body of

FIG. 746.—Coronal section of descending horn of lateral ventricle. (Diagrammatic.)



the ventricle forms the vascular fringed margin of a triangular process of pia mater, named the *velum interpositum*, and projects from under cover of the outer edge of the fornix. It lies upon the upper surface of the thalamus, from which the epithelium is reflected over the plexus on to the edge of the fornix. The portion in relation to the descending horn lies in the concavity of the hippocampus major and overlaps the fimbria: from the outer edge of the latter the epithelium is reflected over the plexus on to the roof of the cornu (fig. 746). It consists of minute and highly vascular villous processes, each with an afferent and an efferent vessel. The cells of the epithelium which covers it often contain yellowish fat molecules. The *arteries* of the plexus are: (*a*) the anterior choroidal, a branch of the internal carotid, which enters the plexus at the extremity of the descending horn; and (*b*) the posterior choroidal, one or two small branches of the posterior cerebral, which pass forwards under the splenium. The *veins* of the choroid plexus unite to form a prominent vein, which courses from behind forwards to the foramen of Monro and joins with the vein of the corpus striatum to form the corresponding vein of Galen.

When the choroid plexus is pulled away, the continuity of the epithelium which covers it, with that which lines the ventricle, is severed, and a cleft-like space is produced. This is named the *choroidal fissure*; like the plexus, it extends from the foramen of Monro to the extremity of the descending horn.

The upper part of this fissure, i.e. the part nearest the foramen of Monro, is situated between the lateral edge of the fornix and the upper surface of the thalamus; further back, at the beginning of the descending horn, it is between the commencement of the fimbria and the posterior end of the thalamus, while in the descending horn it lies between the fimbria in the floor and the tænia semicircularis in the roof of the cornu: through this part of the fissure the descending horn opens on to the tentorial surface of the hemisphere.

The **velum interpositum,** or **tela chorioidea ventriculi tertii** (fig. 745), is a double fold of pia mater, triangular in shape, which lies beneath the fornix. The lateral portions of its lower surface rest upon the thalami, while its mesial portion is in contact with the epithelial roof of the third ventricle. Its apex is situated at the foramen of Monro; its base corresponds with the splenium of the corpus callosum, and occupies the interval between that structure above and the corpora quadrigemina and pineal body below. This interval, together with the lower portions of the choroidal fissures, is sometimes spoken of as the *great transverse fissure* of the brain. At its base the two layers of the velum separate from each other, and are continuous with the pia mater investing the brain in this region. Each of its lateral margins is modified to form the highly vascular fringed structure which constitutes the choroid plexus of the lateral ventricle. It is supplied by the anterior and posterior choroidal arteries already described. The veins of the velum interpositum are named the *venæ Galeni*; they are two in number, and run backwards between its layers, each being formed at the foramen of Monro by the union of the vein of the corpus striatum with the choroid vein. The venæ Galeni unite posteriorly into a single trunk, the *vena magna Galeni*, which passes out beneath the splenium and ends in the straight sinus.

Structure of the Cerebral Hemispheres

The cerebral hemispheres are composed of grey and white matter: the former covers their surfaces, and is termed the *cortex*; the latter occupies the interior of the hemispheres, and is named the *medullary centre.*

The **white matter of the cerebral hemispheres** consists of medullated fibres, varying in size and arranged in bundles, separated by neuroglia. They may be divided into three distinct systems, according to the course they take. 1. Projection fibres, which connect the hemisphere with the lower parts of the brain and with the spinal cord. 2. Transverse or commissural fibres, which unite together the two hemispheres. 3. Association fibres, which connect different structures in the same hemisphere; these are, in many instances, collateral branches of the projection fibres, but others are the axons of independent cells.

1. The **projection fibres** consist of efferent and afferent fibres which connect the cortex with the lower parts of the brain and with the spinal cord. The principal efferent strands are: (1) the motor tract, which occupies the genu and anterior two-thirds of the posterior limb of the internal capsule, and consists of (*a*) the geniculate fibres, which decussate and end in the motor nuclei of the cranial nerves of the opposite side; and (*b*) the pyramidal fibres, which are prolonged through the pyramid of the medulla into the spinal cord: (2) the cortico-pontine fibres, which end in the nuclei pontis. The chief afferent fibres are: (1) those fibres of the fillet which are not interrupted in the thalamus; (2) those fibres of the superior cerebellar peduncles which are not interrupted in the red nucleus and thalamus; (3) the numerous fibres which arise within the thalamus, and pass through its stalks to the different parts of the cortex (page 848); (4) the optic and acoustic fibres, the former passing to the occipital, the latter to the temporal lobe.

2. The **transverse** or **commissural fibres** connect the two hemispheres. They include: (*a*) the transverse fibres of the corpus callosum, (*b*) the anterior commissure, (*c*) the posterior commissure, and (*d*) the lyra; they have already been described.

3. **Association fibres** (fig. 747).—These connect different parts of the same hemisphere, and are of two kinds: (1) those which unite adjacent convolutions, *short association fibres*; (2) those which pass between more distant parts, *long association fibres.*

The *short association fibres* are situated immediately beneath the grey substance of the cortex of the hemispheres, and connect together adjacent convolutions.

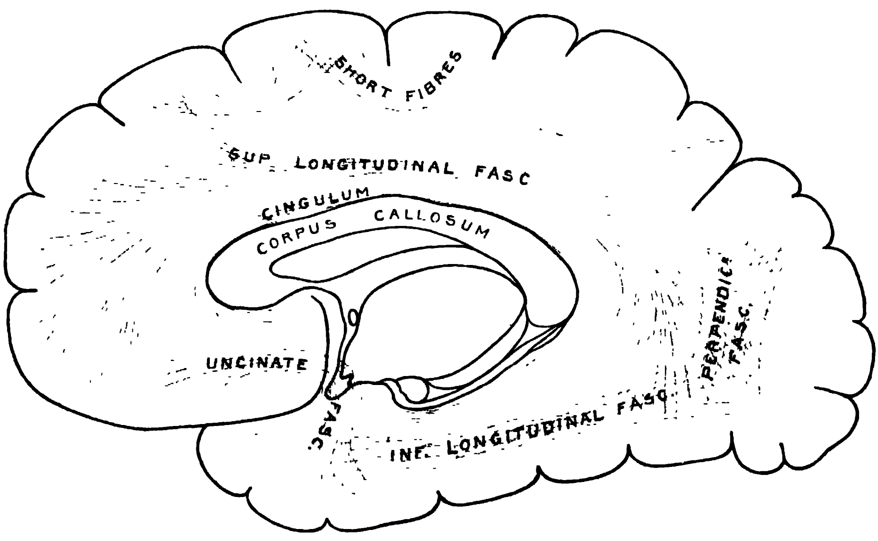
The *long association fibres* include the following : (*a*) the uncinate fasciculus ; (*b*) the cingulum ; (*c*) the superior longitudinal fasciculus ; (*d*) the inferior longitudinal fasciculus ; (*e*) the perpendicular fasciculus ; (*f*) the occipito-frontal fasciculus ; and (*g*) the fornix.

(*a*) The *uncinate fasciculus* passes across the bottom of the Sylvian fissure, and connects the convolutions of the frontal lobe with the anterior end of the temporal lobe.

(*b*) The *cingulum* is a band of white matter which is contained within the callosal convolution. Commencing in front at the anterior perforated space, it passes forwards and upwards parallel with the rostrum, winds round the genu, runs in the convolution from before backwards, immediately above the corpus callosum, turns round its posterior extremity, and passes into the gyrus hippocampi, in the anterior extremity of which it ends.

(*c*) The *superior longitudinal fasciculus* consists of fibres which pass backwards from the frontal lobe above the lenticular nucleus and island of

FIG. 747.—Diagram showing principal systems of association fibres in the cerebrum.



Reil; some of these terminate in the occipital lobe, while others pass downwards and forwards into the temporal lobe.

(*d*) The *inferior longitudinal fasciculus* is a collection of fibres which connect the temporal and occipital lobes, running along the outer wall of the descending and posterior cornua of the lateral ventricle.

(*e*) The *perpendicular fasciculus* runs vertically through the front part of the occipital lobe, and connects the inferior parietal lobule with the fourth temporal convolution.

(*f*) The *occipito-frontal fasciculus* passes backwards from the frontal lobe, along the outer border of the caudate nucleus, and on the mesial aspect of the corona radiata, and its fibres radiate in a fan-like manner and pass into the occipital and temporal lobes on the outer aspect of the posterior and descending cornua. Déjerine regards the fibres of the tapetum as being derived from this fasciculus, and not from the corpus callosum.

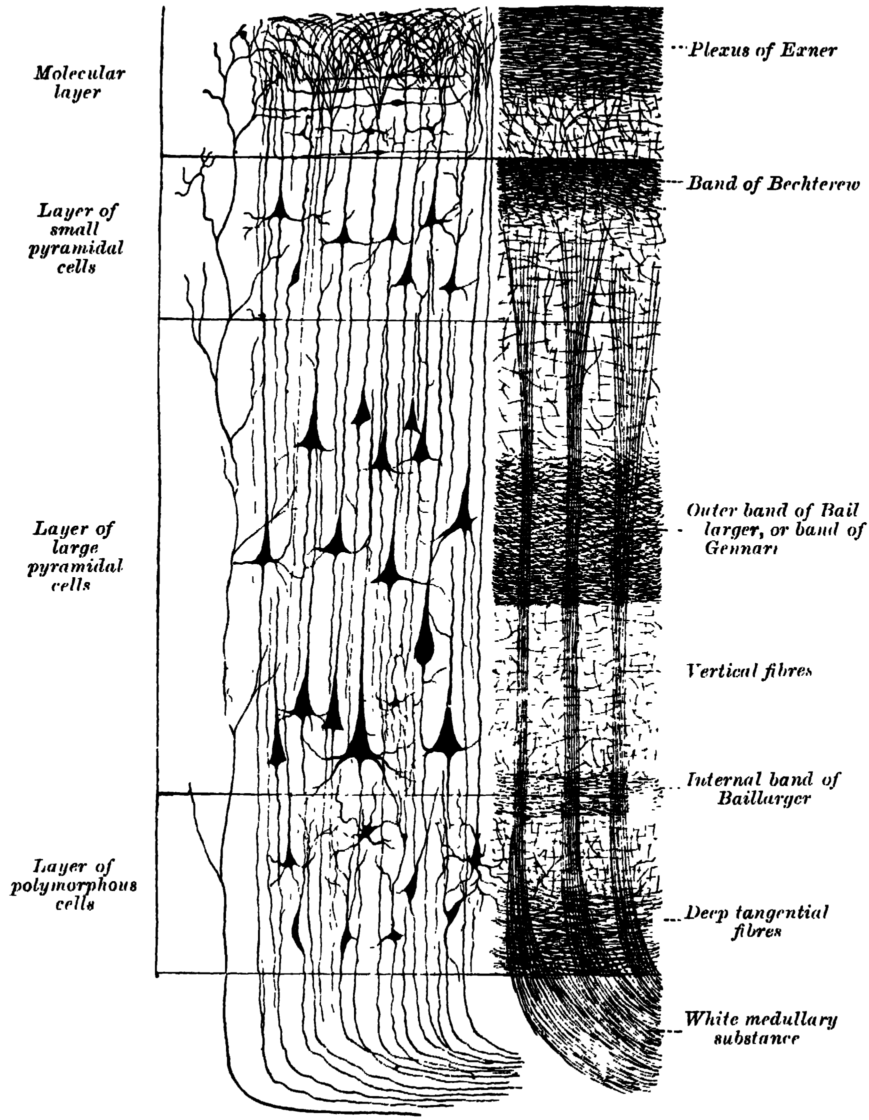
(*g*) The *fornix* connects the hippocampal convolution with the corpus albicans, and, by means of the bundle of Vicq d'Azyr, with the thalamus (see page 875). Through the fibres of the lyra it probably also unites the opposite hippocampal convolutions.

The **grey matter of the hemisphere** is divided into : (1) that of the cerebral cortex, and (2) that of the nucleus caudatus, the nucleus lenticularis, the claustrum, and the nucleus amygdalæ.

Structure of the Cerebral Cortex (fig. 748)

The cerebral cortex differs in its thickness and in its minute structure in different parts of the hemisphere. For instance, it is thinner in the occipital region than in the pre- and postcentral gyri, and it is also much thinner at the bottom of the sulci than on the top of the convolutions. Again, the minute structure of the precentral differs from that of the postcentral gyrus, and areas

Fig. 748.—Cerebral cortex. (Poirier.) To the left, the groups of cells; to the right, the systems of fibres. Quite to the left of the figure a sensory nerve-fibre is shown.



possessing a specialised type of cortex can be mapped out in the occipital lobe.

On examining a section through the cortex with a lens, it is seen to consist of alternating white and grey layers thus disposed from the surface inwards: (1) a thin layer of white substance; (2) a layer of grey substance; (3) a second layer of white substance (outer band of Baillarger or band of Gennari); (4) a second grey layer; (5) a third white layer (inner band of

Baillarger); (6) a third grey layer, which rests on the medullary substance of the convolution.

The cortex is made up of nerve-cells which vary in size and shape, and of nerve-fibres which are either medullated or naked axis-cylinders, imbedded in a matrix of neuroglia.

Nerve-cells.—According to Cajal, whose description is now generally accepted, the nerve-cells are arranged in four layers, named from the surface inwards as follows; (1) the molecular layer, (2) the layer of small pyramidal cells, (3) the layer of large pyramidal cells, (4) the layer of polymorphous cells.

The molecular layer.—In this layer the cells are polygonal, triangular, or fusiform in shape. Each polygonal cell gives off some four or five dendrites, while its axon may arise directly from the cell or from one of its dendrites. The axons and dendrites of these cells ramify in the molecular layer. Each triangular cell gives off two or three dendrites, from one of which the axon arises, the dendrites and the axon ramifying in the molecular layer. The fusiform cells are placed with their long axes parallel to the surface and are mostly bipolar, each pole being prolonged into a dendrite, which runs horizontally for some distance and furnishes ascending branches. Their axons, two or three in number, arise from the dendrites, and, like them, take a horizontal course, giving off numerous ascending collaterals. The distribution of the axons and dendrites of all three sets of cells is limited to the molecular layer.

The **layer of small** and the **layer of large pyramidal cells.**—The cells in these two layers may be studied together, since, with the exception of the difference in size and the more superficial position of the smaller cells, they resemble each other. The average length of the small cells is from 10 to 15 μ; that of the large cells from 20 to 30 μ. The body of each cell is pyramidal in shape, its base being directed to the deeper parts and its apex towards the surface. It contains granular pigment, and stains deeply with ordinary reagents. The nucleus is nucleolated, of large size, and round or oval in shape. The base of the cell gives off the axis-cylinder, and this passes into the central white substance, giving off collaterals in its course, and is distributed as a projection, commissural, or association fibre. Both the apical and basal parts of the cell give off dendrites. The apical dendrite is directed towards the surface, and ends in the molecular layer by dividing into numerous branches, all of which may be seen, when prepared by the silver or methylene-blue method, to be studded with projecting bristle-like processes. The largest pyramidal cells are found in the upper part of the precentral gyrus and in the paracentral lobule. These, which are often arranged in groups or nests of from three to five, are named the *giant-cells of Betz*. In the former situation they may exceed 50 μ in length and 40 μ in breadth, while in the paracentral lobule they may attain a length of 65 μ.

Layer of polymorphous cells.—The cells in this layer, as their name implies, are very irregular in contour; they may be fusiform, oval, triangular, or star-shaped. Their dendrites are directed outwards, towards, but do not reach, the molecular layer; their axons pass into the subjacent white matter.

There are two other kinds of cells in the cerebral cortex, but their axons pass in a direction opposite to that of the pyramidal and polymorphous cells, among which they lie. They are: (*a*) the *cells of Golgi*, the axons of which do not become medullated, but divide, immediately after their origins, into a large number of branches, which are directed towards the surface of the cortex; (*b*) the *cells of Martinotti*, which are chiefly found in the polymorphous layer. Their dendrites are short, and may have an ascending or descending course, while their axons pass out into the molecular layer and form an extensive horizontal arborisation.

Nerve-fibres.—These fill up a large part of the intervals between the cells, and may be medullated or non-medullated—the latter comprising the axons of the smallest pyramidal cells and the cells of Golgi. In their direction the fibres may be either transverse (tangential or horizontal) or vertical (radial). The *tangential fibres* run parallel to the surface of the hemisphere, intersecting the vertical fibres at a right angle. They constitute several strata, of which the following are the most important: (1) a stratum of white fibres covering the superficial aspect of the molecular layer (plexus of Exner); (2) the band of Bechterew, which is situated in the outer part of the layer of small

pyramidal cells; (3) the external band of Baillarger (band of Gennari or band of Vicq d'Azyr), which runs through the layer of large pyramidal cells; (4) the internal band of Baillarger, which intervenes between the layer of large pyramidal cells and the polymorphous layer; (5) the deep tangential fibres which lie in the lower part of the polymorphous layer. According to Cajal, the transverse fibres consist of (*a*) the collaterals of the pyramidal and polymorphous cells and of the cells of Martinotti; (*b*) the arborisations of the axons of Golgi's cells; (*c*) the collaterals and terminal arborisations of the projection, commissural, or association fibres. *The vertical fibres.*—Some of these, viz. the axons of the pyramidal and polymorphous cells, are directed towards the central white matter, while others, the terminations of the projection, commissural, or association fibres, pass outwards to end in the cortex. The axons of the cells of Martinotti are also ascending fibres.

Special Types of Cerebral Cortex

It has been already pointed out that the minute structure of the cortex differs in different regions of the hemisphere; and A. W. Campbell * has endeavoured to prove, as the result of an exhaustive examination of a series of human and anthropoid brains, 'that there exists a direct correlation between physiological function and histological structure.' The principal regions where the 'typical' structure is departed from will now be referred to.

1. In the calcarine fissure and the convolutions bounding it, the inner band of Baillarger is absent, while the band of Gennari is of considerable thickness, and forms a characteristic feature of this region of the cortex. If a section be examined microscopically, an additional layer is seen to be interpolated between the molecular layer and the layer of small pyramidal cells. This extra layer consists of two or three strata of fusiform cells, the long axes of which are at right angles to the surface. Each cell gives off two dendrites, external and internal, from the latter of which the axon arises and passes into the white central substance. In the layer of small pyramidal cells, fusiform cells, identical with the above, are seen, as well as ovoid or star-like cells with ascending axons (cells of Martinotti). This is the *visual area* of the cortex, and it has been shown by J. S. Bolton † that in old-standing cases of optic atrophy the thickness of Gennari's band is reduced by nearly 50 per cent.

A. W. Campbell says: 'Histologically, two distinct types of cortex can be made out in the occipital lobe. The first of these coats the walls and bounding convolutions of the calcarine fissure, and is distinguished by the well-known line of Gennari or Vicq d'Azyr; the second area forms an investing zone a centimetre or more broad around the first, and is characterised by a remarkable wealth of fibres, as well as by curious pyriform cells of large size richly stocked with chromophilic elements—cells which seem to have escaped the observation of Ramón y Cajal, Bolton, and others who have worked at this region. As to the functions of these two regions there is abundant evidence, anatomical, embryological, and pathological, to show that the first or calcarine area is that to which visual sensations primarily pass, and we are gradually obtaining proof to the effect that the second investing area is constituted for the interpretation and further elaboration of these sensations. These areas therefore deserve the names *visuo-sensory* and *visuo-psychic*.'

2. The precentral gyrus is characterised by the presence of the giant-cells of Betz and by 'a wealth of nerve-fibres immeasurably superior to that of any other part' (Campbell), and in these respects differs from the postcentral gyrus. These two gyri, together with the paracentral lobule, have long been regarded as containing the 'motor areas' of the hemisphere; but Sherrington and Grünbaum have shown ‡ that in the chimpanzee the motor area never extends on to the free face of the postcentral convolution, but 'occupies unbrokenly the whole length of the precentral convolution, and in most cases the greater part or the whole of its width. It extends into the depth of the Rolandic fissure, occupying the anterior wall, and in some places the floor, and in some extending even into the deeper part of the posterior wall of the fissure.'

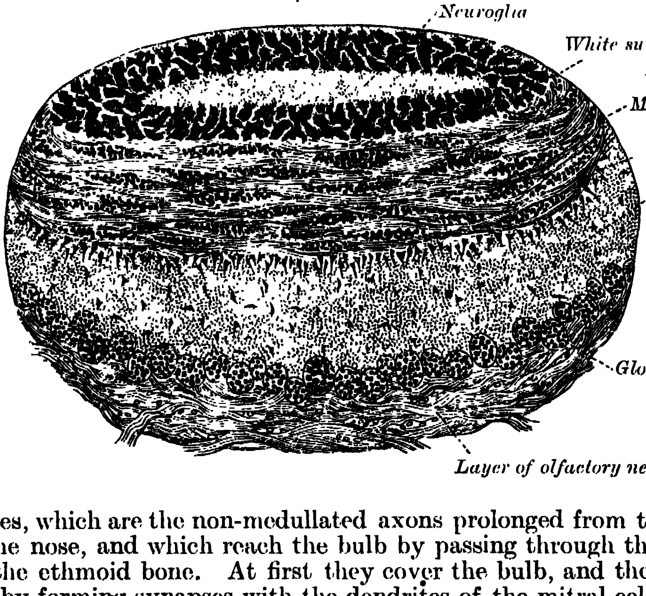
3. In the hippocampus major the molecular layer is very thick and contains a large number of Golgi cells. It has been divided into three strata: (*a*) s. convolutum or s. granulosum, containing many tangential fibres; (*b*) s. lacunosum, presenting numerous lymphatic or vascular spaces; (*c*) s. radiatum, exhibiting a rich plexus of fibrils. The two layers of pyramidal cells are condensed into one, and the cells are mostly of large size. The axons of the cells in the polymorphous layer may run in an ascending, a descending, or a horizontal direction. Between the polymorphous layer and the ventricular ependyma is the white substance of the alveus.

4. In the rudimentary dentate convolution the molecular layer contains some pyramidal cells, while the layer of pyramidal cells is almost entirely represented by small ovoid cells.

5. The olfactory bulb.—In many of the lower animals this contains a cavity which communicates through the hollow olfactory stalk with the lateral ventricle. In man the original cavity is filled up by neuroglia and its wall becomes thickened, but much more so on its ventral than on its dorsal aspect. Its dorsal part contains a small amount of grey and white matter, but it is scanty and ill defined. A section through the ventral part (fig. 749) shows it to consist of the following layers from without inwards: (1) A layer of olfactory

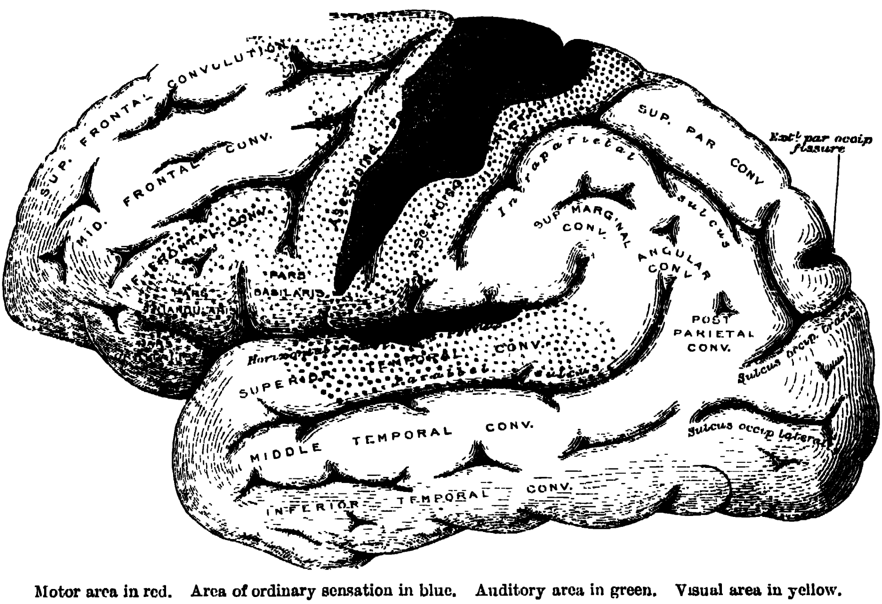
FIG. 749.—Coronal section of olfactory bulb. (Schwalbe.)



nerve-fibres, which are the non-medullated axons prolonged from the olfactory cells of the nose, and which reach the bulb by passing through the cribriform plate of the ethmoid bone. At first they cover the bulb, and then penetrate it to end by forming synapses with the dendrites of the mitral cells, presently to be described. (2) *Glomerular layer.*—This contains numerous spheroidal reticulated enlargements, termed *glomeruli*, which are produced by the branching and arborisation of the processes of the olfactory nerve-fibres with the descending dendrite of the mitral cells. (3) *Molecular layer.*—This is formed of a matrix of neuroglia, imbedded in which are the *mitral cells.* These cells are pyramidal in shape, and the basal part of each gives off a thick dendrite which descends into the glomerular layer, where it arborises as indicated above, and others which interlace with similar dendrites of neighbouring mitral cells. The axons pass through the next layer into the white matter of the bulb, from which, after becoming bent on themselves at a right angle, they are continued into the olfactory tract. (4) *Nerve-fibre layer.*—This lies next the central core of neuroglia, and its fibres consist of the axons or afferent processes of the mitral cells which are passing to the brain; some efferent fibres are, however, also present, and terminate in the molecular layer, but nothing is known as to their exact origin.

Weight of the encephalon.—The average weight of the brain, in the adult male, is 49½ oz., or a little more than 3 lb. avoirdupois; that of the female, 44 oz.; the average difference between the two being from 5 to 6 oz. The prevailing weight of the brain, in the male, ranges between 46 oz. and 53 oz.; and, in the female, between 41 oz. and 47 oz. In the male, the maximum weight out of 278 cases was 65 oz. and the minimum weight 34 oz. The maximum weight of the adult female brain, out of 191 cases, was 56 oz., and the minimum weight 31 oz. According to Luschka, the average weight of a man's brain is 1,424 grammes (about 45 oz.), of a woman's 1,272 grammes (about 41 oz.); and according to Krause, 1,570 grammes (about 48½ oz.) for the male, and 1,350 grammes (about 43 oz.) for the female. It appears that the weight of the brain increases rapidly up to the seventh year, more slowly to between sixteen and twenty, and still more slowly to between thirty and forty, when it reaches its maximum. As age further advances and the mental faculties decline, the brain diminishes slowly in weight, to the extent of about

FIG. 750.—Areas of localisation on outer surface of hemisphere.



Motor area in red. Area of ordinary sensation in blue. Auditory area in green. Visual area in yellow.

an ounce for each subsequent decennial period. These results apply alike to both sexes.

The size of the brain was formerly said to bear a general relation to the intellectual capacity of the individual. Cuvier's brain weighed rather more than 64 oz., that of the late Dr. Abercrombie 63 oz., and that of Dupuytren 62½ oz. But these facts are by no means conclusive, and it is well known that these weights have been equalled by the brains of persons who never displayed any remarkable intellect. Haldennan, of Cincinnati, has recorded the case of a mulatto, aged 45, whose brain weighed 68⅜ oz.; he had been a slave, and was never regarded as particularly intelligent; he was illiterate, but is said to have been reserved, meditative, and economical. Ensor, district medical officer at Port Elizabeth, reports that the brain of Carey, the Irish informer, weighed 61 oz. On the other hand, the brain of an idiot seldom weighs more than 23 oz. M. Nikiforoff has published an article on the subject of the weight of brains in the 'Novosti.' According to him, the weight of the brain has no influence whatever on the mental faculties. It ought to be remembered that the significance of the weight of the brain should depend upon the proportion it bears to the dimensions of the whole body and to the age of the individual. It is equally important to know what was the cause of death, for long illness or old age exhausts the brain. To define the real degree of development of the brain, it is therefore necessary to have a knowledge of

the condition of the whole body; and, as this is usually lacking, the mere record of weight possesses little significance.

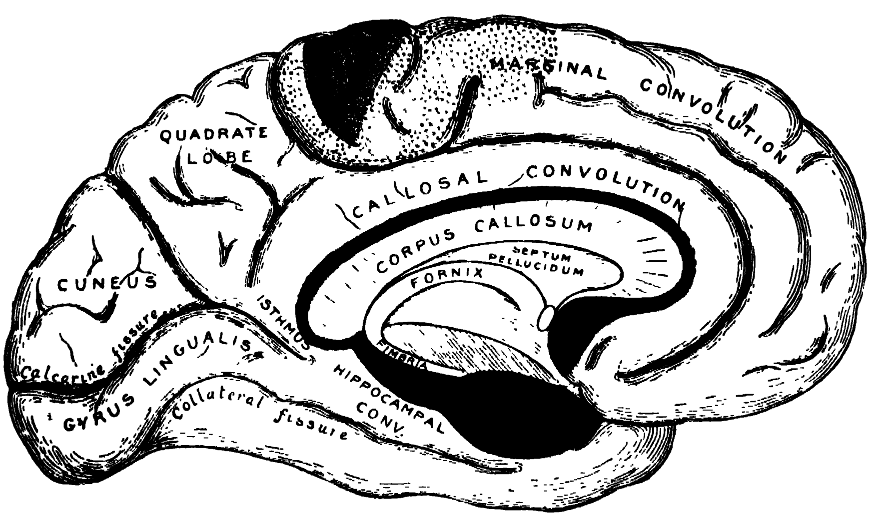
The human brain is heavier than that of any of the lower animals, except the elephant and whale. The brain of the former weighs from eight to ten pounds; and that of a whale, in a specimen seventy-five feet long, weighed rather more than five pounds.

Cerebral Localisation.—Physiological and pathological research have now gone far to prove that a considerable part of the surface of the brain may be mapped out into a series of more or less definite areas, each of which is intimately connected with some well-defined function.

The chief areas are indicated in figs. 750 and 751.

Motor areas.—The motor area occupies the precentral and frontal gyri and the paracentral lobule. The centres for the lower limb are located on the uppermost part of the precentral gyrus and its continuation on to the paracentral lobule; those for the trunk are on the upper portion, and those for the upper limb on the middle portion of the precentral gyrus. The facial centres are situated on the lower part of the precentral gyrus, those for the tongue, larynx, muscles of mastication, and pharynx on the frontal opercula, while those for the head and neck occupy the posterior end of the mid-frontal region.

FIG. 751.—Areas of localisation on inner surface of hemisphere.



Motor area in red. Area of ordinary sensation in blue. Visual area in yellow. Olfactory area in purple.

Sensory areas.—Tactile and temperature senses are located on the postcentral gyrus, while the sense of form and solidity is on the superior parietal gyrus and precuneus. With regard to the special senses, the area for the sense of taste is probably related to the uncus and hippocampal gyrus. The auditory area occupies the middle third of the superior temporal gyrus and the adjacent gyri in the Sylvian fissure; the visual area, the calcarine fissure and cuneus; the olfactory area, the rhinencephalon. As special centres of much importance may be noted: the emissive centre for speech on the left inferior frontal and precentral gyri; the auditory receptive centre on the marginal and superior temporal gyri, and the visual receptive centre on the angular gyrus.

Cerebral Topography.—The relation of the principal fissures and convolutions of the cerebrum to the outer surface of the scalp has been the subject of much investigation, and many systems have been devised by which one may localise these parts from an examination of the external surface of the head (fig. 752).

These plans can only be regarded as approximately correct for several reasons: in the first place, because the relations of the convolutions and sulci to the surface vary in different individuals; secondly, because the surface area of the scalp is greater than the surface area of the brain, so that lines drawn on the one cannot correspond exactly to sulci or convolutions on the other; and thirdly, because the sulci and convolutions in two individuals are never precisely alike. Nevertheless, the principal fissures and convolutions can be mapped out with sufficient accuracy for all practical purposes, so that any particular convolution can be exposed by removing with the trephine a certain portion of the skull.

The various landmarks on the outside of the skull, which can be easily felt, and which serve as indications of the position of the parts beneath, have been already referred to (see page 280), but there are certain other points or landmarks which require alluding to, in order to facilitate the description of the relation of the fissures and convolutions of the brain to the external surface of the skull.

A line drawn horizontally backwards from the middle of the infra-orbital margin, through the centre of the outlet of the external auditory meatus, will represent what is known as *Reid's base-line*. A spot on this base-line in the hollow between the tragus of the ear and the condyle of the mandible is known as the *pre-auricular point*.

The longitudinal fissure.—This corresponds to a line drawn from the nasion to the inion.

The Sylvian fissure.—In order to mark out this fissure, a point must be defined by carrying horizontally backwards a line for $1\frac{3}{8}$ of an inch (thirty-five millimetres) from the

FIG. 752.—Drawing of a cast by Cunningham to illustrate the relations of the brain to the skull.

external angular process of the frontal bone, and from the posterior extremity of this line a vertical line upwards for half an inch (twelve millimetres); the upper end of this second line is the point in question, and is known as the *Sylvian point*. It marks the spot where the Sylvian fissure divides. Another and simple plan of defining the Sylvian point has been devised by E. H. Taylor. He divides the distance between the nasion and inion into four equal parts, and draws one line from the junction of the third and fourth parts, reckoning from before backwards, to the external angular process of the frontal bone; and a second line, from the junction of the first and second segments to the centre of the external auditory meatus. The Sylvian point will be the spot where these two lines cross one another, and the first line from this point onwards will lie over the posterior limb of the fissure of Sylvius. The *Sylvian line*—that is to say, the line on the surface of the skull which lies over the posterior limb of the fissure of Sylvius—is usually marked out by drawing a line from the Sylvian point to the lower part of the parietal

eminence. The ascending limb of the fissure of Sylvius may be marked out by drawing a line upwards, at right angles to the Sylvian line, for nearly an inch (two centimetres); and the horizontal limb by a line of the same length, drawn horizontally forwards from the same point.

The fissure of Rolando.—Thane defines this fissure by taking the centre of a line between the nasion and the inion and fixes the *superior Rolandic point* at half an inch behind this. The *inferior Rolandic point* is defined by drawing a line at right angles to the base-line of Reid, from the pre-auricular point to the Sylvian line; this it meets about an inch from the Sylvian point. By joining these two points, the *Rolandic line*, which overlies the fissure of Rolando, is mapped out. It forms an angle opening forwards, of about seventy degrees with the median line. Reid has devised another plan for mapping out this fissure. He draws two perpendicular lines from the base-line to the top of the head; one from the pre-auricular point, and the other from the posterior border of the mastoid process at its root. A line drawn from the upper extremity of the posterior

line to the point where the Sylvian line crosses the anterior one would indicate the position of the fissure of Rolando.

The *external parieto-occipital fissure* runs outwards at right angles to the great longitudinal fissure for about an inch, from a point one-fifth of an inch in front of the lambda (posterior fontanelle). Reid states that if the posterior limb of the fissure of Sylvius be continued backwards to the sagittal suture, the last inch of this line will indicate the position of the sulcus.

The *precentral* and *postcentral sulci* are situated three-fifths of an inch in front of and behind the Rolandic fissure respectively; they are nearly parallel with this fissure, and extend as low as the Sylvian line.

The *superior frontal fissure* may be mapped out by drawing a line from the junction of the upper and middle third of the precentral sulcus, in a direction parallel with the longitudinal fissure, to a point midway between the middle line of the forehead and the temporal ridge, an inch and a half above the supra-orbital notch.

The *inferior frontal fissure* follows the course of the superior temporal ridge, commencing at the junction of the middle and lower thirds of the precentral sulcus.

The *intraparietal fissure* begins on a level with the junction of the middle and lower third of the fissure of Rolando, on a line carried across the head from the back of the root of one auricle to that of the other. After passing upwards, it curves backwards, lying parallel to the longitudinal fissure, midway between it and the parietal eminence; it then curves downwards to end midway between the lambda and the parietal eminence.

The *lateral ventricles* may be circumscribed, according to Poirier, by describing a quadrilateral figure on the side of the head. The upper limit is a horizontal line drawn two inches above and parallel with the zygoma: this defines the roof of the ventricular cavity. The lower limit is a second horizontal line drawn half an inch above the zygoma: this indicates the level of the extremity of the descending horn of the ventricle. Two vertical lines—one drawn through the junction of the anterior and middle thirds of the zygomatic arch, and the other two inches behind the tip of the mastoid process—indicate the extent of the anterior horn in front and the posterior horn behind.

Applied Anatomy.—The *internal capsule* is of great interest to the clinician because it is so often the seat of hæmorrhage (from the lenticulo-striate and lenticulo-optic arteries, Charcot's 'arteries of cerebral hæmorrhage'), or of thrombosis, in patients whose vessels are weakened by old age or disease. A 'stroke,' or 'apoplexy' is the result; blood is effused from the ruptured vessel and tears up the surrounding brain tissue, and also interferes with the neighbouring fibres by the compression set up by its mass. If the hæmorrhage is sudden and at all large, rapid and complete loss of consciousness follows, with paralysis of the opposite side of the body and loss of control over the sphincters. If it is the hinder part of the internal capsule that is involved, the paralysis will be more marked in the leg than in the arm, and will be associated with hemianæsthesia, and also with homonymous hemianopsia (or blindness of the corresponding halves of the two retinæ, the patient being unable to see objects on the opposite side of the body). If the hæmorrhage is very extensive blood often makes its way into the ventricles, and death may follow in a few hours or days without recovery of consciousness, and with hyperpyrexia. If the hæmorrhage is small, consciousness is soon regained, and a fair degree of recovery from the paralysis follows, particularly in the leg. If the hæmorrhage takes place very slowly, the hemiplegia sets in gradually (ingravescent apoplexy), with headache and gradual clouding of the faculties. It is the upper motor neuron (see page 889) that is injured in cerebral hæmorrhage; hence the muscles on the affected side of the body become spastic, with increased reflexes, while such muscular atrophy as follows is mainly due to disuse.

Motor and Sensory Tracts

The anatomy of the various parts of the central nervous system having been described, a short account will now be given of the course taken by the motor and sensory nerve-tracts. The methods employed in elucidating this complex subject have already been referred to (page 804).

Motor Tract (fig. 754)

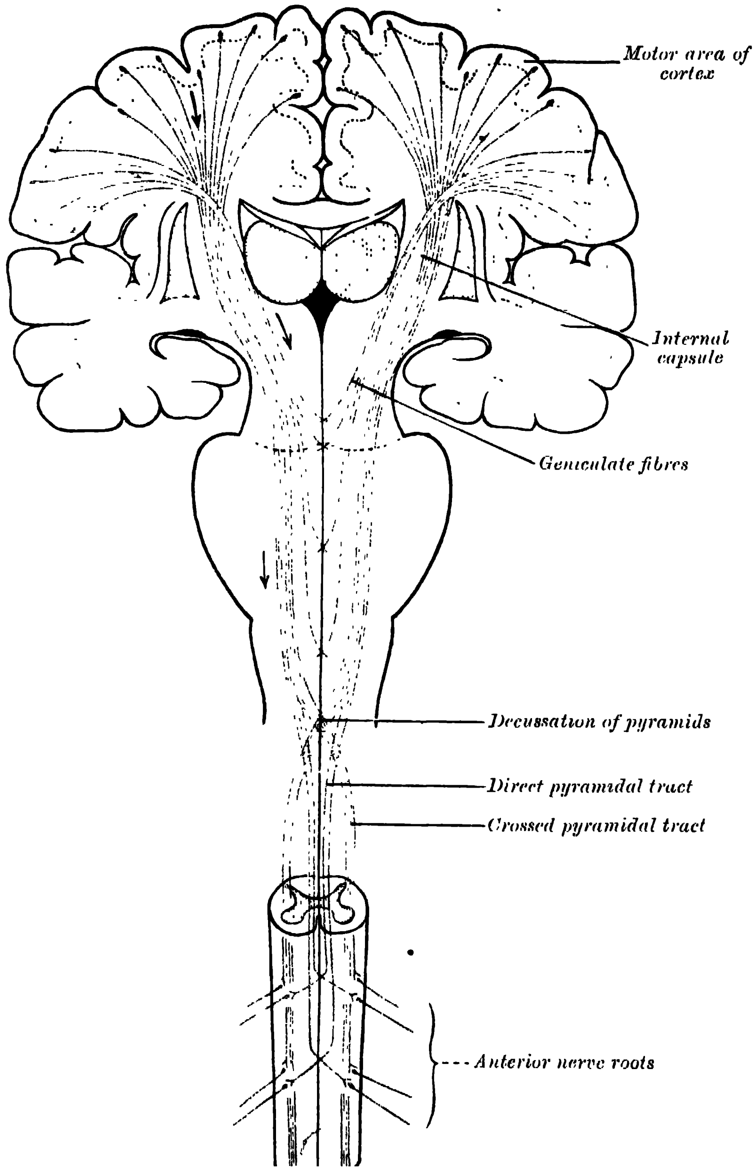
The constituent fibres of this tract are the axis-cylinder processes of cells situated in the motor area of the cortex. At first they are somewhat widely diffused, but as they descend through the corona radiata they gradually approach each other, and pass between the lenticular nucleus and thalamus, in the genu and anterior two-thirds of the posterior limb of the internal capsule; those which occupy the genu are named the geniculate fibres, while the remainder constitute the pyramidal fibres. Proceeding downwards they enter the crusta or pes of the crus cerebri, the pyramidal fibres occupying the middle three-fifths, and the geniculate fibres the innermost fifth of this structure. The geniculate fibres then decussate in the middle line with the corresponding fibres of the opposite side, and end by arborising around the cells of the motor nuclei of the cranial nerves. The pyramidal fibres are continued downwards into the anterior pyramids of the medulla, and the transit of the fibres from the medulla is effected by two paths. The fibres nearest to the anterior median fissure cross the middle line, forming the *decussation of the pyramids*, and descend in the opposite side of the cord, as the indirect or crossed pyramidal tract. Throughout the length of the spinal cord fibres from this column pass into the grey matter, to terminate by ramifying around the cells of the anterior horn. The more laterally placed portion of the motor tract does not decussate in the medulla, but descends as the direct or uncrossed pyramidal tract; these fibres, however, end in the anterior grey horn of the opposite side of the spinal cord by passing across in the anterior white commissure. There is considerable variation in the extent to which decussation takes place in the medulla, the commonest condition being that in which about two-thirds or

three-fourths of the fibres decussate in the medulla and the remainder in the cord.

The axons of the motor cells in the anterior horn pass out as the fibres of the anterior roots of the spinal nerves, along which the impulses are conducted to the muscles of the trunk and limbs.

From this it will be seen that all the fibres of the motor tract pass to the nuclei of the motor nerves on the opposite side of the brain or cord, a fact

Fig. 754.—The motor tract. (Modified from Poirier.)



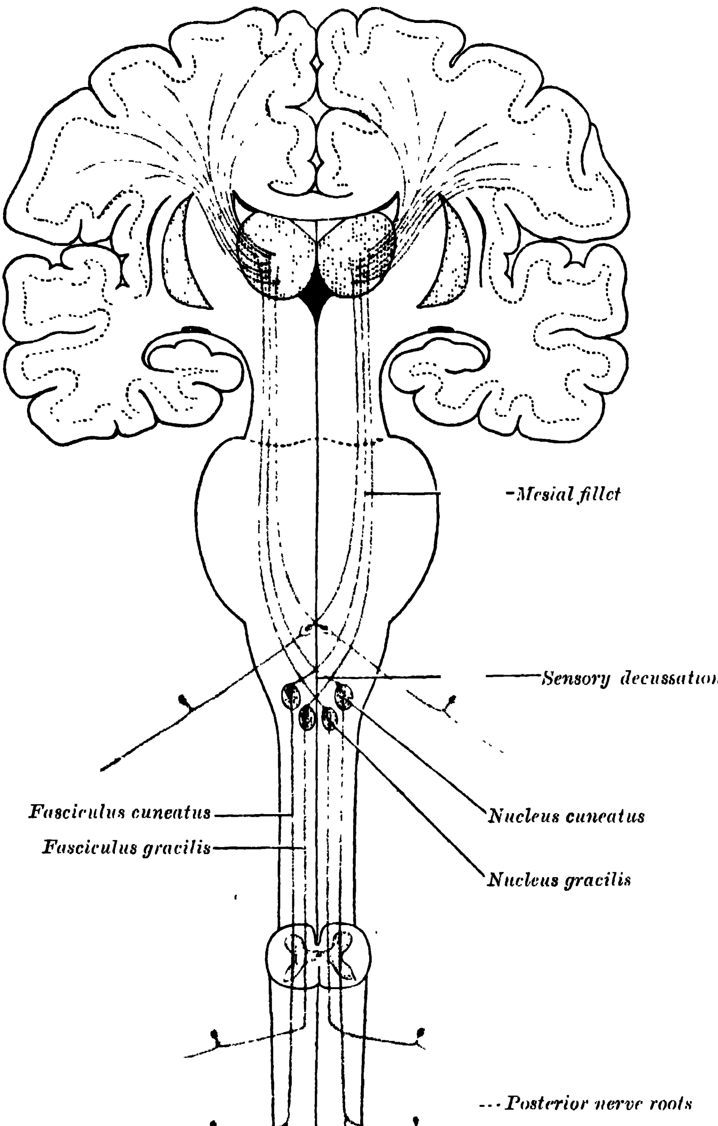
which explains why a lesion involving the motor area of one side causes paralysis of the muscles of the opposite side of the body. Further, it will be seen that there is a break in the continuity of the motor chain: in the case of the cranial nerves this break occurs in the nuclei of these nerves; and in the case of the spinal nerves, in the anterior horn of grey matter. For clinical purposes it is convenient to emphasise this break and divide the motor tract into two portions: (1) a series of *upper motor neurons* which comprises the motor cells in the

cortex and their descending fibres down to the nuclei of the motor nerves; (2) a series of *lower motor neurons* which includes the cells of the nuclei of the motor cranial nerves or the cells of the anterior horns of the cord and their axis-cylinder processes to the periphery.*

Sensory Tract (fig. 755)

Sensory impulses are conveyed to the spinal cord through the posterior roots of the spinal nerves. On entering the cord these root-fibres divide into

Fig. 755.—The sensory tract. (Modified from Poirier.)



descending and ascending branches; the former soon enter the grey matter: of the latter some end in the grey matter after a longer or shorter course, while

* As already mentioned (footnote, page 805) a neuron in the posterior horn of the cord is probably interposed between each upper and lower motor neuron.

others are continued directly into the posterior columns of the cord, where they form the fasciculus gracilis and fasciculus cuneatus. From the cells of the posterior horn, fibres arise which cross the middle line and ascend in the peripheral part of the lateral column as the tract of Gowers. Certain observers maintain that some of the sensory fibres ascend in the anterior column. The fibres of the fasciculus gracilis and fasciculus cuneatus end by arborising around the cells of the gracile and cuneate nuclei, and from these cells the fibres of the mesial fillet take origin and cross to the opposite side in the *sensory decussation.* The mesial fillet is then joined by the fibres of Gowers' tract, which have already crossed in the cord, and in its further course receives fibres from the cranial sensory nuclei of the opposite side, with the exception of the cochlear division of the auditory nerve. Ascending through the crus, the fillet gives off some fibres to the lenticular nucleus and island of Reil, but the greater part of it is carried into the thalamus, where most of its fibres terminate—only a small proportion being continued directly into the cerebral cortex. From the grey matter of the thalamus the fibres of the third link in the chain arise and pass to the cerebral cortex. The fibres from the terminal nuclei of the cochlear nerve pass upwards in the lateral fillet, and are carried through the posterior part of the internal capsule to the temporal lobe. Further, Gowers' tract gives off a fasciculus which reaches the cerebellum through its superior peduncles. It will be evident, therefore, that in most cases there are three cell-stations interposed in the course of the sensory impulses. For clinical purposes, therefore, three neurons are described. (1) The series of *lower sensory neurons* comprises the cells of the posterior root ganglia and their peripheral and central processes. Of the *two upper sensory neurons*, (2) the lower series includes the cells of the nuclei cuneati and graciles and their processes, while (3) the upper group contains the cells of the thalami and the fibres passing from these to the cerebral cortex.

Applied Anatomy.—The chief symptoms of diseases of the brain and spinal cord depend upon the particular systems of neurons picked out for attack, and some of them may be briefly summarised as follows. *Motor paralysis* of the *spastic* type, with rigidity of the muscles and increased reflexes, follows destruction of the upper motor neurons; *flaccid* paralysis, with loss of the reflexes and rapid muscular atrophy, follows destruction of the lower motor neuron. *Sensory paralysis* follows injury to any part of the sensory path; in tabes it is due to injury of the lower sensory neuron, in hemiplegia to destruction of the upper sensory axon as it traverses the posterior part of the internal capsule. *Dissociation of sensations*, or the loss of some forms of sensation while others remain unimpaired, is seen in a number of conditions such as tabes or syringomyelia; it shows that the paths through which various forms of sensation travel to the brain are different. *Abnormalities of reflex actions* are of very great help in the diagnosis of nervous complaints. The numerous *superficial* or *skin reflexes* (*e.g.* the scapular, irritation of the skin over the scapula produces contraction of the scapular muscles; the abdominal, stroking the abdomen causes its retraction; the cremasteric, stroking the inner side of the thigh causes retraction of that side of the scrotum; the plantar, tickling the sole of the foot brings on plantar flexion of the toes), if present, show that the reflex arcs on whose integrity their existence depends are intact; but they are often absent in health, and so cannot be trusted to indicate disease. The *deep reflexes* or *tendon reactions*, such as the knee-jerk or the tendo Achillis jerk, are increased in chronic degeneration of, or gradually increasing pressure on, the pyramidal fibres (upper motor neuron), in nervous or hysterical patients, and when the irritability of the anterior cornual cells (lower motor neuron) is increased, as happens in tetanus or in poisoning by strychnine. They are lost when the lower motor or lower sensory neurons are diseased, and in a few other conditions; absence of the knee-jerk is very rare in health, and suggests disease in some part of its reflex arc, in the third and fourth lumbar segments of the cord, or else, more rarely, grave intracranial or spinal disease cutting off the lower from the higher nervous centres. The *organic reflexes* of the pupil, bladder, and rectum, are of the greatest practical importance. The commonest defect in the reflexes of the pupil is reflex iridoplegia, or failure to contract on exposure to light, without failure to contract on convergence or accommodation ('Argyll Robertson' pupil). The pupil is also contracted (miosis), and may or may not dilate when the skin of the neck is pinched (the cilio-spinal reflex). Micturition is a spinal reflex much under the control of the brain; if the centre for micturition in the second sacral segment is destroyed the sphincter and the walls of the bladder are paralysed, the bladder becomes distended with urine, and incontinence from overflow results. If this centre escapes injury but is cut off more or less completely from impulses descending to it from above, there will be more or less interference with micturition. This varies in degree from the 'precipitate micturition' of tabetic patients, who must perforce hurry to pass water the moment the impulse seizes them, to the

state of 'reflex incontinence,' when the bladder automatically empties itself from time to time, almost without the patient's knowledge. Defæcation is a very similar spinal reflex, and is liable to very similar disorders of function.

The *upper motor neuron* (page 889) is affected in hemiplegia, the *lower motor neuron* (page 890) in infantile spinal paralysis; both these systems of neurons are diseased together in the somewhat rare disorders known as amyotrophic lateral sclerosis and progressive muscular atrophy. The chief symptom here is wasting and weakness in certain groups of muscles; the palsy will be flaccid, with loss of the reflexes, or spastic, with increased reflexes, according as the degeneration mainly involves the lower or the upper motor neuron. The sphincters are affected only in the later stages of these diseases.

Pathological changes in the *lower sensory neuron* are the cause of tabes dorsalis or locomotor ataxy, which occurs almost entirely in adults who have had syphilis. In the early or pre-ataxic stage the patient may exhibit the Argyll-Robertson pupil (page 891), and loss of the knee-jerks, and complain of sharp, stabbing pains ('lightning pains') in the limbs, difficult or precipitate micturition, and sometimes of severe and painful attacks of indigestion (gastric crises). In the second or ataxic stage, coming on perhaps years later, he will complain, in addition, of interference with his powers of getting about and turning, although his muscular strength is well preserved. He is unable to stand steady with his eyes shut or in the dark, his gait becomes exaggerated and stamping in character, he has to use a stout stick to walk with, and he may suffer from painful crises in various parts of the body. Control over the sphincters is further weakened, and on examination there will be found marked inco-ordination of the limbs, zones of anæsthesia about the trunk or down the limbs, and marked analgesia (or insensitiveness to pain) when pressure is applied to the bones, tendons, trachea, tongue, eyeballs, mammæ, and testes.* The ataxy progresses till the third or bed-ridden stage is reached; control over the sphincters is still further lost, and the patient is likely to die of intercurrent disease or of general paralysis of the insane.

No nervous disease is recognised as dependent upon degeneration of either or both of the two *upper sensory neurons*.

MENINGES OF THE BRAIN AND SPINAL CORD

The brain and spinal cord are enclosed within three membranes. These are named from without inwards: the dura mater, the arachnoid membrane, and the pia mater.

The Dura Mater

The **dura mater** is a thick and dense inelastic membrane, which forms an external covering for the brain and spinal cord. The portion which encloses the brain differs in several essential particulars from that which surrounds the spinal cord, and therefore it is necessary to describe them separately; but at the same time it must be distinctly understood that the two form one complete membrane, and are continuous with each other at the foramen magnum.

The **cranial dura mater** lines the interior of the skull, and serves the twofold purpose of an internal periosteum to the bones, and a membrane for the protection of the brain. It is composed of two layers closely connected together, except in certain situations, where, as already described (page 737), they separate to form sinuses for the passage of venous blood. Upon the outer surface of the cranial dura mater, in the situation of the longitudinal sinus, may be seen numerous small whitish bodies, the *glandulæ Pacchionii*. Its outer surface is rough and fibrillated, and adheres closely to the inner surface of the bones, the adhesion being most marked opposite the sutures and at the base of the skull. Its inner surface is smooth and lined by a layer of endothelium. It sends inwards four processes which divide the cavity of the skull into a series of freely communicating compartments, for the lodgment and protection of the different parts of the brain; and it is prolonged to the outer surface of the skull, through the various foramina which exist at the base, and thus becomes continuous with the pericranium; its fibrous layer forms sheaths for the nerves which pass through these apertures. At the base of the skull, it sends a fibrous prolongation into the foramen cæcum; it sends a series of tubular prolongations round the filaments of the olfactory nerves as they pass through the cribriform plate, and another round the nasal nerve as it passes through the nasal slit; a prolongation is also continued

* J. Grasset, *Le Tabes, Maladie de la Sensibilité profonde*: Montpellier, 1909.

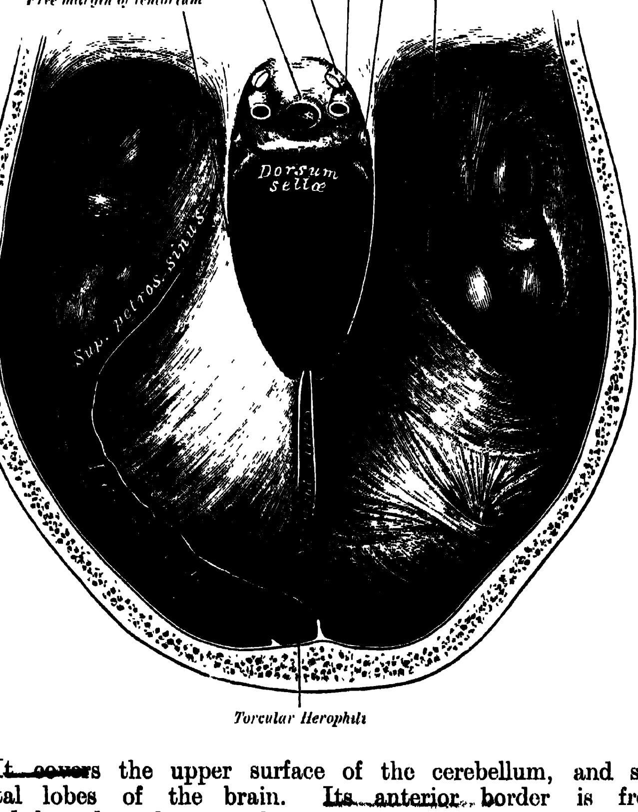
through the sphenoidal fissure into the orbit, and another is carried into the same cavity through the optic foramen, forming a sheath for the optic nerve, which is continued as far as the eyeball. In the posterior fossa it sends a process into the internal auditory meatus, ensheathing the facial and auditory nerves; another through the jugular foramen, forming a sheath for the structures which pass through this opening; and a third through the anterior condyloid foramen. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the spinal dura mater.

Processes.—The processes of the cranial dura mater, which project into the cavity of the skull, are formed by reduplications of the inner or meningeal layer of the membrane, and are four in number: the falx cerebri, the tentorium cerebelli, the falx cerebelli, and the diaphragma sellæ.

The *falx cerebri*, so named from its sickle-like form, is a strong, arched process which descends vertically in the longitudinal fissure between the hemispheres of the brain. It is narrow in front, where it is attached to the crista galli of the ethmoid; and broad behind, where it is connected with the upper surface of the tentorium cerebelli. Its upper margin is convex, and attached to the inner surface of the skull in the middle line, as far back as the internal occipital protuberance; it contains the superior longitudinal sinus. Its lower margin is free, concave, and presents a sharp curved edge, which contains the inferior longitudinal sinus.

The *tentorium cerebelli* (fig. 756) is an arched lamina of dura mater, elevated in the middle, and inclining downwards towards the circum-

FIG. 756.—Tentorium cerebelli seen from above.



ference. It covers the upper surface of the cerebellum, and supports the occipital lobes of the brain. Its anterior border is free and concave, and bounds a large oval opening, the *incisura tentorii*, for the transmission of the crura cerebri. It is attached, behind, by its convex border to the transverse ridges upon the inner surface of the occipital bone,

and there encloses the lateral sinuses; in front, to the superior margin of the petrous portion of the temporal bone on either side, enclosing the superior petrosal sinuses, and at the apex of this bone the free or anterior border and the attached or external border meet, and, crossing one another, are continued forwards to be fixed to the anterior and posterior clinoid processes respectively. To the middle line of its upper surface the posterior border of the falx cerebri is attached, the straight sinus being placed at their line of junction.

The *falx cerebelli* is a small triangular process of dura mater, received into the indentation between the two lateral lobes of the cerebellum behind. Its base is attached, above, to the under and back part of the tentorium; its ~~posterior margin~~, to the lower division of the vertical crest on the inner surface of the occipital bone. As it descends, it sometimes divides into two smaller folds, which are lost on the sides of the foramen magnum.

The *diaphragma sellæ* is a small circular horizontal fold, which constitutes a roof for the sella turcica. This almost completely covers the pituitary body, presenting merely a small central opening for the infundibulum to pass through.

Structure.—The cranial dura mater consists of white fibrous tissue, with connective-tissue cells and elastic fibres arranged in flattened laminæ which are imperfectly separated by lacunar spaces and blood-vessels into two layers, *endosteal* and *meningeal*. The *endosteal layer* is the internal periosteum for the cranial bones, and contains the blood-vessels for their supply. At the margin of the foramen magnum it is continuous with the periosteum lining the spinal canal. The *meningeal* or *supporting layer* is lined on its inner surface by a layer of nucleated endothelium, similar to that found on serous membranes: these cells were formerly regarded as belonging to the arachnoid membrane. By its reduplication the meningeal layer forms the falx cerebri, the tentorium and falx cerebelli, and the diaphragma sellæ. The two layers are connected by fibres which intersect each other obliquely.

The *arteries* of the dura mater are very numerous. Those in the anterior fossa are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid, and a branch from the middle meningeal. Those in the middle fossa are the middle and small meningeal of the internal maxillary; a branch from the ascending pharyngeal, which enters the skull through the foramen lacerum medium; branches from the internal carotid, and a recurrent branch from the lachrymal. Those in the posterior fossa are meningeal branches from the occipital, one of which enters the skull through the jugular foramen, and the other through the mastoid foramen; the posterior meningeal from the vertebral; occasional meningeal branches from the ascending pharyngeal, which enter the skull through the jugular and condyloid foramina; and a branch from the middle meningeal.

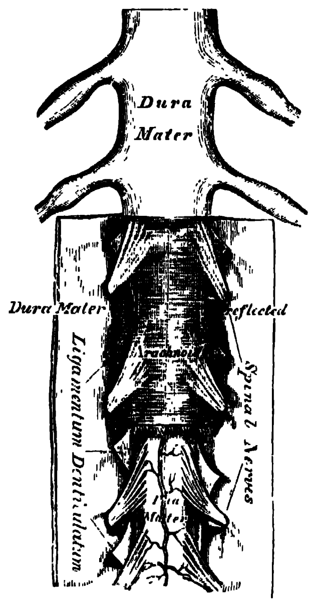
The *veins* which return the blood from the cranial dura mater anastomose with the diploic veins. They terminate in the various sinuses, with the exception of the two which accompany the middle meningeal artery; these pass out of the skull at the foramen spinosum to join the pterygoid plexus, through which their contents are drained into the internal maxillary vein; above, they communicate with the superior longitudinal sinus. Many of the meningeal veins do not open directly into the sinuses, but indirectly through a series of ampullæ, termed *venous lacunæ*. These are found on either side of the superior longitudinal sinus, especially near its middle portion, and are often invaginated by Pacchionian bodies; they also exist near the lateral and straight sinuses. They communicate with the underlying cerebral veins, and also with the diploic and emissary veins.

The *nerves* of the cranial dura mater are filaments from the Gasserian ganglion, from the ophthalmic, superior maxillary, inferior maxillary, vagus, and hypoglossal nerves, and from the sympathetic.

The **spinal dura mater** (fig. 757) forms a loose sheath around the cord, and represents only the inner or meningeal layer of the cranial dura mater; the outer or endosteal layer ceases at the foramen magnum, its place being taken by the periosteum lining the spinal canal. The dura mater is separated from the bony walls of the spinal canal by a space, the *epidural space*, which contains a quantity of loose areolar tissue and a plexus of veins; the situation of these veins between the dura mater of the cord and the periosteum of the vertebræ

corresponds therefore to that of the cranial sinuses between the meningeal and endosteal layers of the cranial dura mater. It is attached to the circumference of the foramen magnum, and to the second and third cervical vertebræ; it is also connected to the posterior common ligament, especially near the lower end of the spinal canal, by fibrous slips; it extends below as far as the lower border of the second sacral vertebra, where its cavity terminates; below this level it closely invests the filum terminale and descends to the back of the coccyx, where it blends with the periosteum. The sheath of dura mater is much larger than is necessary for the accommodation of its contents, and its size is greater in the cervical and lumbar regions than in the thoracic. Its inner surface is smooth. On each side may be seen the double openings which transmit the two roots of the corresponding spinal nerve, the dura mater being continued in the form of tubular prolongations on them as they pass through the intervertebral foramina. These prolongations are short in the upper part of the spine, but gradually become longer below, forming a number of tubes of fibrous membrane, which enclose the lower spinal nerves and are contained in the spinal canal.

FIG. 757.—The spinal cord and its membranes.



Structure.—The spinal dura mater resembles in structure the meningeal or supporting layer of the cranial dura mater, consisting of white fibrous and elastic tissue arranged in bands or lamellæ which, for the most part, are parallel with one another and have a longitudinal arrangement. Its internal surface is covered by a layer of endothelium, which gives this surface its smooth appearance. It is sparingly supplied with blood-vessels, and some few nerves have been traced into it.

Subdural space.—The dura mater is separated from the arachnoid by a potential space, the *subdural space*. The two membranes are, in fact, in contact with each other, except where they are separated by a minute quantity of fluid, which just serves to keep the two opposing surfaces moist.

The Arachnoid Membrane

The **arachnoid membrane** is a delicate membrane which envelops both the brain and cord, lying between the pia mater internally and the dura mater externally.

The *cranial part of the arachnoid* invests the brain loosely, and does not dip into the sulci between the convolutions, nor into the fissures, with the exception of the longitudinal fissure. On the upper surface of the cerebrum the arachnoid is thin and transparent, and may be easily demonstrated by injecting a stream of air beneath it. At the base of the brain the arachnoid is thicker, and slightly opaque towards the central part where it extends across between the two temporal lobes in front of the pons Varolii, so as to leave a considerable interval between it and the brain.

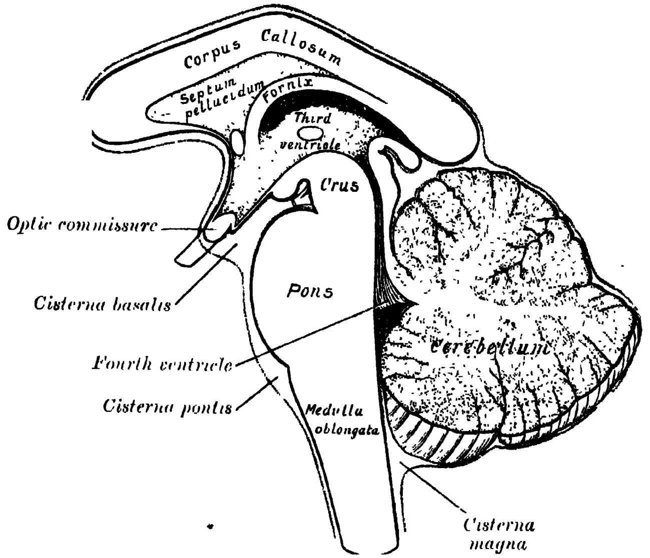
The *spinal part of the arachnoid* is a thin, delicate, tubular membrane which loosely invests the cord. Above, it is continuous with the cerebral arachnoid; below, it widens out and invests the cauda equina and the nerves proceeding from this. Its outer surface is in contact with the inner surface of the dura mater, but for the most part the membranes are not connected together, though here and there they may be joined together by isolated connective-tissue trabeculæ, which are most numerous on the posterior surface of the cord. The space between the two membranes is the *subdural space*.

The arachnoid membrane surrounds the nerves which arise from the brain and spinal cord, and encloses them in loose sheaths as far as their points of exit from the skull and spinal canal.

Structure.—The arachnoid consists of bundles of white fibrous and elastic tissue intimately blended together. Its outer surface is covered with a layer of endothelium. Vessels of considerable size, but few in number, and, according to Bochdalek, a rich plexus of nerves derived from the motor division of the fifth, the facial, and the spinal accessory nerves, are found in the arachnoid.

The **subarachnoid space** is the interval between the arachnoid and pia mater. It is not, properly speaking, a *space*, for it is occupied everywhere by a spongy tissue consisting of trabeculæ of delicate connective tissue, and intercommunicating channels in which the subarachnoid fluid is contained. This so-called space is small on the surface of the hemispheres of the brain ; on the summit of each convolution the pia mater and arachnoid membrane are in close contact ; but in the sulci between the convolutions, triangular spaces are left, in which the subarachnoid trabecular tissue is found, for the pia mater dips into the sulci, whereas the arachnoid bridges across them from convolution to convolution. At the base of the brain, in certain situations, the arachnoid is separated by wider intervals from the pia mater, forming larger spaces, which have received the name of *cisternæ*, and in these the subarachnoid tissue is less abundant and the communicating channels larger than in those regions where the two membranes are more closely approximated.

FIG. 758.—Diagram showing the positions of the three principal subarachnoid cisternæ.

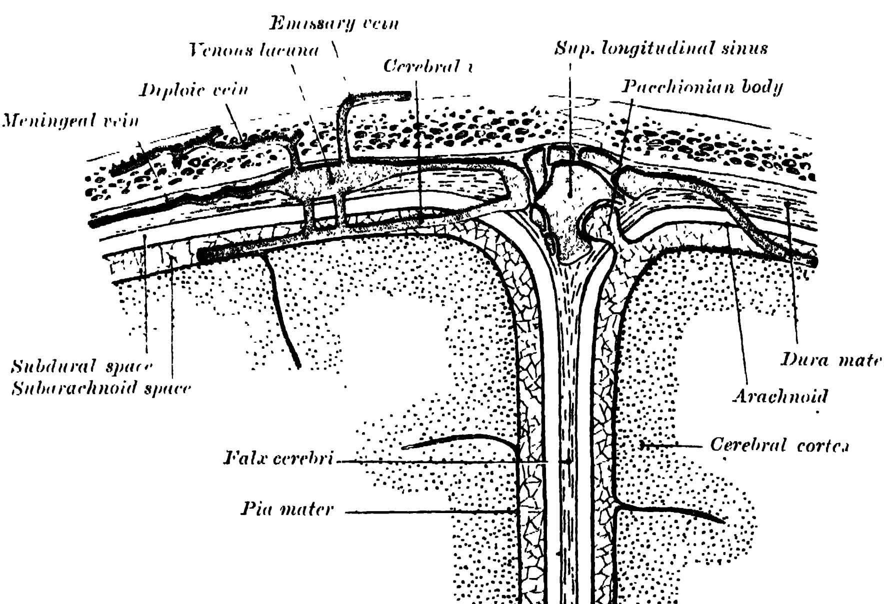


The three principal spaces have been named the *cisterna magna*, the *cisterna pontis*, and the *cisterna basalis* (fig. 758) ; but it should be clearly understood that these spaces communicate freely with each other. The *cisterna magna* is a space, triangular on sagittal section, caused by the arachnoid bridging over the interval between the medulla and the under surfaces of the hemispheres of the cerebellum ; it is continuous with the subarachnoid space of the cord at the level of the foramen magnum. The *cisterna pontis* is a considerable interval between the pia mater and the arachnoid on the ventral aspect of the pons Varolii. It contains the basilar artery, and is continuous behind with the subarachnoid space of the spinal cord, and with the cisterna magna ; and in front of the pons with the cisterna basalis. The *cisterna basalis* is a wide interval left between the pia mater and the arachnoid, where the latter membrane extends across between the two temporal lobes. It encloses the crura cerebri and the structures contained in the interpeduncular space, and contains the circle of Willis. In front, the cisterna basalis extends forwards on to the upper surface of the corpus callosum, for the arachnoid stretches across from one cerebral hemisphere to the other immediately beneath the free border of the falx cerebri, and thus leaves a space

in which the anterior cerebral arteries are contained. Again, another space is formed in front of either temporal lobe by the arachnoid bridging across the fissure of Sylvius without dipping down to the bottom of the fissure. This space is a prolongation from the cisterna basalis, and contains the middle cerebral artery. The subarachnoid space communicates with the general ventricular cavity of the brain by three openings: one of these, the *foramen of Majendie*, is in the middle line at the inferior boundary of the fourth ventricle; the other two are at the extremities of the lateral recesses of the fourth ventricle, behind the upper roots of the glosso-pharyngeal nerves; they are named the *foramina of Key and Retzius* or *of Luschka*. It is stated by Meckel that the lateral ventricles also communicate with the subarachnoid space at the apices of their descending horns. There is no direct communication between the subdural and subarachnoid spaces.

The spinal part of the subarachnoid space is a very wide interval between the arachnoid membrane and the pia mater, and is largest at the lower part of the spinal canal, where the arachnoid membrane encloses the nerves which form the cauda equina. Superiorly, it is continuous with the cranial subarachnoid

FIG. 759.—Diagrammatic representation of a section across the top of the skull, showing the membranes of the brain, &c. (Modified from Testut.)



space, through which it communicates with the general ventricular cavity of the brain, by means of the openings, in the roof of the fourth ventricle (*foramen of Majendie* and *foramina of Key and Retzius*). It is partially divided by a longitudinal membranous septum, the *septum posticum*, which serves to connect the arachnoid with the pia mater, opposite the posterior median fissure of the spinal cord, and forms a partition, which is incomplete and cribriform above, but more perfect in the thoracic region; it consists of bundles of white fibrous tissue interlacing with each other. Each of these divisions of the spinal subarachnoid space is further subdivided by the *ligamenta denticulata*, which will be described with the pia mater.

The cerebro-spinal fluid fills up the subarachnoid space. In the spine it is so abundant as to completely fill up the whole of the space included in the dura mater. It is a clear limpid fluid, having a saltish taste, and a slightly alkaline reaction. According to Lassaigne, it consists of 98·5 parts of water, the remaining 1·5 per cent. being solid matters, animal and saline. It varies in

quantity, being most abundant in old persons, and is quickly secreted. Its chief use is probably to afford mechanical protection to the nervous centres, and to prevent the effects of concussions communicated from without.

The **glandulæ Pacchionii**, or **arachnoid villi** (fig. 759), are small, fleshy-looking elevations, usually collected into clusters of variable size, which may be seen upon the outer surface of the dura mater, in the vicinity of the superior longitudinal sinus, and in some other situations. Little pits or depressions will be found on the corresponding parts of the calvarium, into which these elevations are received. Upon laying open the superior longitudinal sinus, villi will be found protruding into its interior. They are not glandular in structure, but, according to Luschka, are enlarged normal villi of the arachnoid. On each side of the sinus, and communicating with it, are large venous spaces, named *lacunæ laterales*, situated in the dura mater, and into these the villi project. As they grow they push the thinned dura mater before them, and cause absorption of the bone from pressure, and so produce the pits or depressions on the inner wall of the calvarium. A Pacchionian body consists of the following parts: 1. In the interior is a core of subarachnoid tissue, which is continuous with the meshwork of the general subarachnoid tissue through a narrow pedicle, by which the Pacchionian body is attached to the arachnoid. 2. Around this tissue is a layer of arachnoid membrane, which limits and encloses the subarachnoid tissue. 3. Outside this, again, is the thinned wall of the lacuna, which is separated from the arachnoid covering the body by a space which corresponds to and is continuous with the subdural space. 4. And finally, if the body projects into the longitudinal sinus, it will be covered by the greatly thinned upper walls of the sinus. It will be seen, therefore, that fluid injected into the subarachnoid space will find its way into the Pacchionian bodies, and it has been found experimentally that it passes by osmosis from these bodies into the venous sinuses into which these bodies project. The Pacchionian bodies are supposed to be the means by which excess of cerebro-spinal fluid is got rid of, when its quantity is increased above normal.

These bodies are not seen in infancy, and very rarely until the third year. They are usually found after the seventh year; and from this period they increase in number as age advances.

The Pia Mater

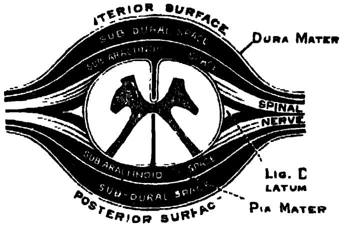
The **pia mater** is a vascular membrane, consisting of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. The *cerebral pia mater* invests the entire surface of the brain, dips down between the convolutions and laminæ, and is prolonged into the interior, as an invagination forming the velum interpositum or tela chorioidea superior, and the choroid plexuses of the lateral and third ventricles. As it passes over the roof of the fourth ventricle, it forms the tela chorioidea inferior and the choroid plexuses of this ventricle. Upon the surfaces of the hemispheres, where it covers the grey matter of the convolutions, it gives off from its inner surface a multitude of sheaths, which surround minute vessels, that extend perpendicularly for some distance into the cerebral substance (see fig. 589, page 653). On the cerebellum the membrane is more delicate; the vessels from its inner surface are shorter, and its relations to the cortex are not so intimate.

The *spinal pia mater* is thicker, firmer, and less vascular than that of the brain: this is due to the fact that it consists of two layers, the outer or additional one being composed of bundles of connective-tissue fibres, arranged for the most part longitudinally. Between the layers are cleft-like spaces which communicate with the subarachnoid space, and a number of blood-vessels which are enclosed in perivascular lymphatic sheaths. The spinal pia mater covers the entire surface of the cord, and is very intimately adherent to it; in front it sends a process backwards into the anterior fissure. A longitudinal fibrous band, called by Haller the *linea splendens*, extends along the middle line of the anterior surface; and a somewhat similar band, the *ligamentum denticulatum*, is situated on either side. At the point where the cord terminates, the pia mater becomes contracted and is continued down as a long, slender filament (*filum terminale*), which descends through the centre of the mass of nerves forming the cauda equina. It blends with the dura mater at the

level of the lower border of the second sacral vertebra, and extends downwards as far as the base of the coccyx, where it blends with the periosteum. It assists in maintaining the cord in its position during the movements of the trunk; and is, from this circumstance, called the *central ligament of the cord.*

The pia mater of both the brain and the spinal cord forms sheaths for the nerves as they emerge from the central nervous matter. This sheath is closely connected with the nerve, and blends with its common membranous investment.

Fig. 760.—Transverse section of the spinal cord and its membranes.



The **ligamentum denticulatum** (figs. 757, 760) is a narrow fibrous band situated on either side of the spinal cord throughout its entire length, and separating the anterior from the posterior roots of the spinal nerves. It has received its name from the serrated appearance which it presents. Its inner border is continuous with the pia mater at the side of the cord. Its outer border presents a series of triangular tooth-like processes, the points of which are fixed at intervals to the dura mater. These processes are twenty-one in number, on either side, the first being attached to the dura mater, opposite the margin of the foramen magnum, between the vertebral artery and the hypoglossal nerve; and the last near the lower end of the cord. Its function is to support the cord in the fluid by which it is surrounded.

Applied Anatomy.—Evidence of great value in the diagnosis of meningitis may sometimes be obtained by puncturing the membranes of the cord and withdrawing some of the cerebro-spinal fluid; moreover the operation of lumbar puncture is in many cases curative, under the supposition that the draining of some of the cerebro-spinal fluid relieves the patient by diminishing the intracranial pressure. The operation is performed by inserting a trocar, of the smallest size, between the laminæ of the third and fourth, or of the fourth and fifth lumbar vertebræ, through the ligamentum subflavum. The spinal cord, even of a child at birth, does not reach below the third lumbar vertebra, and therefore the canal may be punctured between the third and fourth lumbar vertebræ without any risk of injuring this structure. The point of puncture is indicated by laying the child on its side and dropping a perpendicular line from the highest point of the crest of the ilium; this will cross the upper border of the spine of the fourth lumbar vertebra, and will indicate the level at which the trocar should be inserted a little to one side of the middle line. The puncture may require to be repeated more than once, and the greatest precaution must be taken not to allow septic infection of the meninges. If there be any appreciable increase of pressure, the fluid will flow through the trocar with the greatest freedom.

In addition to the constitutional signs and symptoms of fever, *acute spinal meningitis* exhibits certain characteristic features. Pain and tenderness to pressure along the spinal column are common, and so are pains in the limbs or round the trunk from irritation of the posterior nerve-roots by the inflammatory products. Irritation of the anterior nerve-roots is shown by the increased tone of the muscles, which may go on to the point where they pass into a state of spasm with much increased reflexes; this is often seen in the retraction of the head and neck. Later in the disease the reflexes are often lost, when, also, the urine and fæces may be passed involuntarily.

CRANIAL NERVES (NERVI CEREBRALES)

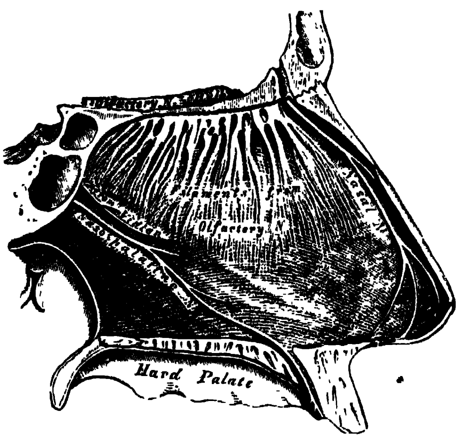
There are twelve pairs of cranial nerves; they are attached to the brain and are transmitted through foramina in the base of the cranium. Taken in their order, from before backwards, the different pairs are named as follows:

1st.	Olfactory.	7th.	Facial.
2nd.	Optic.	8th.	Auditory.
3rd.	Motor oculi.	9th.	Glosso-pharyngeal.
4th.	Trochlear (Pathetic).	10th.	Pneumogastric or Vagus.
5th.	Trifacial (Trigeminus).	11th.	Spinal accessory.
6th.	Abducent.	12th.	Hypoglossal.

The area of attachment of a cranial nerve to the surface of the brain is termed its *superficial or apparent origin.* The fibres of the nerve can, in all

cases, be traced into the substance of the brain to a special centre of grey matter, termed the *nucleus*. The motor or efferent cranial nerves arise from groups of nerve-cells situated within the brain, and such groups of cells constitute their *nuclei of origin*. The sensory or afferent cranial nerves arise outside the brain from groups of nerve-cells or ganglia derived from the neural crest or ganglion ridge, and situated on the trunks of the nerves ; these ganglia must therefore be looked upon as their *nuclei of origin*. The central processes of these ganglion-cells grow into the brain, and there end by arborising around the cells of certain nuclei or collections of nerve-cells, which are termed their *nuclei of termination*. The nuclei of origin of the motor nerves and the nuclei of termination of the sensory nerves are brought into relationship with the cerebral cortex, the former through the geniculate bundle of the internal capsule, the latter through the fillet. The geniculate fibres arise from the cells of the motor area of the cortex, and, after crossing the middle line, end by arborising around the cells of the nuclei of origin of the motor nerves. On the other hand, fibres arise from the cells of the nuclei of termination of the sensory nerves, and after crossing the opposite side, join the fillet, and thus connect these nuclei, directly or indirectly, with the cerebral cortex. As already stated in the chapter on Embryology (page 127), the cranial nerves, with the exception of the first and second, are developed in a similar manner to the spinal nerves.

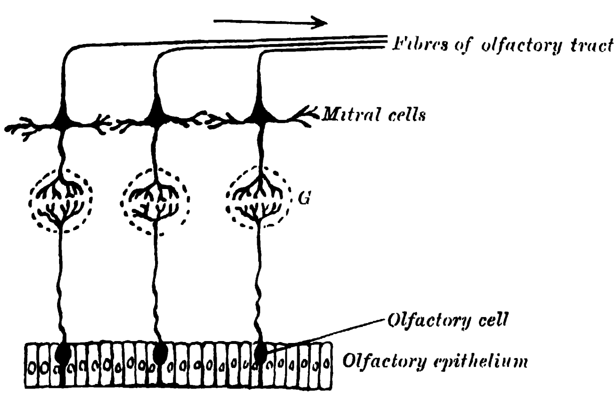
Fig. 761.—Nerves of septum of nose. Right side.



First Nerve (fig. 761)

The **Olfactory nerves** (nn. olfactorii) are the nerves of smell, and are distributed to the mucous membrane of the olfactory region of the nose : this

Fig. 762.—Plan of olfactory neurons.



region comprises the ~~superior turbinated process~~ Concha nasalis superior of the ethmoid, and the corresponding part of the nasal septum. The nerves originate from the central or deep processes of the olfactory cells of the nasal mucous membrane. They form a plexiform network in the mucous membrane, and are then collected into about twenty branches, which pierce the cribriform plate of the ethmoid bone in two groups, an outer and an inner, and terminate in the glomeruli of the olfactory bulb (figs. 749 and 762). Each branch receives tubular sheaths

from the dura mater and pia mater, the former being lost in the periosteum of the nose, the latter in the neurilemma of the nerve.

The olfactory nerves differ in structure from other nerves in being composed exclusively of non-medullated fibres. They consist of axis-cylinders with distinct nucleated sheaths, in which there are, however, fewer nuclei than are found in ordinary non-medullated nerve-fibres.

The olfactory centre in the cortex is generally associated with the rhinencephalon (p. 863).

Applied Anatomy.—In severe injuries to the head involving the anterior fossa of the base of the skull, the olfactory bulb may become separated from the olfactory nerves, thus producing loss of smell (*anosmia*), and with this there is a considerable loss in the sense of taste, since much of the perfection of the sense of taste is due to the substances being also odorous, and simultaneously exciting the sense of smell.

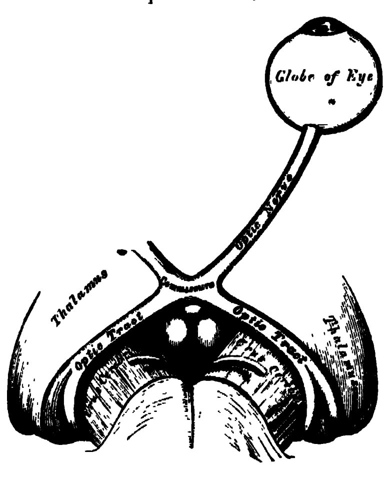
Anosmia often occurs after influenza or other acute infection of the nose. *Parosmia*, or a perversion of the sense of smell, may occur in lesions of the cortical olfactory centres, or in insanity.

Second Nerve (fig. 763)

The **Second** or **Optic nerve** (n. opticus), the nerve of sight, is distributed exclusively to the eyeball. The nerves of opposite sides are connected together at the commissure, and from the back of the commissure they may be traced to the brain, under the name of the *optic tracts*.

The *optic tract*, at its connection with the brain, is divided into two bands, external and internal. The *external* band is the larger; it arises from the external geniculate body and from the pulvinar of the thalamus, and is partly continuous with the brachium of the upper quadrigeminal body. The *internal* band curves round the crusta, and ends in the internal geniculate body; its fibres are merely commissural, forming Gudden's commissure. From these origins the tract winds obliquely across the under surface of the crus cerebri in the form of a flattened band, and is attached to the crus by its anterior margin. It then assumes a cylindrical form, and, as it passes forwards, is connected with the tuber cinereum and lamina terminalis. It finally joins with the tract of the opposite side to form the *optic commissure*.

Fig. 763.—The left optic nerve and optic tracts.



The *optic commissure* or *chiasma*, somewhat quadrilateral in form, rests upon the olivary eminence and on the anterior part of the diaphragma sellæ, being bounded above, by the lamina terminalis; behind, by the tuber cinereum; on either side, by the anterior perforated space. Within the commissure, the optic nerves of the two sides undergo a partial decussation. The fibres which form the inner margin of each tract and posterior part of the commissure have no connection with the optic nerves. They simply pass across the commissure from one hemisphere of the brain to the other, and connect the internal geniculate bodies of the two sides. They are known as the *commissure of Gudden*. The remaining and principal part of the commissure consists of two sets of fibres, crossed and uncrossed. The *crossed*, which are the more numerous, occupy the central part of the commissure, and pass from the optic nerve of one side to the optic tract of the other, decussating in the commissure with similar fibres of the opposite optic nerve. The *uncrossed* fibres occupy the outer part of the chiasma, and pass from the nerve of one side to the tract of the same side.*

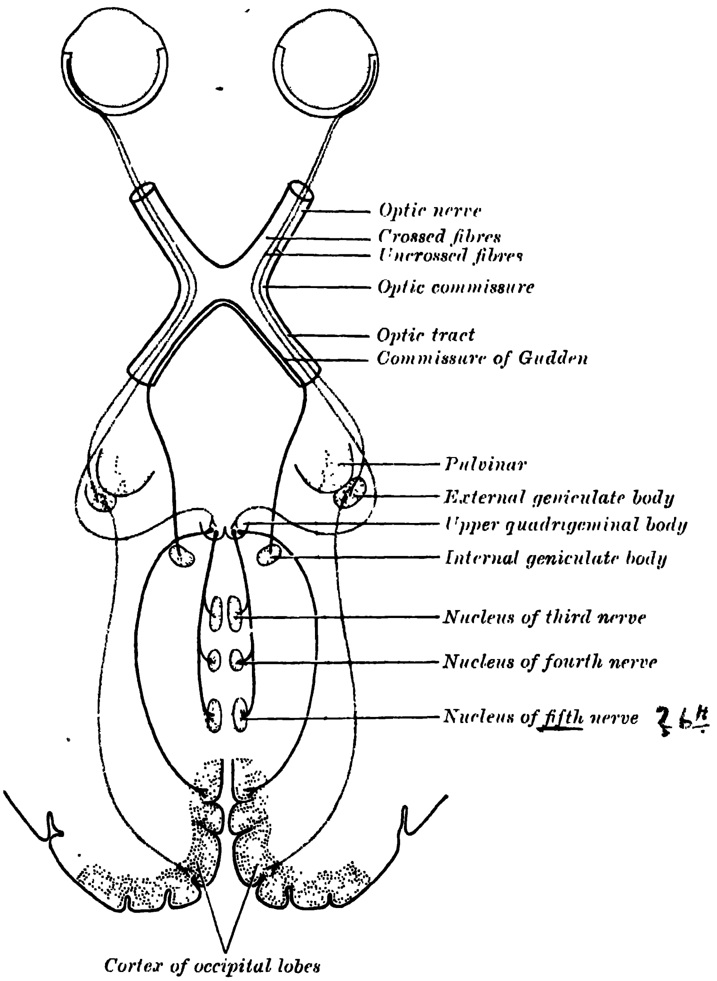
The great majority of the fibres of the optic nerve (fig. 764) consist of the afferent axons of nerve-cells in the retina; a few, however, are efferent fibres, and grow out from the brain. They become medullated during the last month of

* A specimen of congenital absence of the optic commissure is to be found in the Museum of the Westminster Hospital. See also Henle, *Nervenlehre*, p. 393, ed. 2.

fœtal life. The afferent fibres end in arborisations around the cells in the external geniculate body, pulvinar, and upper quadrigeminal body, which constitute the *lower visual centres*. From these nuclei other fibres are prolonged to the *cortical visual centre*, which, according to most observers, is situated in the cuneus, and in the neighbourhood of the calcarine fissure.

Some fibres are detached from the optic tract, and pass through the crus cerebri to the nucleus of the third nerve. These fibres are small, and may be regarded as afferent branches for the Sphincter pupillæ and Ciliary muscles. Other fibres pass to the cerebellum through its superior peduncles, while others, again, are lost in the pons.

FIG. 764.—Scheme showing central connections of the optic nerve and optic tract.



The *optic nerves* arise from the fore part of the commissure, and, diverging from one another, each becomes rounded in form and firm in texture, and is enclosed in a sheath derived from the pia mater and arachnoid. As the nerve passes through the corresponding optic foramen, it receives a sheath from the dura mater; and as it enters the orbit this sheath divides into two layers, one of which becomes continuous with the periosteum of the orbit; the other forms the proper sheath of the nerve, and surrounds it as far as the sclera. The nerve passes forwards and outwards through the cavity of the orbit, pierces the sclera and the choroid coat at the back part of the eyeball, about one-eighth of an inch to the nasal side of its centre, and expands into the internal layer of the retina. A small artery, the *arteria centralis retinæ*,

perforates the optic nerve a little behind the globe, and runs along its interior in a tubular canal of fibrous tissue. It supplies the inner surface of the retina, and is accompanied by corresponding veins. The retina is described with the anatomy of the eyeball.

Applied Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affections of the central nervous system, and as a rule the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease. (1) From its mode of development, and from its structure, the optic nerve must be regarded as a prolongation of the brain-substance, rather than as an ordinary cerebro-spinal nerve. (2) As it passes from the brain it receives sheaths from the three cerebral membranes, a perineural sheath from the pia mater, an intermediate sheath from the arachnoid, and an outer sheath from the dura mater, which is also connected with the periosteum as it passes through the optic foramen. These sheaths are separated from each other by spaces, which communicate with the subdural and subarachnoid spaces respectively. The innermost or perineural sheath sends a process around the arteria centralis retinæ into the interior of the nerve, and enters intimately into its structure. Thus inflammatory affections of the meninges or of the brain may readily extend along these spaces, or along the interstitial connective tissue in the nerve.

The course of the fibres in the optic commissure has an important pathological bearing, and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each optic tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time Charcot believes, and his view has met with general acceptation, that the fibres which do not decussate at the optic commissure have already decussated in the corpora quadrigemina, so that the lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed ; whereas if one tract, say the right, be destroyed by disease, there will be blindness of the right half of both retinæ.

An antero-posterior section through the commissure would divide the decussating fibres, and would therefore produce blindness of the inner half of each eye ; while a section at the margin of the side of the optic commissure would produce blindness of the external half of the retina of the same side. An early symptom of tumour-growth in the pituitary body would be pressure on the commissure.

The optic nerve may also be affected in injuries or diseases involving the orbit ; in fractures of the anterior fossa of the base of the skull ; in tumours of the orbit itself, or those invading this cavity from neighbouring parts.

THIRD NERVE (figs. 765, 766, 767, 769)

The **Third** or **Motor-oculi nerve** (n. oculomotorius) supplies all the muscles of the orbit, except the Superior oblique and External rectus ; it also supplies, through its connection with the ciliary ganglion, the Sphincter muscle of the iris and the Ciliary muscle. It is a rather large nerve, of rounded form and firm texture.

The fibres of the third nerve arise from a nucleus which lies in the grey matter of the floor of the aqueduct of Sylvius and extends in front of the aqueduct for a short distance into the floor of the third ventricle. From their nucleus of origin the fibres pass forwards through the tegmentum, the red nucleus and the inner part of the substantia nigra, forming a series of curves with their convexity outwards, and emerge from the oculo-motor sulcus on the inner side of the crus cerebri.

The nucleus of the oculo-motor nerve does not consist of a continuous column of cells, but is broken up into a number of smaller nuclei, which may be arranged in two groups, anterior and posterior. Those of the posterior group are six in number, five of which are symmetrical on the two sides of the middle line, while the sixth is centrally placed and is common to the nerves of both sides. The anterior group consists of two nuclei, an antero-internal and an antero-external (fig. 765).

The nucleus of the third nerve is said to give fibres to the seventh nerve, which probably supply the Orbicularis palpebrarum, Corrugator supercilii, and anterior belly of the Occipito-frontalis.* It is also connected with the nuclei

* See footnote, p. 841.

of the fourth and sixth nerves, with the cerebellum, upper quadrigeminal body and cortex of the occipital lobe of the cerebrum.

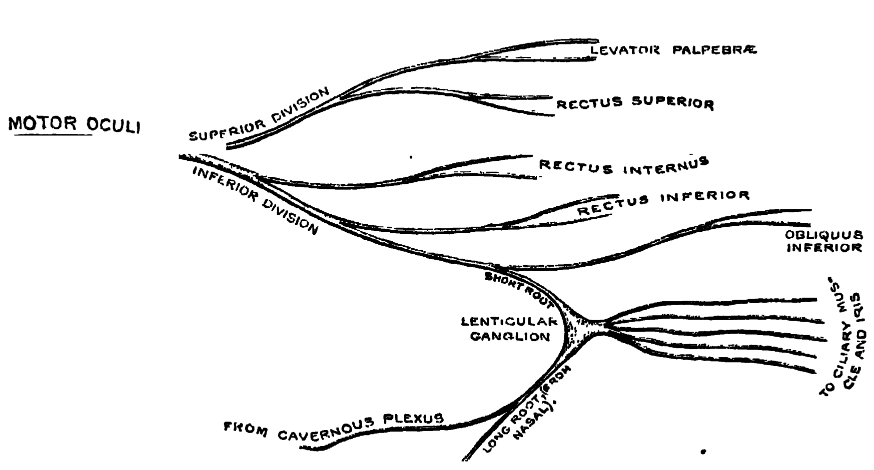
Crossed fibr Trochlear nerve, wit its nucleus of origin and 9'', its decussa 10. Third ven ricle. M, M. Median line.

The nucleus of the third nerve, considered from a physiological standpoint, can be subdivided into several smaller groups of cells, each group controlling a particular muscle. The nerves to the different muscles appear to take their origin from behind forwards, as follows: Inferior oblique, Inferior rectus, Superior rectus, Levator palpebræ, and Internal rectus; while from the anterior end of the nucleus the fibres for accommodation and for the Sphincter pupillæ take their origin.

On emerging from the brain, the nerve is invested with a sheath of pia mater, and enclosed in a prolongation from the arachnoid. It passes between the superior cerebellar and posterior cerebral arteries, and then pierces the dura mater in front of and external to the posterior clinoid process, passing between the free and attached borders of the tentorium, which are prolonged forwards to be connected with the anterior and posterior clinoid processes of the sphenoid bone. It passes along the outer wall of the cavernous sinus, above the other orbital nerves, receiving in its course one or two filaments from the cavernous plexus of the sympathetic, and a communicating branch from the first division of the fifth. It then divides into two branches, which enter the orbit through the sphenoidal fissure, between the two heads of the External rectus muscle. On passing

Fig. 766.—Plan of the motor oculi nerve. (After Flower.)



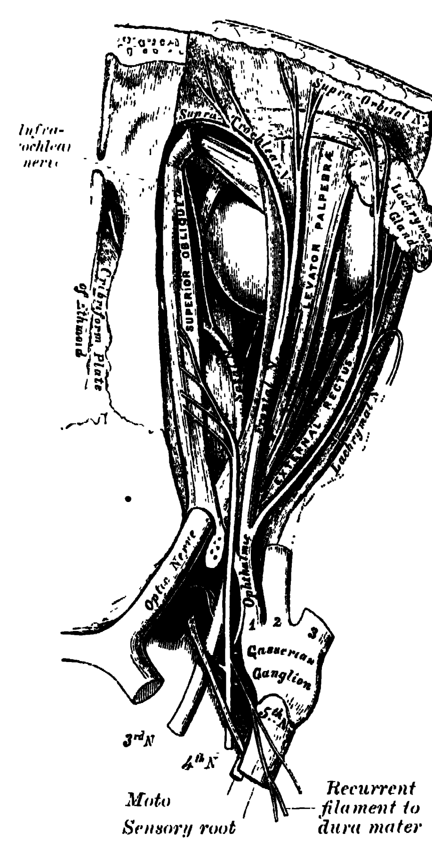
through the fissure, the nerve is placed below the fourth nerve and the frontal and lachrymal branches of the ophthalmic nerve, while the nasal nerve is placed between its two divisions.

The *superior division* (ramus superior), the smaller, passes inwards over the optic nerve, and supplies the Superior rectus and Levator palpebræ. The *inferior division* (ramus inferior), the larger, divides into three branches. One passes beneath the optic nerve to the Internal rectus; another, to the Inferior rectus; and the third, the longest of the three, runs forwards between the Inferior and External recti to the Inferior oblique. From this latter a short thick branch (radix brevis ganglii ciliaris) is given off to the lower part of the lenticular ganglion, and forms its inferior root. All these branches enter the muscles on their ocular surfaces, with the exception of the nerve to the Inferior oblique, which enters the muscle at its posterior border.

Applied Anatomy.—Paralysis of the third nerve may be the result of many causes, such as cerebral disease; or conditions causing pressure on the cavernous sinus; or periostitis of the bones entering into the formation of the sphenoidal fissure. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebræ being paralysed; (2) external strabismus, on account of the unopposed action of the External rectus and Superior oblique muscles, which are not supplied by the third nerve and are therefore not paralysed; (3) dilation of the pupil, because the sphincter fibres of the iris are paralysed; (4) loss of power of accommodation and of contraction on exposure to light, as the Sphincter pupillæ, the Ciliary muscle, and the Internal rectus are paralysed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed; (6) the patient will complain most of the diplopia, or double vision that occurs, the false image being higher than the true, and the separation of the two images increasing with movements inwards. Occasionally paralysis may affect only a part of the nerve—that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Internal rectus; accommodation for near objects only, from spasm of the Ciliary muscle; or miosis (contraction of the pupil) from irritation of the Sphincter of the pupil.

The third nerve is particularly liable to become involved in a syphilitic periarteritis as it leaves the base of the brain, when passing between the posterior cerebral and superior cerebellar arteries; associated with locomotor ataxia various partial or complete paralyses of the nerve are often seen.

Fig. 767.—Nerves of the orbit. Seen from above.



Fourth Nerve (fig. 767)

The **Fourth** or **Trochlear nerve** (n. trochlearis), the smallest of the cranial nerves, supplies the Superior oblique muscle of the eyeball.

It arises from a nucleus situated in the floor of the Sylvian aqueduct, opposite the upper part of the lower quadrigeminal body. From its origin the nerve runs outwards and downwards through the tegmentum, and then turns backwards and inwards into the upper part of the valve of Vieussens. Here it decussates with the corresponding nerve of the opposite side and emerges from the surface of the valve at the side of the frænulum veli, immediately behind the lower quadrigeminal body.

Emerging from the valve of Vieussens, the nerve is directed outwards across the superior peduncle of the cerebellum, and then winds forwards round the outer side of the crus cerebri, immediately above the pons Varolii, pierces the dura mater in the free border of the tentorium cerebelli, just behind, and external to, the posterior clinoid process, and passes forwards in the outer wall of the cavernous sinus, between the third nerve and the ophthalmic division of the fifth. It crosses the third nerve, and enters the orbit through the sphenoidal fissure. It now becomes the highest of all the nerves, and lies at the inner extremity of the fissure internal to the frontal nerve. In the orbit it passes inwards, above the origin of the Levator palpebræ, and finally enters the orbital surface of the Superior oblique.

Branches of communication.—In the outer wall of the cavernous sinus the fourth nerve forms communications with the ophthalmic division of the fifth and with the cavernous plexus of the sympathetic. In the sphenoidal fissure it occasionally gives off a branch to the lachrymal nerve. *Branches of distribution.*—It gives off a recurrent branch, which passes backwards between the layers of the tentorium, dividing into two or three filaments which may be traced as far back as the wall of the lateral sinus.

Applied Anatomy.—When the fourth nerve is paralysed there is loss of function in the Superior oblique, so that the patient is unable to turn his eye downwards and outwards. Should the patient attempt to do this, the eye of the affected side is twisted inwards, producing diplopia or double vision. Single vision exists in the whole of the field so long as the eyes look above the horizontal plane, but diplopia occurs on looking downwards. To counteract this the patient holds his head forwards, and also inclines it to the sound side.

Fifth Nerve

The **Fifth** or **Trifacial nerve** (n. trigeminus) is the largest cranial nerve. It resembles a spinal nerve: (1) in arising by two roots, a motor and a sensory; and (2) in having a ganglion developed on its sensory root. It is the great sensory nerve of the head and face, and the motor nerve of the muscles of mastication. It divides into three divisions, the first and second of which are entirely sensory, the third is partly sensory and partly motor.

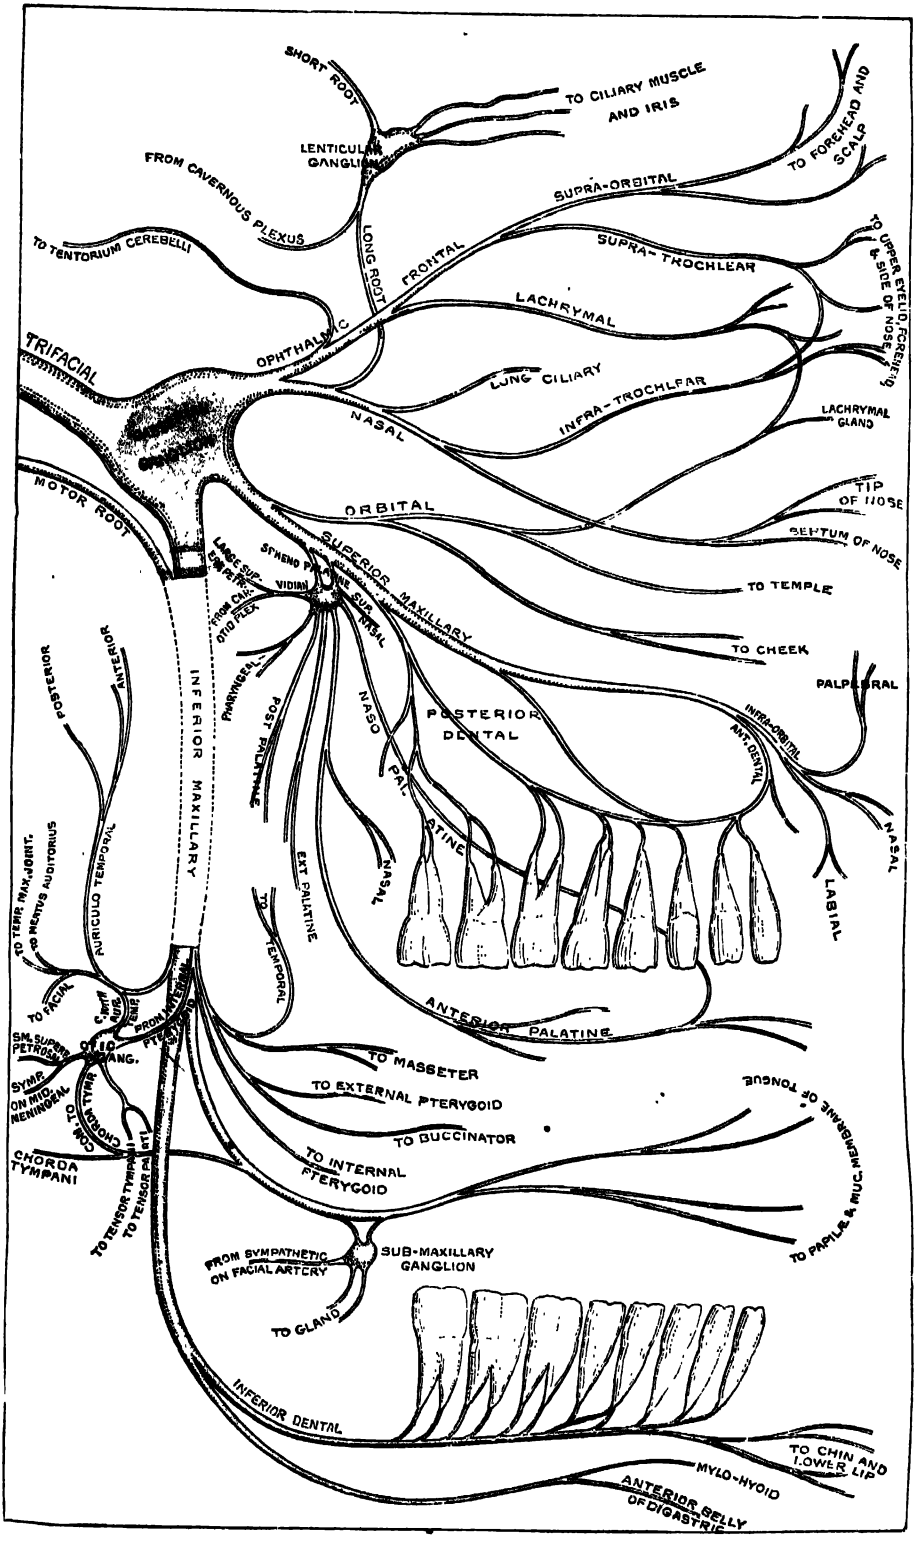
It emerges from the side of the pons Varolii, near its upper border, by a small *motor* and a large *sensory* root—the former being situated in front and to the inner side of the latter.

The fibres of the *motor root* arise from two nuclei, an upper and a lower. The *upper nucleus* consists of a strand of cells which occupies the whole length of the lateral portion of the grey matter of the Sylvian aqueduct. The *lower* or *chief nucleus* is situated in the upper part of the pons Varolii, close to its dorsal surface, and along the line of the lateral margin of the fourth ventricle. The fibres from the upper nucleus constitute the *mesencephalic* or *Sylvian root*: they descend through the mid-brain, and, entering the pons, join with the fibres from the lower nucleus; and the motor root, thus formed, passes forwards through the pons to its point of emergence.

The fibres of the *sensory root* arise from the cells of the Gasserian ganglion which lies in a cavity of the dura mater near the apex of the petrous part of the temporal bone. They pass backwards and inwards below the superior petrosal sinus and tentorium cerebelli, and, entering the pons, divide into upper and lower roots. The upper root terminates partly in a nucleus which is situated in the pons on the outer side of the lower motor nucleus, and partly in the locus cœruleus; the lower root descends through the pons and medulla, and ends in the upper part of the substantia gelatinosa of Rolando. This lower root is sometimes named the *ascending root* of the fifth nerve. Medullation of the fibres of the sensory root begins about the fifth month of fœtal life, but the whole of its fibres are not medullated until the third month after birth.

The **Gasserian ganglion** (ganglion semilunare) occupies a cavity (*cavum Meckelii*) in the dura mater which is situated on a depression near the apex of the petrous part of the temporal bone. It is somewhat crescentic in shape, with its convexity directed forwards; internally it is in relation with the internal carotid artery and the posterior part of the cavernous sinus. The motor root runs forwards and outwards in front and to the inner side of the sensory root, and then passes below the ganglion without having any connection with it;

FIG. 768.—Plan of the fifth cranial nerve. (After Flower.)



it leaves the skull through the foramen ovale, and, immediately below this foramen, joins the inferior maxillary nerve. Besides the motor root, the large superficial petrosal nerve lies underneath the ganglion.

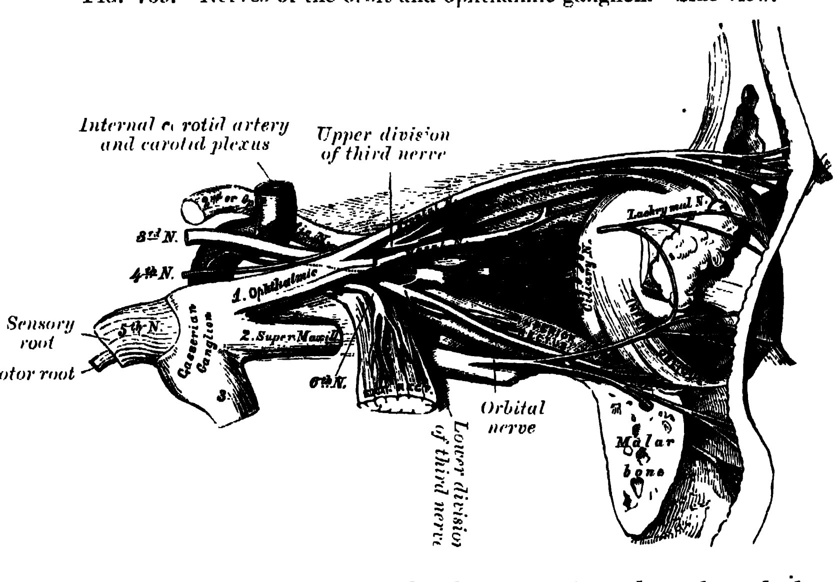
Branches of communication.—This ganglion receives, on its inner side, filaments from the carotid plexus of the sympathetic. *Branches of distribution.*—It gives off minute branches to the tentorium cerebelli, and to the dura mater in the middle fossa of the cranium. From its convex border, which is directed forwards and outwards, three large branches proceed, viz. *the ophthalmic, superior maxillary*, and *inferior maxillary*. The ophthalmic and superior maxillary consist exclusively of fibres derived from the ganglion, and are solely nerves of common sensation. The third division, or inferior maxillary, is joined outside the cranium by the motor root, and is, therefore, strictly speaking, the only portion of the fifth nerve which can be said to resemble a spinal nerve.

Associated with the three divisions of the fifth nerve are four small ganglia. The *ophthalmic ganglion* is connected with the first division; the *spheno-palatine* or *Meckel's ganglion* with the second; and the *otic* and *submaxillary ganglia* with the third. All the four receive sensory filaments from the fifth, and motor and sympathetic filaments from various sources; these filaments are called the *roots of the ganglia.*

Ophthalmic Nerve (figs. 767, 768, 769)

The **Ophthalmic nerve** (n. ophthalmicus), or first division of the fifth, is a sensory nerve. It supplies sensory branches to the cornea, ciliary muscle, and iris; to the lachrymal gland and conjunctiva; to a part of the mucous membrane of the nasal fossæ; and to the integument of the eyelids, eyebrow, forehead, and nose. It is the smallest of the three divisions of the fifth, and arises from the upper part of the Gasserian ganglion as a short, flattened band, about an inch in length, which passes forwards along the outer wall of the cavernous sinus, below the third and fourth nerves; just before entering the orbit,

Fig. 769.—Nerves of the orbit and ophthalmic ganglion. Side view.



through the sphenoidal fissure, it divides into three branches, *lachrymal, frontal*, and *nasal.*

Branches of communication.—The ophthalmic nerve is joined by filaments from the cavernous plexus of the sympathetic, and communicates with the third, fourth, and sixth nerves.

Branches of distribution.—The ophthalmic nerve gives off a recurrent filament which passes between the layers of the tentorium: it then divides into:

Lachrymal. Frontal. Nasal.

The **lachrymal nerve** (n. lacrimalis) is the smallest of the three branches of the ophthalmic. It sometimes receives a filament from the fourth nerve, but this is possibly derived from the branch of communication which passes from the ophthalmic to the fourth. It passes forward in a separate tube of dura mater, and enters the orbit through the narrowest part of the sphenoidal fissure. In the orbit it runs along the upper border of the External rectus muscle, with the lachrymal artery, and communicates with the temporo-malar branch of the superior maxillary. It enters the lachrymal gland and gives off several filaments, which supply the gland and the conjunctiva. Finally it pierces the superior palpebral ligament, and terminates in the integument of the upper eyelid, joining with filaments of the facial nerve. The lachrymal nerve is occasionally absent, and in such cases its place is taken by the temporal branch of the superior maxillary. Sometimes the latter branch is absent, and a continuation of the lachrymal is substituted for it.

The **frontal nerve** (n. frontalis) is the largest division of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit through the sphenoidal fissure, and runs forwards along the middle line, between the Levator palpebræ and the periosteum. Midway between the apex and base of the orbit it divides into two branches, supratrochlear and supraorbital.

The *supratrochlear nerve* (n. supratrochlearis), the smaller of the two, passes inwards, above the pulley of the Superior oblique muscle, and gives off a descending filament, which joins with the infratrochlear branch of the nasal nerve. It then escapes from the orbit between the pulley of the Superior oblique and the supraorbital foramen, curves up on to the forehead close to the bone, ascends beneath the Corrugator supercilii and Occipito-frontalis muscles, and dividing into branches, which pierce these muscles, it supplies the integument of the lower part of the forehead on either side of the middle line and sends filaments to the conjunctiva and skin of the upper eyelid.

The *supraorbital nerve* (n. supraorbitalis) passes forwards through the supraorbital foramen, and gives off, in this situation, palpebral filaments to the upper eyelid. It then ascends upon the forehead, and terminates in two branches, an inner and an outer, which supply the integument of the cranium, reaching nearly as far back as the parieto-occipital suture. They are at first situated beneath the Occipito-frontalis, the inner branch perforating the frontal portion of the muscle, the outer branch its tendinous aponeurosis. From its two branches, small twigs pass to the pericranium.

The **nasal nerve** (n. nasociliaris) is intermediate in size between the frontal and lachrymal, and is more deeply placed than the other branches of the ophthalmic. It enters the orbit between the two heads of the External rectus, and runs obliquely inwards across the optic nerve, beneath the Superior rectus and Superior oblique muscles, to the inner wall of the orbit. Here it passes through the anterior ethmoidal foramen, and, entering the cavity of the cranium, traverses a shallow groove on the front part of the cribriform plate of the ethmoid bone, and runs down, through the slit by the side of the crista galli, into the nose, where it divides into two branches, an internal and an external. The *internal branch* supplies the mucous membrane near the fore part of the septum of the nose. The *external branch* descends in a groove on the inner surface of the nasal bone, and supplies a few filaments to the mucous membrane covering the fore part of the outer wall of the nares as far as the inferior turbinated bone; it then leaves the cavity of the nose, between the lower border of the nasal bone and the upper lateral cartilage, and, passing down beneath the Compressor nasi, supplies the integument of the ala and the tip of the nose, joining with the facial nerve.

The branches of the nasal nerve are, the *ganglionic*, *long ciliary*, and *infratrochlear*.

The *ganglionic branch* (radix longa ganglii ciliaris), about half an inch in length, usually arises from the nasal between the two heads of the External rectus. It passes forwards on the outer side of the optic nerve, and enters the postero-superior angle of the ciliary ganglion, forming its superior or long root. It is sometimes joined by a filament from the cavernous plexus of the sympathetic, or from the superior division of the third nerve.

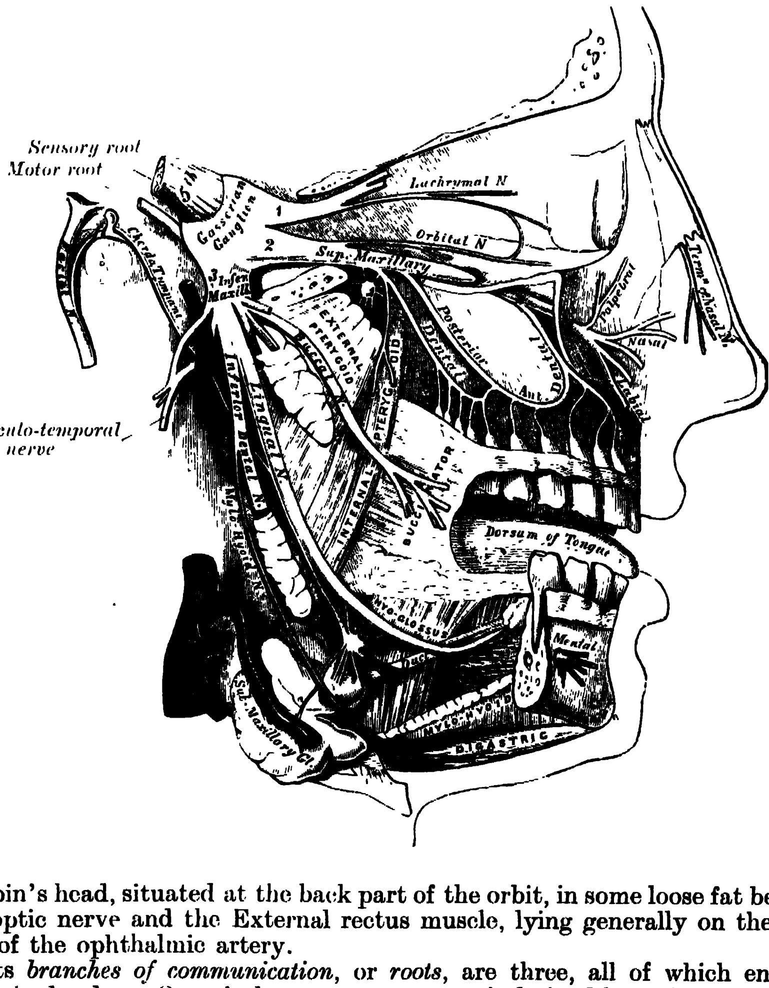
The *long ciliary nerves* (nn. ciliares longi), two or three in number, are given off from the nasal, as it crosses the optic nerve. They accompany the short ciliary nerves from the ciliary ganglion, pierce the posterior part of the sclerotic, and running forwards between it and the choroid, are distributed to the Ciliary muscle, iris, and cornea.

The *infratrochlear nerve* (n. infratrochlearis) is given off just before the nasal nerve enters the anterior ethmoidal foramen. It runs forwards along the upper border of the Internal rectus, and is joined, near the pulley of the Superior oblique, by a filament from the supratrochlear nerve. It then passes to the inner angle of the eye, and supplies the integument of the eyelids and side of the nose, the conjunctiva, lachrymal sac, and caruncula lacrimalis.

Ophthalmic Ganglion (figs. 766, 769)

The **ophthalmic or lenticular ganglion** (ganglion ciliare) is a small, quadrangular, flattened ganglion, of a reddish-grey colour, and about the size

Fig. 770.—Distribution of the second and third divisions of the fifth nerve, and submaxillary ganglion.



of a pin's head, situated at the back part of the orbit, in some loose fat between the optic nerve and the External rectus muscle, lying generally on the outer side of the ophthalmic artery.

Its *branches of communication*, or *roots*, are three, all of which enter its posterior border. One, the long or sensory root, is derived from the nasal branch of the ophthalmic, and joins its postero-superior angle. The second, the short or motor root, is a short, thick nerve, occasionally divided into two parts, which is derived from the branch of the third nerve to the Inferior oblique muscle, and is connected with the postero-inferior angle of the ganglion. The third, the

sympathetic root, is a slender filament from the cavernous plexus of the sympathetic. This is frequently blended with the long root, though it sometimes passes to the ganglion separately. According to Tiedemann, this ganglion receives a filament of communication from the spheno-palatine ganglion.

Its *branches of distribution* are the short ciliary nerves (nn. ciliares breves). These are delicate filaments, from six to ten in number, which arise from the fore part of the ganglion in two bundles connected with its superior and inferior angles ; the lower bundle is the larger. They run forwards with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are accompanied by the long ciliary nerves from the nasal. They pierce the sclera at the back part of the globe, pass forwards in delicate grooves on its inner surface, and are distributed to the Ciliary muscle, iris, and cornea. Tiedemann has described one small branch as penetrating the optic nerve with the arteria centralis retinæ.

Superior Maxillary Nerve (fig. 770)

The **Superior maxillary nerve** (n. maxillaris), or second division of the fifth, is a sensory nerve. It is intermediate, both in position and size, between the ophthalmic and inferior maxillary. It commences at the middle of the Gasserian ganglion as a flattened plexiform band, and, passing horizontally forwards, it leaves the skull through the foramen rotundum, where it becomes more cylindrical in form, and firmer in texture. It then crosses the spheno-maxillary fossa, inclines outwards on the back of the maxilla, and enters the orbit through the spheno-maxillary fissure ; it traverses the infraorbital groove and canal in the floor of the orbit, and appears upon the face at the infraorbital foramen.* At its termination, the nerve lies beneath the Levator labii superioris muscle, and divides into a leash of branches which spread out upon the side of the nose, the lower eyelid, and the upper lip, joining with filaments of the facial nerve.

Branches of distribution.—The branches of this nerve may be divided into four groups, according as they are given off in the cranium, in the spheno-maxillary fossa, in the infraorbital canal, or on the face.

In the cranium . . .	Meningeal.
In the spheno-maxillary fossa	Orbital or temporo-malar. Spheno-palatine. Posterior superior dental.
In the infraorbital canal .	Middle superior dental. Anterior superior dental.
On the face .	Palpebral. Nasal. Labial.

The **meningeal branch** (n. meningeus medius) is given off from the nerve directly after its origin from the Gasserian ganglion ; it accompanies the middle meningeal artery and supplies the dura mater.

The **orbital or temporo-malar branch** (n. zygomaticus) arises in the spheno-maxillary fossa, enters the orbit by the spheno-maxillary fissure, and divides at the back of that cavity into two branches, temporal and malar.

The *temporal branch* (ramus zygomaticotemporalis) runs along the outer wall of the orbit in a groove in the malar bone, receives a branch of communication from the lachrymal, and, passing through a foramen in the malar bone, enters the temporal fossa. It ascends between the bone, and substance of the Temporal muscle, pierces the temporal fascia about an inch above the zygoma, and is distributed to the integument covering the temple and side of the forehead, communicating with the facial nerve and with the auriculo-temporal branch of the inferior maxillary. As it pierces the temporal fascia, it gives off a slender twig, which runs between the two layers of the fascia to the outer angle of the orbit.

The *malar branch* (ramus zygomaticofacialis) passes along the external inferior angle of the orbit, emerges upon the face through a foramen in the

* After it enters the infraorbital canal, the nerve is frequently called the *infraorbital*.

malar bone, and, perforating the Orbicularis palpebrarum muscle, supplies the skin on the prominence of the cheek. It joins with the facial nerve and with the palpebral branches of the superior maxillary.

The **spheno-palatine branches,** two in number, descend to the spheno-palatine ganglion.

The **posterior superior dental branches** (rami alveolares superiores posteriores) arise from the trunk of the nerve just as it is about to enter the infraorbital groove; they are generally two in number, but sometimes arise by a single trunk, and immediately divide and pass downwards on the tuberosity of the maxilla. They give off several twigs to the gums and neighbouring parts of the mucous membrane of the cheek. They then enter the posterior dental canals on the zygomatic surface of the maxilla, and, passing from behind forwards in the substance of the bone, communicate with the middle dental nerve, and give off branches to the lining membrane of the antrum and three twigs to each molar tooth. These twigs enter the foramina at the apices of the fangs, and supply the pulp.

The **middle superior dental branch** (ramus alveolaris superior medius) is given off from the superior maxillary nerve in the back part of the infraorbital canal, and runs downwards and forwards in a special canal in the outer wall of the antrum to supply the two biscupid teeth. It forms a plexus (plexus dentalis superior) with the posterior and anterior dental branches.

At its point of communication with the posterior branch is a slight thickening which has received the name of the *ganglion of Valentin*; and at its point of communication with the anterior branch is a second enlargement, which is called the *ganglion of Bochdalek*. Neither of these is a true ganglion.

The **anterior superior dental branch** (ramus alveolaris superior anterior), of considerable size, is given off from the superior maxillary nerve just before its exit from the infraorbital foramen; it enters a special canal in the anterior wall of the antrum, and divides into a series of branches which supply the incisor and canine teeth. It communicates with the middle dental nerve, and gives off a *nasal branch*, which passes through a minute canal into the nasal fossa, and supplies the mucous membrane of the fore part of the inferior meatus and the floor of this cavity, communicating with the nasal branches from Meckel's ganglion.

The **palpebral branches** (rami palpebrales inferiores) pass upwards beneath the Orbicularis palpebrarum. They supply the integument and conjunctiva of the lower eyelid, joining at the outer angle of the orbit with the facial nerve and malar branch of the orbital.

The **nasal branches** (rami nasales externi) pass inwards; they supply the integument of the side of the nose, and join with the nasal branch of the ophthalmic.

The **labial branches** (rami labiales superiores), the largest and most numerous, descend beneath the Levator labii superioris, and are distributed to the integument of the upper lip, the mucous membrane of the mouth, and labial glands.

All these branches are joined, immediately beneath the orbit, by filaments from the facial nerve, forming an intricate plexus, the *infraorbital.*

Spheno-palatine Ganglion (fig. 771)

The **spheno-palatine ganglion** (ganglion sphenopalatinum), or ganglion of Meckel, the largest of the ganglia associated with the branches of the fifth nerve, is deeply placed in the spheno-maxillary fossa, close to the spheno-palatine foramen. It is triangular or heart-shaped, of a reddish-grey colour, and is situated just below the superior maxillary nerve as it crosses the fossa.

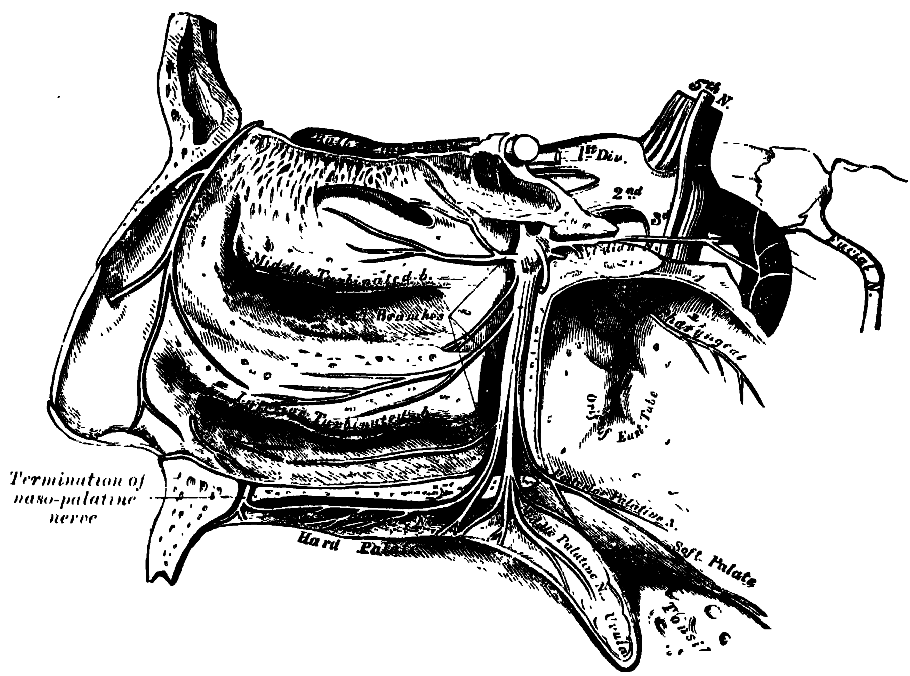
Branches of communication.—Like the other ganglia of the fifth nerve, the spheno-palatine possesses a motor, a sensory, and a sympathetic root. Its *sensory root* is derived from the superior maxillary nerve through its two spheno-palatine branches. These branches of the nerve, given off in the spheno-maxillary fossa, descend to the ganglion. Their fibres, for the most part, pass in front of the ganglion, as they proceed to their destination, in the palate and nasal fossa, and are not incorporated in the ganglionic mass; some few of the fibres, however,

enter the ganglion, constituting its sensory root. Its *motor root* is probably derived from the facial nerve through the large superficial petrosal nerve but this nerve consists chiefly of sensory fibres, and its *sympathetic root*, from the carotid plexus, through the large deep petrosal nerve. These two nerves join together to form a single nerve, the ***Vidian***, before their entrance into the ganglion.

The *large superficial petrosal branch* (n. petrosus superficialis major) is given off from the geniculate ganglion of the facial nerve in the aqueductus Fallopii; it passes through the hiatus Fallopii, enters the cranial cavity, and runs forwards contained in a groove on the anterior surface of the petrous portion of the temporal bone, lying beneath the dura mater. It then enters the cartilaginous substance which fills in the foramen lacerum medium, and joining with the large deep petrosal branch forms the Vidian nerve.

The *large deep petrosal branch* (n. petrosus profundus) is given off from the carotid plexus, and runs through the carotid canal on the outer side of the internal carotid artery. It then enters the cartilaginous substance which fills in the foramen lacerum medium, and joins with the large superficial petrosal nerve to form the Vidian.

FIG. 771.—The spheno-palatine ganglion and its branches.



The *Vidian nerve* (n. canalis pterygoidei), formed by the junction of the two preceding nerves in the cartilaginous substance which fills in the middle lacerated foramen, passes forwards, through the Vidian canal, with the artery of the same name, and is joined by a small ascending branch, the *sphenoidal branch*, from the otic ganglion. Finally, it enters the spheno-maxillary fossa, and joins the posterior angle of Meckel's ganglion.

Branches of distribution.—These are divisible into four groups, viz. *ascending* branches, which pass to the orbit; *descending*, to the palate; *internal*, to the nose; and *posterior*, to the nasopharynx.

The *ascending branches* (rami orbitales) are two or three delicate filaments, which enter the orbit by the spheno-maxillary fissure, and supply the periosteum. According to Luschka, some filaments pass through foramina in the suture between the os planum of the ethmoid and frontal bone to supply the mucous membrane of the posterior ethmoidal and sphenoidal sinuses.

The *descending* or *palatine branches* (nn. palatini) are distributed to the roof of the mouth, soft palate, tonsil, and lining membrane of the nose. They are

almost a direct continuation of the spheno-palatine branches of the superior maxillary nerve, and are three in number: anterior, middle, and posterior.

The *anterior palatine nerve* (n. palatinus anterior) descends through the posterior palatine canal, emerges upon the hard palate at the posterior palatine foramen, and passes forwards in a groove in the hard palate, nearly as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the termination of the naso-palatine nerve. While in the posterior palatine canal, it gives off *inferior nasal branches*, which enter the nose through openings in the palate bone, and ramify over the inferior turbinated bone and middle and inferior meatuses; and, at its exit from the canal, a palatine branch is distributed to both surfaces of the soft palate.

The *middle palatine nerve* (n. palatinus medius) descends, through one of the accessory palatine canals, distributing branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The *posterior palatine nerve* (n. palatinus posterior) descends through the posterior palatine canal, and emerges by a separate opening behind the posterior palatine foramen. It supplies the soft palate, tonsil, and uvula, and was formerly believed to supply the Levator palati and Azygos uvulæ muscles, but these are probably supplied by the spinal accessory through the pharyngeal plexus. The middle and posterior palatine join with the tonsillar branches of the glosso-pharyngeal to form a plexus around the tonsil (*circulus tonsillaris*).

The *internal branches* are distributed to the septum and outer wall of the nasal fossa. They are the superior nasal and the naso-palatine.

The *superior nasal branches*, four or five in number, enter the back part of the nasal fossa by the spheno-palatine foramen. They supply the mucous membrane covering the superior and middle turbinated bones, and the lining of the posterior ethmoidal cells, a few being prolonged to the upper and back part of the septum.

The *naso-palatine nerve* (n. nasopalatinus) also enters the nasal fossa through the spheno-palatine foramen; it passes inwards across the roof of the nose, below the orifice of the sphenoidal sinus to reach the septum, and then runs obliquely downwards and forwards along the lower part of the septum, to the anterior palatine foramen, lying between the periosteum and mucous membrane. It descends to the roof of the mouth through the anterior palatine canal. The two nerves are here contained in separate and distinct canals, situated in the intermaxillary suture, and termed the *foramina of Scarpa*, the left nerve being anterior to the right one. In the mouth, they become united, supply the mucous membrane behind the incisor teeth, and join with the anterior palatine nerves. The naso-palatine nerve furnishes a few small filaments to the mucous membrane of the septum.

Posterior branch.—The *pharyngeal nerve* is a small branch arising from the back part of the ganglion. It passes through the pterygo-palatine canal with the pterygo-palatine artery, and is distributed to the mucous membrane of the upper part of the pharynx, behind the Eustachian tube.

Inferior Maxillary Nerve (figs. 768, 770, 772)

The **Inferior maxillary nerve** (n. mandibularis) distributes branches to the teeth and gums of the lower jaw, the integument of the temple and external ear, the lower part of the face and lower lip, and the muscles of mastication; it also supplies a large branch to the tongue. It is the largest of the three divisions of the fifth, and is made up of two roots: a large or sensory root proceeding from the inferior angle of the Gasserian ganglion; and a small or motor root, which passes beneath the ganglion, and unites with the sensory root, just after its exit from the skull through the foramen ovale. Immediately beneath the base of the skull, the nerve divides into two trunks, anterior and posterior. Previous to its division, the primary trunk gives off from its inner side a recurrent (meningeal) branch, and the nerve to the Internal pterygoid.

The **recurrent branch** (n. spinosus) is given off directly after its exit from the foramen ovale. It passes backwards into the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery

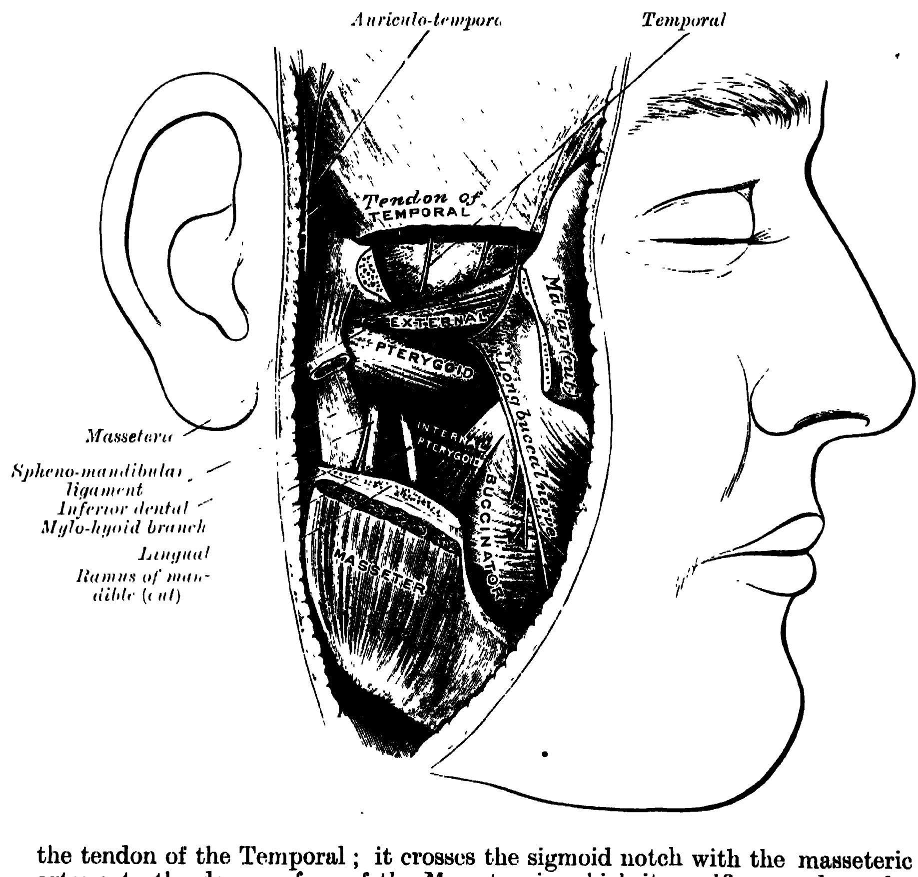
and supply the dura mater. The posterior branch also supplies the mucous lining of the mastoid cells. The anterior branch communicates with the meningeal branch of the superior maxillary nerve.

The nerve to the **internal pterygoid** (n. pterygoideus internus), given off from the inferior maxillary before it divides, is intimately connected at its origin with the otic ganglion. It is a slender branch, which passes inwards and enters the deep surface of the Internal pterygoid.

The *anterior* and smaller division, which receives nearly the whole of the motor root, divides into branches which supply the muscles of mastication and the skin and mucous membrane of the cheek. They are the masseteric, deep temporal, long buccal, and external pterygoid.

The **masseteric branch** (n. massetericus) passes outwards, above the External pterygoid, in front of the temporo-mandibular articulation, and behind

Fig. 772.—The External pterygoid muscle and the branches of the inferior maxillary nerve in relation to it.



the tendon of the Temporal; it crosses the sigmoid notch with the masseteric artery, to the deep surface of the Masseter, in which it ramifies nearly as far as its anterior border. It gives a filament to the temporo-mandibular joint.

The **deep temporal branches** (nn. temporales profundi) are two in number, anterior and posterior. They pass above the upper border of the External pterygoid and enter the deep surface of the Temporal. The *posterior branch*, of small size, is placed at the back of the temporal fossa. It sometimes arises in common with the masseteric branch. The *anterior branch* is frequently given off with the buccal nerve, and then turns upwards over the upper head of the External pterygoid. Frequently a third branch (*middle deep temporal*) is present.

The **long buccal branch** (n. buccinatorius) passes forwards between the two heads of the External pterygoid, and downwards beneath or through

the fibres of the Temporal; it emerges from under the anterior border of the Masseter, ramifies on the surface of the Buccinator, and unites with the buccal branches of the facial nerve. It gives a branch to the External pterygoid during its passage through that muscle, and may give off the anterior deep temporal nerve. The long buccal branch supplies the integument over the Buccinator muscle, and the mucous membrane lining its inner surface.

The nerve to the **external pterygoid** (n. pterygoideus externus) frequently arises in conjunction with the long buccal, but it may be given off separately from the anterior trunk of the nerve. It enters the muscle on its inner surface.

The *posterior* and larger division of the inferior maxillary nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into three branches: auriculo-temporal, lingual, and inferior dental.

The **auriculo-temporal nerve** (n. auriculotemporalis) generally arises by two roots, between which the middle meningeal artery passes. It runs backwards beneath the External pterygoid muscle to the inner side of the neck of the mandible. It then turns upwards with the temporal artery, between the external ear and condyle of the mandible, under cover of the parotid gland, and, escaping from beneath this structure, ascends over the zygoma, and divides into two temporal branches.

Branches of communication.—The auriculo-temporal nerve communicates with the facial nerve and with the otic ganglion. The branches of communication with the facial, usually two in number, pass forwards, from behind the neck of the condyle of the mandible, to join this nerve at the posterior border of the Masseter muscle. The filaments of communication with the otic ganglion are derived from the commencement of the auriculo-temporal nerve.

Branches of distribution.—The branches of distribution of the auriculo-temporal nerve are:

Anterior auricular.	Articular.
Branches to the meatus auditorius.	Parotid.
Superficial temporal.	

The *anterior auricular branches* are usually two in number. They supply the front of the upper part of the pinna, being distributed principally to the skin covering the front of the helix and tragus.

Branches to the meatus auditorius, two in number, enter the canal between the bony and cartilaginous portions of the meatus. They supply the skin lining the meatus; the upper one sending a filament to the membrana tympani.

A *branch to the temporo-mandibular articulation* is usually derived from the auriculo-temporal nerve.

The *parotid branches* supply the parotid gland.

The *superficial temporal* accompanies the temporal artery to the vertex of the skull, and supplies the integument of the temporal region, communicating with the facial nerve, and with the temporal branch of the temporo-malar from the superior maxillary.

The **lingual nerve** (n. lingualis) supplies the mucous membrane of the anterior two-thirds of the tongue, and is deeply placed throughout the whole of its course. It lies at first beneath the External pterygoid, to the inner side and in front of the inferior dental nerve, and is occasionally joined to this nerve by a branch which may cross the internal maxillary artery. The chorda tympani also joins it at an acute angle in this situation. The nerve then passes between the Internal pterygoid muscle and the inner side of the ramus of the mandible, and crosses obliquely to the side of the tongue over the Superior constrictor and Stylo-glossus, and then between the Hyo-glossus and deep part of the submaxillary gland; it finally runs across Wharton's duct, and along the tongue to its tip, lying immediately beneath the mucous membrane.

The *branches of communication* are with the facial (through the chorda tympani), the inferior dental and hypoglossal nerves, and the submaxillary ganglion. The branches to the submaxillary ganglion are two or three in number; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyo-glossus.

The *branches of distribution* supply the mucous membrane of the mouth, the gums, the sublingual gland, and the mucous membrane of the anterior

two-thirds of the tongue; the terminal filaments communicate, at the tip of the tongue, with the hypoglossal nerve.

The **inferior dental nerve** (n. alveolaris inferior) is the largest of the three branches of the inferior maxillary nerve. It passes downwards with the inferior dental artery, at first beneath the External pterygoid muscle, and then between the internal lateral ligament and the ramus of the mandible to the dental foramen. It then passes forwards in the inferior dental canal, lying beneath the teeth, as far as the mental foramen, where it divides into two terminal branches, incisive and mental.

The branches of the inferior dental are the mylo-hyoid, dental, incisive, and mental.

The *mylo-hyoid nerve* (n. mylohyoideus) is derived from the inferior dental just as that nerve is about to enter the dental foramen. It descends in a groove on the inner surface of the ramus of the mandible, and reaching the under surface of the Mylo-hyoid supplies this muscle and the anterior belly of the Digastric.

The *dental branches* supply the molar and biscupid teeth. They correspond in number to the fangs of those teeth; each nerve entering the orifice at the point of the fang, and supplying the pulp of the tooth.

The *incisive branch* is continued onwards within the bone to the middle line, and supplies the canine and incisor teeth.

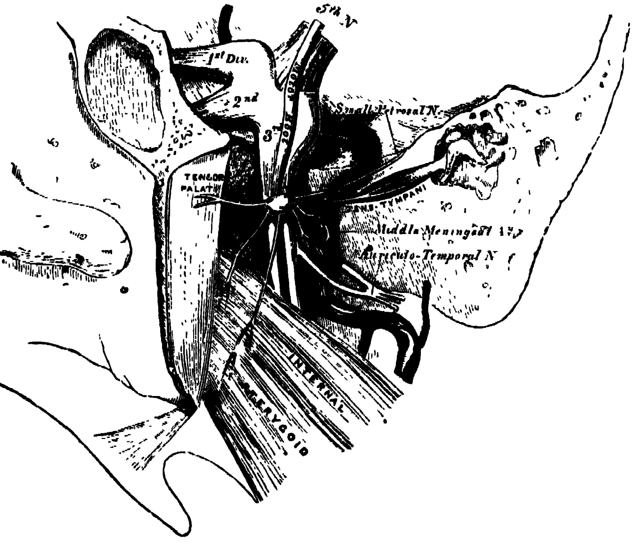
The *mental nerve* (n. mentalis) emerges from the bone at the mental foramen, and divides beneath the Depressor anguli oris into three branches; one descends to supply the skin of the chin, and two ascend to supply the skin and mucous membrane of the lower lip. These branches communicate freely with the facial nerve.

Two small ganglia are connected with the inferior maxillary nerve: the otic with the trunk of the nerve; and the submaxillary with its lingual branch.

Otic Ganglion (fig. 773)

The **otic ganglion** (ganglion oticum) is a small, oval-shaped, flattened ganglion of a reddish-grey colour, situated immediately below the foramen ovale; it lies on the inner surface of the inferior maxillary nerve, and surrounds the origin of the internal pterygoid nerve. It is in relation, *externally*,

Fig. 773.—The otic ganglion and its branches.



with the trunk of the inferior maxillary nerve, at the point where the motor root joins the sensory portion; *internally*, with the cartilaginous part of the Eustachian tube, and the origin of the Tensor palati muscle; *behind*, with the middle meningeal artery.

Branches of communication.—It is connected by two or three short delicate filaments with the internal pterygoid branch of the inferior maxillary nerve, from which it may obtain a motor, and possibly also a sensory root. It communicates with the glosso-pharyngeal and facial nerves, through the small superficial petrosal nerve continued from the tympanic plexus, and through this communication it probably receives a sensory root from the glosso-pharyngeal and a motor root from the facial; its communication with the sympathetic is effected by a filament from the plexus surrounding the middle meningeal artery. The ganglion also communicates with the auriculo-temporal nerve by a branch which is probably derived from the glosso-pharyngeal, and which passes to the ganglion, and then through it and the auriculo-temporal nerve to the parotid gland. A slender filament (*sphenoidal*) ascends from it to the Vidian nerve, and a small branch communicates with the chorda tympani.

Its *branches of distribution* are, a filament to the Tensor tympani, and one to the Tensor palati. The former passes backwards, on the outer side of the Eustachian tube; the latter arises from the ganglion, near the origin of the internal pterygoid nerve, and passes forwards. The fibres of these nerves are, however, mainly derived from the nerve to the Internal pterygoid.

Submaxillary Ganglion (fig. 770)

The **submaxillary ganglion** (ganglion submaxillare) is of small size and is fusiform in shape. It is situated above the deep portion of the submaxillary gland, on the Hyo-glossus muscle, near the posterior border of the Mylo-hyoid, and is connected by filaments with the lower border of the lingual nerve.

Branches of communication.—This ganglion is suspended from the lingual nerve by two filaments which join the front and back parts of the ganglion. It also receives a branch from the chorda tympani nerve, and communicates with the sympathetic by filaments from the sympathetic plexus around the facial artery.

Branches of distribution.—These are five or six in number; they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth and Wharton's duct, some being lost in the submaxillary gland. The branch of communication from the lingual to the fore part of the ganglion is by some regarded as a branch of distribution, through which filaments of the chorda tympani pass from the ganglion to the nerve, and by it are conveyed to the sublingual gland and the tongue.

Surface Marking.—It will be seen from the above description that the terminal branches of the three divisions of the fifth nerve emerge from foramina on to the face: the terminal branch of the first division emerging through the supraorbital foramen; that of the second through the infraorbital foramen; and that of the third through the mental foramen. The supraorbital foramen is situated at the junction of the internal and middle thirds of the supraorbital arch. If a straight line be drawn from this point to the lower border of the mandible, so that it passes between the lower two bicuspid teeth, it will pass over the infraorbital and mental foramina; the former being situated about one centimetre (two-fifths of an inch) below the margin of the orbit, while the latter varies in position according to the age of the individual. In the adult it is midway between the upper and lower borders of the mandible; in the child it is nearer the lower border, and in the edentulous jaw of old age it is close to the upper margin.

Applied Anatomy.—Paralysis of the fifth nerve causes anæsthesia of the corresponding anterior half of the scalp, and of the face, excepting over a small area near the angle of the jaw supplied by the cervical nerves, and of the cornea and conjunctiva, and of the mucous membrane of the nose, mouth, and tongue. Taste is lost (*ageusia*) on the affected side. Paralysis and atrophy follow in the Temporal, Masseter, and Pterygoid muscles, possibly also in the Tensor tympani; when the mouth is opened the mandible is thrust over towards the paralysed side. Interference with the secretion of the tears, the nasal mucus, and the saliva, causes dryness of the corresponding mucous membranes. The sense of smell is gradually lost on the affected side from the trophic changes that follow in the Schneiderian membrane. Inflammation of the eyeball, under these circumstances known as neuroparalytic ophthalmia, is not rare, and is due to the dryness and insensitiveness of the conjunctiva; it is not a 'trophic' phenomenon, but depends on the occurrence and neglect of traumatic inflammation in the anæsthetic eye.

Fifth nerve reflexes.—Pains referred to various branches of the fifth cranial nerve are of very frequent occurrence, and should always lead to a careful examination in order to discover a local cause. As a general rule the diffusion of pain over the various branches

of the nerve is at first confined to one only of the main divisions, and the search for the causative lesion should always commence with a thorough examination of all those parts which are supplied by that division; although in severe cases pain may radiate over the branches of the other main divisions. The commonest example of this condition is the neuralgia which is so often associated with dental caries—here, although the tooth itself may not appear to be painful, the most distressing referred pains may be experienced, and these are at once relieved by treatment directed to the affected tooth.

Many other examples of 'fifth nerve' reflexes could be quoted, but it will be sufficient to mention the more common ones. Dealing with the ophthalmic division, severe supra-orbital pain is commonly associated with acute glaucoma or with disease of the frontal or ethmoidal air-cells. Malignant growths or empyema of the maxillary antrum, or unhealthy conditions about the inferior turbinateds or the septum of the nose, are often found giving rise to 'second division' neuralgia, and should be always looked for in the absence of dental disease in the maxilla.

It is on the third division, however, that some of the most striking reflexes are seen. It is quite common to meet with patients who complain of pain in the ear, in whom there is no sign of aural disease, and the cause is usually to be found in a carious tooth in the mandible. Moreover, with an ulcer or cancer of the tongue, often the first pain to be

FIG. 774.—Diagram showing cutaneous areas of face and scalp.

experienced is one which radiates to the ear and temporal fossa, over the distribution of the auriculo-temporal nerve.

The fifth nerve is often the seat of severe neuralgia for which no local cause can be discovered; each of the three divisions has been divided, or a portion of the nerve excised, for this affection, usually, however, with only temporary relief. The supraorbital nerve may be exposed by making an incision an inch and a half in length along the supra-orbital margin, below the eyebrow which is to be drawn upwards, the centre of the incision corresponding to the supraorbital notch. The skin and Orbicularis palpebrarum having been divided, the nerve can be easily found emerging from the notch, and lying in some loose cellular tissue. It should be drawn up by a blunt hook and divided, or, better, a portion of it removed. The infraorbital nerve has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infraorbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with Meckel's ganglion as far back as the foramen rotundum may be removed, but even then a return of the neuralgia in some other branches of the fifth nerve is the rule rather than the exception. The operation is performed as follows: the superior maxillary bone is first exposed by a T-shaped incision, one limb passing along the lower margin of the orbit, the other from the centre of this vertically down the cheek to the angle of the mouth. The nerve is to be found, divided, and a piece of silk tied to it as a guide.

A small trephine (half-inch) is applied to the bone, below, but including the infraorbital foramen, and the antrum opened. The trephine is then applied to the posterior wall of the antrum, and the spheno-maxillary fossa exposed. The infraorbital canal is opened up from below, and the nerve drawn down into the trephine hole, it being held on the stretch by means of the piece of silk; it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided. The inferior dental nerve can be reached by a transverse incision over the ramus of the jaw placed so as to avoid injury to the facial nerve; the Masseter muscle having been divided, a small trephine is applied to the ramus immediately beneath the masseteric notch, and, when the bone has been removed, the nerve is found lying on the Internal pterygoid just as it enters the inferior dental canal, and it can here be resected.

The lingual (gustatory) nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line be drawn from the middle of the crown of the last molar tooth to the angle of the jaw it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. The tongue should be pulled forwards and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue, and can be easily seized with a sharp hook and divided or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of a nerve is required, the operation is not practicable.

In severe cases of neuralgia of the fifth nerve, the Gasserian ganglion has been removed in whole or in part with a considerable measure of success. Rose was the first to perform this operation; and he reached the ganglion by trephining the base of the skull in the position of the foramen ovale, after dividing the zygomatic arch, in front and behind, and turning it and the Masseter muscle downwards, and cutting through the coronoid process of the lower jaw, and turning it and the Temporal muscle upwards. A more efficient method appears to be that known as the Krause-Hartley method. The bone forming the temporal fossa having been removed to a sufficient extent, the temporal lobe of the brain, with the dura mater, is gradually raised from the middle fossa, until the foramen spinosum, with the middle meningeal artery passing through it, is exposed. This vessel is to be ligatured in two places, and divided between the ligatures; and then by further raising the temporal lobe, the foramina ovale and rotundum will be exposed, with the second and third divisions of the fifth nerve passing through them. These nerves are to be clearly defined and divided. The dura mater is then to be raised from the ganglion, when the ophthalmic nerve will be exposed and must be divided, and the ganglion, by means of a little careful dissection, raised from its bed and removed. In some cases where the neuralgia has been limited to the second division of the nerve an intracranial resection of that division alone has been performed with great success. In other cases where the disease has not affected the ophthalmic division, resection of the outer half of the ganglion only, with the superior and inferior maxillary nerves, has been performed, thus leaving the sensory nerve supply to the cornea intact. The motor root is usually resected with the third division of the nerve, leading to complete paralysis of the muscles of mastication on that side.

Fig. 775.—Figure showing the mode of innervation of the Internal and External recti muscles of the eye (after Duval and Laborde). (Testut.)

Nucleus sixth nerv[illegible] Nucle[illegible] [illegible]hird nerv[illegible] 6. Sixth nerve 7 [illegible] Intern. arising from the n[illegible] of t[illegible]e third [illegible] the same side 7'. Nerv[illegible] the Inter[illegible] rectus of the other side arising from th[illegible] opposite nucleus. 8. Decussation of t[illegible] fibres of sixth nerve to Internal recti.

Sixth Nerve (figs. 769, 775)

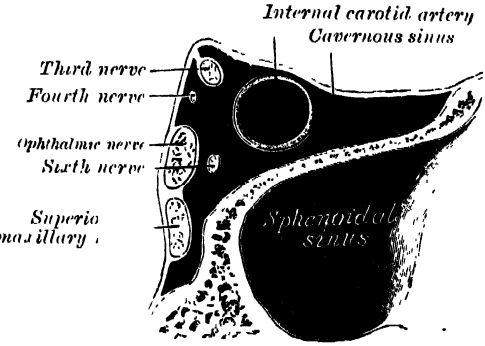
The **Sixth nerve** (n. abducens) supplies the External rectus muscle of the eyeball.

Its fibres arise from a small nucleus situated in the upper part of the floor of the fourth ventricle, close to the middle line and beneath the eminentia teres. They pass downwards and forwards through the pons, and emerge in the furrow

between the lower border of the pons and the upper end of the pyramid of the medulla oblongata.

From the nucleus of the sixth nerve, fibres pass through the posterior longitudinal bundle to the oculo-motor nerve of the opposite side, along which they are carried to the Internal rectus muscle. The External rectus of one eye and the Internal rectus of the other may therefore be said to receive their nerves from the same nucleus—a factor of great importance in connection with the conjugate movements of the eyeball, and one that may explain certain paralytic phenomena of the Recti, which are often associated with lesions in the pons.

Fig. 776.—Oblique section through the right cavernous sinus.



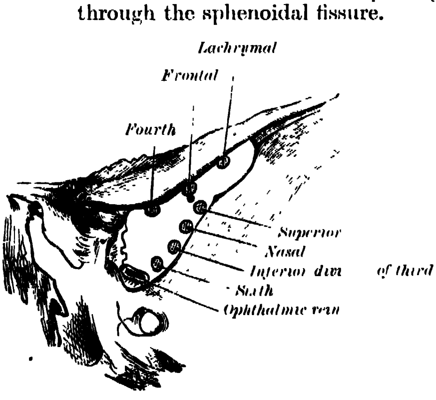
The nerve pierces the dura mater on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forwards through the sinus, lying on the outer side of the internal carotid artery. It enters the orbit through the sphenoidal fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura mater. It then passes between the two heads of the External rectus, and is distributed to that muscle on its ocular surface.

Branches of communication.- The sixth nerve is joined by several filaments from the carotid and cavernous plexuses, and by one from the ophthalmic nerve.

The sixth nerve, together with the third, fourth, and the ophthalmic division of the fifth, as they pass to the orbit, bear a certain relation to each other in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the *cavernous sinus* (fig. 776), the third and fourth nerves and the ophthalmic division of the fifth are placed on the outer wall of the sinus, in their numerical order, both from above downwards, and from within outwards. The sixth nerve lies at the outer side of the internal carotid artery. As these nerves pass forwards to the sphenoidal fissure, the third and fifth nerves become divided into branches, and the sixth approaches the rest; so that their relative position becomes considerably changed.

Fig. 777.—Relations of structures passing through the sphenoidal fissure.



In the *sphenoidal fissure* (fig. 777), the fourth nerve, and the frontal and lachrymal divisions of the ophthalmic lie in this order from within outwards upon the same plane; they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus. The superior division of the third is the highest of these; beneath this lies the nasal branch of the ophthalmic;- then the inferior division of the third; and the sixth lowest of all.

In the *orbit*, the fourth, and the frontal and lachrymal divisions of the ophthalmic lie on the same plane immediately beneath the periosteum, the

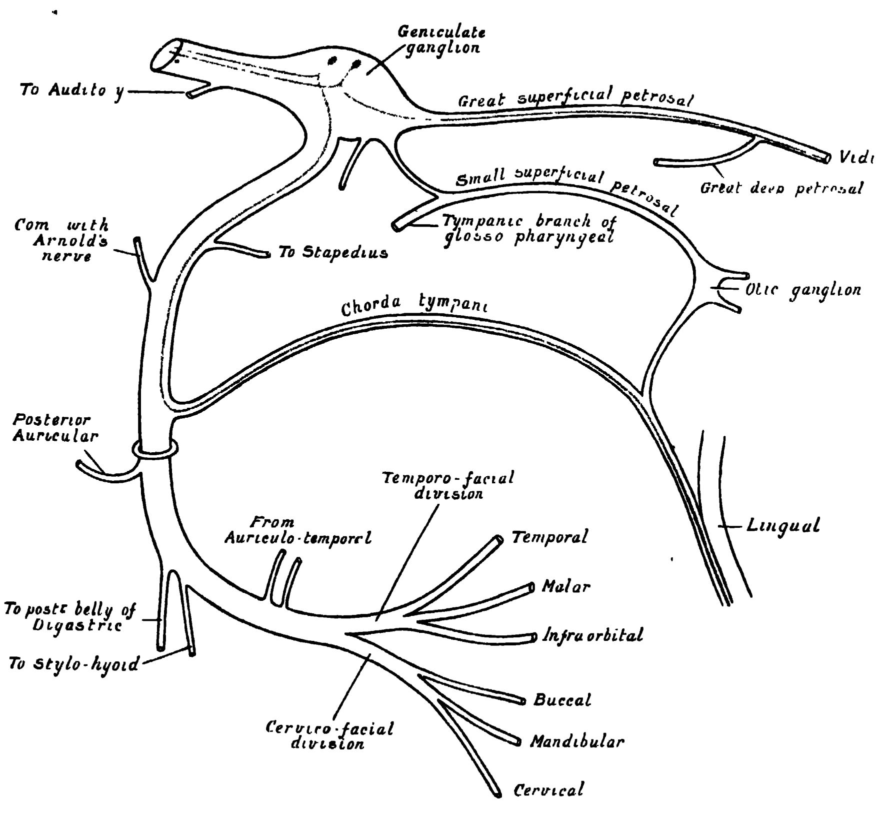
fourth nerve being internal and resting on the Superior oblique, the frontal resting on the Levator palpebræ, and the lachrymal on the External rectus. The superior division of the third nerve lies immediately beneath the Superior rectus, while the nasal branch of the ophthalmic crosses the optic nerve to reach the inner side of the orbit. Beneath these is the optic nerve, surrounded in front by the ciliary nerves, and having the lenticular ganglion on its outer side, between it and the External rectus. Below the optic nerve are the inferior division of the third, and the sixth, the latter lying on the outer side of the orbit.

Applied Anatomy.—The sixth nerve is more frequently involved in fractures of the base of the skull than any other cranial nerve. The result of paralysis of this nerve is internal or convergent squint. Diplopia is also present. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris are conveyed through this nerve.

SEVENTH NERVE (figs. 778, 779, 780)

The **Seventh** or **Facial nerve** (n. facialis), like the fifth, consists of a motor and a sensory part, the latter being frequently described under the name of the *pars intermedia of Wrisberg*. The two parts emerge separately at the lower border of the pons Varolii in the recess between the olivary and restiform

FIG. 778.—Plan of the seventh nerve. The course of the sensory fibres is represented by the blue lines.



bodies, the motor part being the more internal; immediately to the outer side of the sensory part is the auditory nerve.

The motor part supplies the muscles of the face, scalp and pinna, the Buccinator and Platysma, the Stylo-hyoid and posterior belly of the Digastric, and the Stapedius muscle of the tympanic cavity; it also contains some fibres

which constitute the vasodilator nerves of the submaxillary and sublingual glands, and are conveyed to these glands through the chorda tympani. The sensory part contains the fibres of taste for the anterior two-thirds of the tongue.

The *motor* root takes origin from a nucleus which lies deeply in the reticular formation of the lower part of the pons Varolii. This nucleus is situated above the nucleus ambiguus, behind the superior olive, and internal to the lower sensory root of the fifth nerve. From this origin the fibres pursue a curved course in the substance of the pons. They first pass backwards and inwards towards the floor of the fourth ventricle, and, reaching the posterior extremity of the nucleus of the sixth nerve, run upwards close to the middle line beneath the eminentia teres. At the anterior end of the nucleus of the sixth nerve they make a second bend, and run downwards and forwards through the pons to their point of emergence between the olivary and restiform bodies.

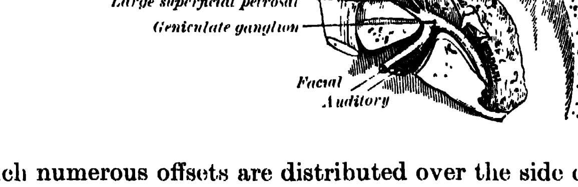
Some fibres from the nucleus of the third nerve are said to descend in the posterior longitudinal fasciculus and join the motor root of the facial nerve before it leaves the pons. These fibres are believed to supply the Orbicularis palpebrarum, Corrugator supercilii, and anterior belly of the Occipito-frontalis, since these muscles have been observed to escape paralysis in lesions of the motor nucleus of the facial nerve.*

The *sensory* root arises from the geniculate ganglion, which is situated on the genu of the facial nerve in the aqueductus Fallopii, behind the hiatus Fallopii. The cells of this ganglion are unipolar, and the single process given off from each divides in a T-shaped manner into a central and a peripheral branch. The central branches run inwards, and, leaving the trunk of the facial nerve in the internal auditory meatus, form the sensory root; the peripheral branches are continued into the chorda tympani and great superficial petrosal nerves. Entering the brain at the lower border of the pons between the motor root internally and the auditory nerve externally, the fibres of the sensory root pass into the substance of the medulla and terminate in the upper part of the nucleus of the glosso-pharyngeal and in the fasciculus solitarius.

From their superficial attachments to the brain, the two roots of the facial nerve pass outwards and forwards with the auditory nerve to the internal auditory meatus. In the meatus the motor root lies in a groove on the upper and anterior surface of the auditory nerve, the sensory root being placed between the two.

At the bottom of the meatus, the facial nerve enters the aqueductus Fallopii, and follows the course of that canal through the petrous portion of the temporal bone, to its termination at the stylo-mastoid foramen. It is at first directed outwards between the cochlea and vestibule towards the inner wall of the tympanum; it then bends suddenly backwards and arches downwards behind the tympanum to the stylo-mastoid foramen. The point where it changes its direction is named the *geniculum*; it presents a reddish gangliform swelling, the *ganglion geniculi*, or nucleus of the sensory root of the nerve (fig. 779). On emerging from the stylo-mastoid foramen, it runs forwards in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the mandible into two primary branches, *temporo-facial* and *cervico-facial*, from which numerous offsets are distributed over the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. As the primary branches and their offsets diverge from each other, they present somewhat the appearance of a bird's foot or claws; hence the name of *pes anserinus* is given to the divisions of the facial nerve in and near the parotid gland.

FIG. 779.—The course and connections of the facial nerve in the temporal bone.



* See footnote, page 841.

Branches of communication.—The communications of the facial nerve may be arranged as follows :

In the internal auditory meatus	With the auditory nerve.
At the geniculate ganglion	With Meckel's ganglion by the large superficial petrosal nerve. With the otic ganglion by a branch which joins the small superficial petrosal nerve. With the sympathetic on the middle meningeal by the external superficial petrosal nerve.
In the Fallopian aqueduct	With the auricular branch of the pneumogastric.
At its exit from the stylo-mastoid foramen	With the glosso-pharyngeal. ,, ,, pneumogastric. ,, ,, great auricular. ,, ,, auriculo-temporal.
Behind the ear	With the small occipital.
On the face	With the three divisions of the fifth.
In the neck	With the superficial cervical.

In the internal auditory meatus some minute filaments pass from the pars intermedia and from the facial to the auditory nerve.

The *large superficial petrosal nerve* arises from the geniculate ganglion, and consists chiefly of sensory branches which are distributed to the mucous membrane of the soft palate ; but it probably also contains a few motor fibres which form the motor root of Meckel's ganglion. It passes forwards through the hiatus Fallopii, and runs in a groove on the anterior surface of the petrous portion of the temporal bone beneath the Gasserian ganglion, to the foramen lacerum medium. It receives a twig from the tympanic plexus, and in the foramen is joined by the great deep petrosal, from the sympathetic plexus on the internal carotid artery, to form the Vidian nerve. This nerve passes forwards through the Vidian canal and ends in Meckel's ganglion. The geniculate ganglion is connected with the otic ganglion, by a branch which joins the small superficial petrosal nerve, and also with the sympathetic filaments accompanying the middle meningeal artery, by the external petrosal (Bidder). From the ganglion, according to Arnold, a twig is sent back to the auditory nerve. Just before the facial nerve emerges from the stylo-mastoid foramen, it generally receives a twig of communication from the auricular branch of the pneumogastric.

After its exit from the stylo-mastoid foramen, the facial sends a twig to the glosso-pharyngeal. and communicates with the auricular branch of the pneumogastric, with the great auricular branch of the cervical plexus, with the auriculo-temporal branch of the inferior maxillary nerve in the parotid gland, and with the small occipital behind the ear ; on the face with the terminal branches of the three divisions of the fifth, and in the neck with the superficial or transverse cervical.

Branches of distribution (fig. 780).—The branches of distribution of the facial nerve may be thus arranged :

Within the aqueductus Fallopii	Tympanic, to the Stapedius muscle. Chorda tympani.	
At its exit from the stylo-mastoid foramen	Posterior auricular. Digastric. Stylo-hyoid.	
On the face	Temporo-facial	Temporal. Malar. Infraorbital.
	Cervico-facial	Buccal. Mandibular. Cervical.

The **tympanic branch** arises from the nerve opposite the pyramid; it passes through a small canal in the pyramid, and supplies the Stapedius muscle.

The **chorda tympani** is given off from the facial as it passes vertically downwards at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It runs from below upwards and forwards in a distinct canal, and enters the cavity of the tympanum, through an aperture (*iter chordæ posterius*) on its posterior wall, close to the inner aspect of the posterior border of the membrana tympani and on a level with the upper end of the handle of the malleus, and becomes invested with mucous membrane. It traverses the cavity of the tympanum, between the fibrous and mucous layers of the membrana tympani, crosses over the handle of the malleus, and emerges from the cavity through a foramen situated at the inner end of the Glaserian fissure, and named the *iter chordæ anterius*, or *canal of Huguier*. It then descends between the two Pterygoid muscles on the inner aspect of the spine of the sphenoid, which it sometimes grooves, and joins, at an acute angle, the posterior border of the lingual nerve. It receives a few efferent fibres from the motor root; these enter the submaxillary ganglion, and through it are distributed to the submaxillary and sublingual glands; the majority of its fibres are afferent and continued onwards through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds; they constitute the nerve of taste for this portion of the tongue. Before joining the lingual nerve the chorda tympani receives a small communicating branch from the otic ganglion.

The **posterior auricular nerve** (n. auricularis posterior) arises close to the stylo-mastoid foramen, and passes upwards in front of the mastoid process; here it is joined by a filament from the auricular branch of the pneumogastric, and communicates with the mastoid branch of the great auricular, and with the small occipital. As it ascends between the meatus and mastoid process it divides into auricular and occipital branches. The *auricular branch* supplies the Retrahens auriculam and the small intrinsic muscles on the cranial surface of the pinna. The *occipital branch*, the larger, passes backwards along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipito-frontalis.

The **digastric branch** (ramus digastricus) arises close to the stylo-mastoid foramen; it divides into several filaments, which supply the posterior belly of the Digastric; one of these perforates that muscle to join the glosso-pharyngeal nerve.

The **stylo-hyoid branch** (ramus stylohyoideus) frequently arises in conjunction with that to the posterior belly of the Digastric; it is long and slender, and passes inwards to enter the Stylo-hyoid about its middle.

The **temporo-facial division**, the larger of the two terminal branches, runs upwards and forwards through the parotid gland, crosses the external carotid artery and temporo-maxillary vein, and passes over the neck of the condyle of the mandible, being connected in this situation with the auriculo-temporal branch of the inferior maxillary nerve. It breaks up into branches, which are distributed over the temple and upper part of the face; these are grouped into three sets: temporal, malar, and infraorbital.

The *temporal branches* (rami temporales) cross the zygoma to the temporal region, supplying the Attrahens and Attollens auriculam muscles, and join with the temporal branch of the temporo-malar, a branch of the superior maxillary, and with the auriculo-temporal branch of the inferior maxillary. The more anterior branches supply the frontal portion of the Occipito-frontalis, the Orbicularis palpebrarum, and the Corrugator supercilii, and join with the supraorbital and lachrymal branches of the ophthalmic.

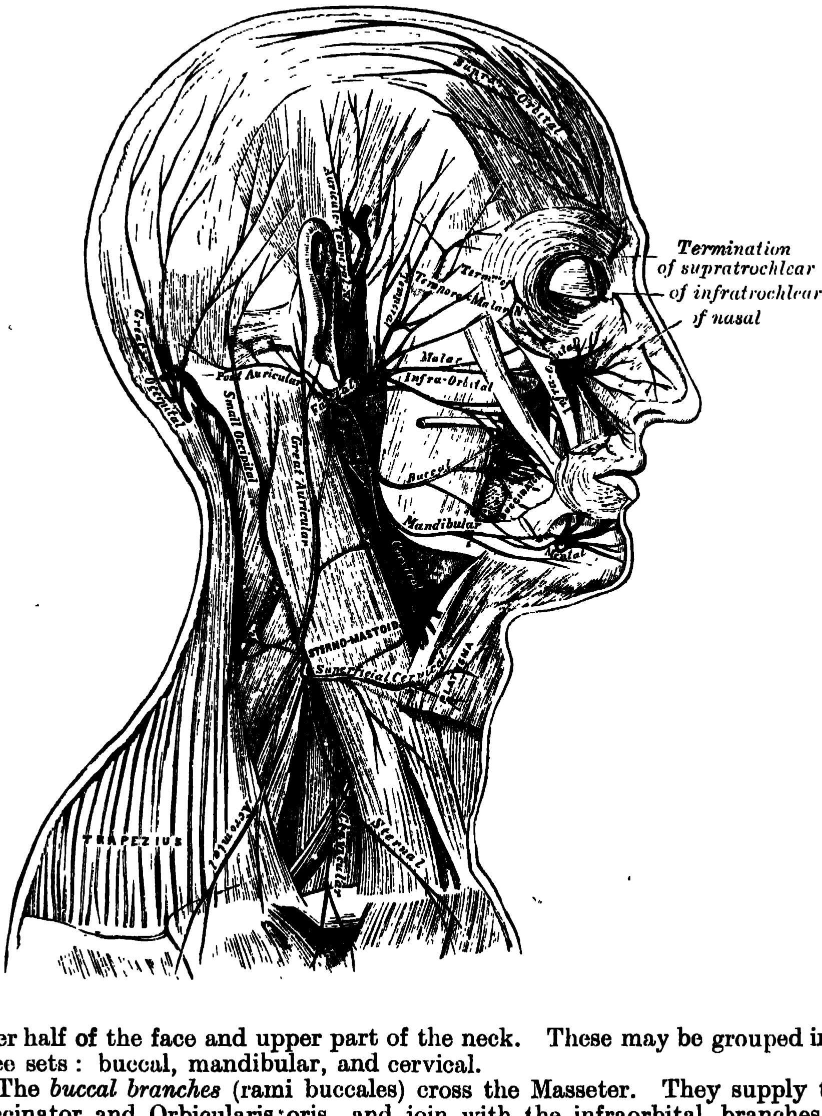
The *malar branches* (rami zygomatici) run across the malar bone to the outer angle of the orbit, where they supply the Orbicularis palpebrarum, and join with filaments from the lachrymal nerve and the malar branch of the superior maxillary nerve.

The *infraorbital branches* (rami infraorbitales), of larger size than the rest, pass horizontally forwards to be distributed between the lower margin of the orbit and the mouth. The *superficial branches* run beneath the skin and above the superficial muscles of the face which they supply: some branches are distributed to the Pyramidalis nasi, joining at the inner angle of the orbit

with the infratrochlear and nasal branches of the ophthalmic. The *deep branches* pass beneath the Zygomatici and the Levator labii superioris, supplying them and the Levator anguli oris, and form a plexus (*infraorbital*) by joining with the infraorbital branch of the superior maxillary nerve and the buccal branches of the cervico-facial. These branches also supply the Levator labii superioris alæque nasi and the small muscles of the nose.

The **cervico-facial division** passes obliquely downwards and forwards through the parotid gland, across the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the mandible it divides into branches which are distributed on the

FIG. 780.—The nerves of the scalp, face, and side of neck.



lower half of the face and upper part of the neck. These may be grouped into three sets: buccal, mandibular, and cervical.

The *buccal branches* (rami buccales) cross the Masseter. They supply the Buccinator and Orbicularis oris, and join with the infraorbital branches of the temporo-facial division of the nerve, and with filaments of the long buccal branch of the inferior maxillary nerve.

The *mandibular branch* (ramus marginalis mandibulæ) passes forwards beneath the Platysma and Depressor anguli oris, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The *cervical branch* (ramus colli) runs forwards beneath the Platysma, and forms a series of arches across the side of the neck over the suprahyoid region. One of the branches descends vertically to join with the superficial cervical nerve from the cervical plexus; others supply the Platysma.

Applied Anatomy.—Facial palsy is commonly unilateral, and may be either: (1) *peripheral*, from lesion of the facial nerve; (2) *nuclear*, from destruction of the facial nucleus; or (3) *central, cerebral*, or *supranuclear*, from injury in the brain to the fibres passing from the cortex through the internal capsule to the facial nucleus, or from injury to the face-area of the motor cortex itself. In supranuclear facial paralysis, which is usually part of a hemiplegia, it is the lower part of the face that is chiefly affected, while the forehead can be freely wrinkled on the palsied side, the eye can be closed fairly well, and the eyeball is not rolled up under the upper lid; emotional movements of the face are much better executed than voluntary; and the electrical reactions of the muscles on the affected side are not altered. If the paralysis is due to lesion of the facial nucleus, the Orbicularis oris escapes, as the nuclear origin of the nerve to this muscle seems to be connected with that of the tongue-nerves; otherwise the symptoms are identical with those of the common peripheral facial palsy, of which several types may be distinguished according to the point in its course at which the facial nerve is injured If the lesion occurs (*a*) in the pons, facial paralysis is produced as in (*d*) below; taste and hearing are not affected, but the sixth nerve also will be paralysed because the fibres of the facial nerve loop round its nucleus in the pons. When the nerve is paralysed (*b*) in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is unable to recognise the difference between bitters and sweets, acids and salines, from involvement of the chorda tympani. The mouth is dry, because the salivary glands are not secreting; and the sense of hearing is affected from paralysis of the Stapedius. When the cause of the paralysis is (*c*) fracture of the base of the skull, the auditory and petrosal nerves are usually involved. But by far the commonest cause of facial palsy is (*d*) exposure of the nerve to cold or injury at or after its exit from the stylomastoid foramen (Bell's paralysis). In these cases the face looks asymmetrical even when at rest, and more so in the old than in the young. The affected side of the face and forehead remains motionless when voluntary or emotional movement is attempted. The lines on the forehead are smoothed out, the eye can be shut only by hand, tears fail to enter the lachrymal puncta because they are no longer in contact with the conjunctiva, the conjunctival reflex is absent, and efforts to close the eye merely cause the eyeball to roll upwards until the cornea lies under the upper lid. The tip of the nose is drawn over towards the sound side; the naso-labial fold is partially obliterated on the affected side, and the ala nasi does not move properly on respiration. The lips remain in contact on the paralysed side, and cannot be put together for whistling; when a smile is attempted the angle of the mouth is drawn up on the unaffected side; on the affected side the lips remain nearly closed, and the mouth assumes a characteristic triangular form. During mastication food accumulates in the cheek, from paralysis of the Buccinator, and dribbles or is pushed out from between the paralysed lips. On protrusion the tongue seems to be thrust over towards the palsied side, but verification of its position by reference to the incisor teeth will show that this is not really so. The Platysma and the muscles of the pinna are paralysed; in severe cases the articulation of labials is impaired. The electrical reactions of the affected muscles are altered (reaction of degeneration), and the degree to which this alteration has taken place after a week or ten days gives a valuable guide to the prognosis. Most cases of Bell's palsy recover completely.

The facial nerve is at fault in cases of so-called 'histrionic spasm,' which consists in an almost constant and uncontrollable twitching of some or all of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient, and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear, from the root of the mastoid process to the angle of the jaw. The parotid is turned forwards and the dissection carried along the anterior border of the Sterno-mastoid muscle and mastoid process, until the upper border of the posterior belly of the Digastric is found. The nerve is parallel to this on about the level of the middle of the mastoid process. When found, the nerve must be stretched by passing a blunt hook beneath it and pulling it forwards and outwards. Too great force must not be used, for fear of permanent injury to the nerve.

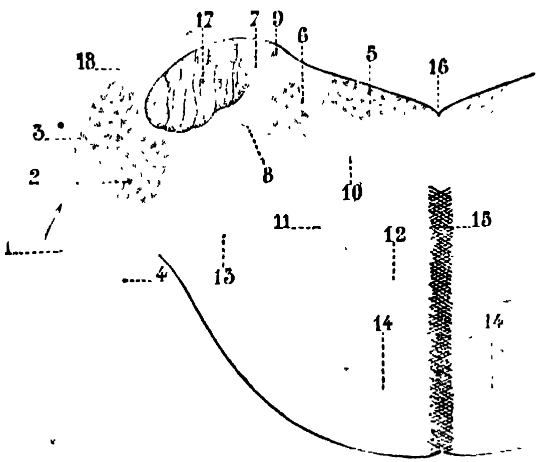
Eighth Nerve

The **Eighth or Auditory nerve** (n. acusticus) is the special nerve of the sense of hearing, being distributed exclusively to the internal ear. It consists of two sets of fibres, which, although differing in their central connections, are both concerned in the transmission of afferent impulses from the internal ear to the medulla and pons, and from there, by means of new fibres which arise from collections of grey matter in these structures, to the cerebrum and cerebellum.

One set of fibres forms the vestibular root of the nerve, and arises from the cells in the ganglion of Scarpa which is situated in the internal auditory meatus; the other set constitutes the cochlear root, and takes origin from the cells in the ganglion spirale or ganglion of Corti, which occupies the spiral canal of the cochlea. Both of these ganglia consist of bipolar nerve-cells; one process from each of the cells passes inwards to the brain, the other outwards to the internal ear. At its connection with the brain the eighth nerve occupies the groove between the pons and medulla, where it is situated between the restiform body which is behind, and the seventh nerve which is in front.

Vestibular root (radix vestibularis) (fig. 781).—The fibres of this root enter the medulla to the inner side of those of the cochlear root, and pass between the restiform body which is to their outer side, and the inferior sensory root of the fifth which lies to their inner side. They then divide into an ascending and a descending set. The fibres of the latter end by arborising round the cells of the *internal nucleus*, which is situated in the *trigonum acusticum* in the floor of the fourth ventricle. The ascending fibres either end in the same manner or in the *external nucleus*, which is situated to the outer side of the trigonum acusticum and farther from the ventricular floor. It is described as consisting of two parts, an inner, the *nucleus of Deiters*, and an outer, the *nucleus of Bechterew*. Some of the axons of the cells of the external nucleus, and possibly also of the internal nucleus, are continued upwards through the restiform body to the roof nuclei of the opposite side of the cerebellum, to which also other fibres of the vestibular root are prolonged without interruption in the nuclei of the medulla. A second set of fibres from the internal and external nuclei end partly in the tegmentum, while the remainder ascend in the posterior longitudinal bundle to arborise around the cells of the nuclei of the oculo-motor nerve.

FIG. 781.—Terminal nuclei of the vestibular root of the auditory nerve, with their upper connections. (Schematic.) (Testut.)



1. Posterior or cochlear root with its two [illegible] let 2. Accessory nucleus. 3. Tuberculum acusticum. 4. Anterior or vestibular root 5 Internal nucleus. 6. Nucleus of Deiters. 7. Nucleus of Be[illegible]hterew. 8. Inferior or descending root of auditory [illegible] 9. Ascending [illegible]erebellar fibres. 10. Fibres going to raphe. 11. Fibres taking an oblique course. 12. Fillet. 13. Inferior sensory root of trigeminal. 14. Pyramidal tract. 15. R[illegible] 16. Fourth [illegible]ntricle 17 Restiform body. 18. Origin of [illegible]ustieæ.

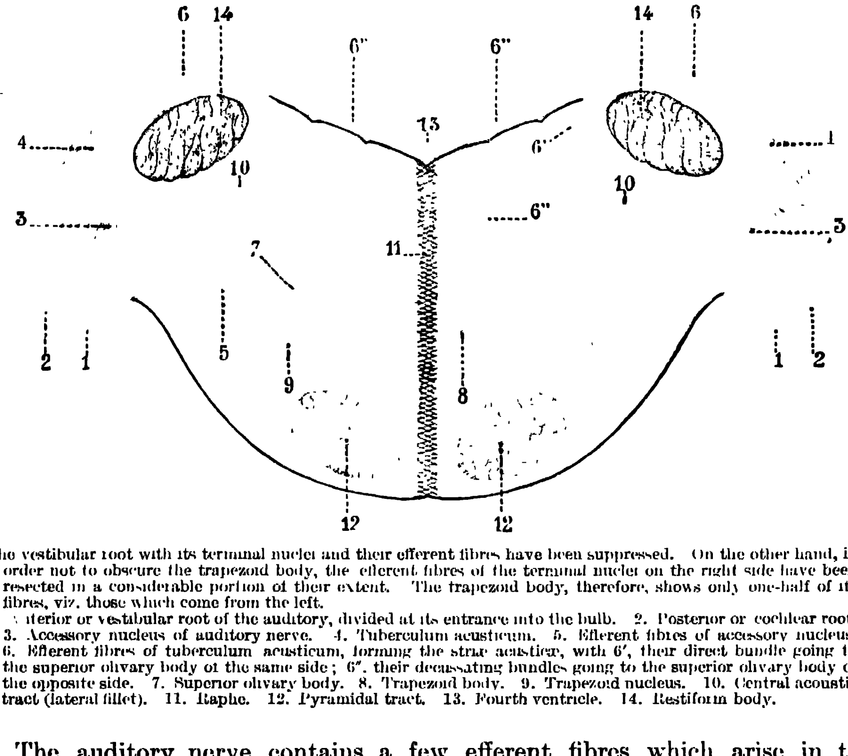
Cochlear root (radix cochlearis) (fig. 782).—This part of the nerve is placed external to the vestibular root.. Its fibres end in two nuclei, one of which, the *accessory nucleus*, lies immediately in front of the restiform body; the other, the *tuberculum acusticum*, somewhat to its outer side.

The striæ acusticæ, or medullary striæ, are the axons of the cells of the tuberculum acusticum. They pass backwards and inwards over the restiform body, and across the floor of the fourth ventricle towards the middle line. Here they dip into the substance of the pons, to end around the cells of the *superior olives* of both sides. There are, however, other fibres, and these are both direct and crossed, which do not arborise around the tegmental nuclei, but pass into the lateral fillet. The cells of the accessory nucleus give origin to fibres which pass transversely in the pons and constitute the trapezium. Of the trapezoid fibres some terminate around the cells of the superior olive or of the *trapezoid nucleus* (which lies ventral to the olive) of the same or opposite side, while others, crossed or uncrossed, pass directly into the lateral fillet.

If the further connections of the cochlear nerve of one side, say the left, be considered, it is found that they lie to the outer side of the main sensory tract, the fillet, and are therefore termed the *lateral fillet*. The fibres comprising the

left lateral fillet arise in the superior olive and trapezoid nucleus of the same or opposite side, while others are the uninterrupted fibres already alluded to, and these are either crossed or uncrossed, the former being the axons of the cells of the right accessory nucleus or of the cells of the right tuberculum acusticum, while the latter are derived from the same cells of the left side. In the upper part of the lateral fillet there is a collection of nerve-cells, the *nucleus of the lateral fillet*, around the cells of which some of the fibres arborise and from the cells of which axons originate to continue upwards the tract of the lateral fillet. The ultimate ending of the left lateral fillet is partly in the opposite internal geniculate body, and partly in both inferior quadrigeminal bodies. From the cells of these bodies new fibres arise which ascend in the posterior limb of the internal capsule to reach the posterior three-fifths of the first left temporal convolution and the transverse temporal gyri of Heschl.

Fig. 782.—Terminal nuclei of the cochlear root of the auditory nerve, with their upper connections. (Schematic.) (Testut.)



The vestibular root with its terminal nuclei and their efferent fibres have been suppressed. On the other hand, in order not to obscure the trapezoid body, the efferent fibres of the terminal nuclei on the right side have been resected in a considerable portion of their extent. The trapezoid body, therefore, shows only one-half of its fibres, viz. those which come from the left.

1. Anterior or vestibular root of the auditory, divided at its entrance into the bulb. 2. Posterior or cochlear root. 3. Accessory nucleus of auditory nerve. 4. Tuberculum acusticum. 5. Efferent fibres of accessory nucleus. 6. Efferent fibres of tuberculum acusticum, forming the striæ acusticæ, with 6′, their direct bundle going to the superior olivary body of the same side; 6″. their decussating bundles going to the superior olivary body of the opposite side. 7. Superior olivary body. 8. Trapezoid body. 9. Trapezoid nucleus. 10. Central acoustic tract (lateral fillet). 11. Raphe. 12. Pyramidal tract. 13. Fourth ventricle. 14. Restiform body.

The auditory nerve contains a few efferent fibres which arise in the quadrigeminal bodies, the nucleus of the lateral fillet, the trapezoid nucleus, and superior olive.

The auditory nerve after leaving the medulla passes forwards across the posterior border of the middle peduncle of the cerebellum, in company with the facial nerve, from which it is partially separated by the auditory artery. It then enters the internal auditory meatus with the facial nerve. At the bottom of the meatus it receives one or two filaments from the facial nerve, and then divides into its two branches, *cochlear* and *vestibular*. The auditory nerve is soft in texture, and is destitute of neurilemma; its distribution will be described with the anatomy of the ear.

Applied Anatomy.—The auditory nerve is frequently injured, together with the facial nerve, in fractures of the middle fossa of the base of the skull implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, or it may be bruised or pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without any fracture of the bones of the skull taking place,

and deafness may arise from loud explosions from dynamite, &c., probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. 'Nerve deafness' as contrasted with deafness due to changes in the middle ear or meatus, is suggested if (1) a sounding tuning-fork placed on the middle line of the head is heard better (Weber's test) by the unaffected ear; or if (2) the sounding tuning-fork is heard longer when held before the affected ear (= air conduction) than when it is stood on the corresponding mastoid (= bone conduction, Rinne's test); or if (3) the sounding tuning-fork applied to the vertex or mastoid is heard less well when the air in the meatus is compressed by the use of a Siegle's speculum (Gellé's test); or if (4) the tuning-fork placed on the mastoid is heard for a shorter time than its sound is perceptible to a normal individual (= evidence that bone conduction is diminished, Schwabach's test). It must be remembered that all these tests are liable to anomalies and exceptions, and are no longer applicable to old people. If, however, concordant results are yielded by the tests of Weber, Rinne, and Gellé, Bezold's 'triad of symptoms,' nerve-deafness rather than deafness due to disease of the conducting structures is rendered highly probable.

Tinnitus aurium, or the hearing of sounds in the ear that have no objective cause outside the body, is said to be present in as many as sixty per cent. of cases of ear disease of all sorts, and is commonest in disease of the labyrinth or of the nerve. It is very variable in intensity; the worst forms are purely subjective and due to irritation of the nerve itself. The sounds heard are of the most varied nature—buzzing, hissing, whistling, rushing, bell-ringing, and so forth—and may occupy the patient's attention so completely that he is no longer able to attend to his business; he may even commit suicide in order to escape from them. In the insane, tinnitus is associated with delusions and hallucinations of hearing; cases of insanity have even been recorded in which cure was effected by the removal of cerumen impacted in the meatus and giving rise to persistent tinnitus.

Ninth Nerve (figs. 783, 784, 786)

The **Ninth** or **Glosso-pharyngeal nerve** (n. glossopharyngeus) contains both motor and sensory fibres, and is distributed, as its name implies, to the tongue and pharynx. It is the nerve of ordinary sensation to the mucous membrane of the pharynx, fauces and tonsil, and the nerve of taste to the parts of the tongue to which it is distributed.

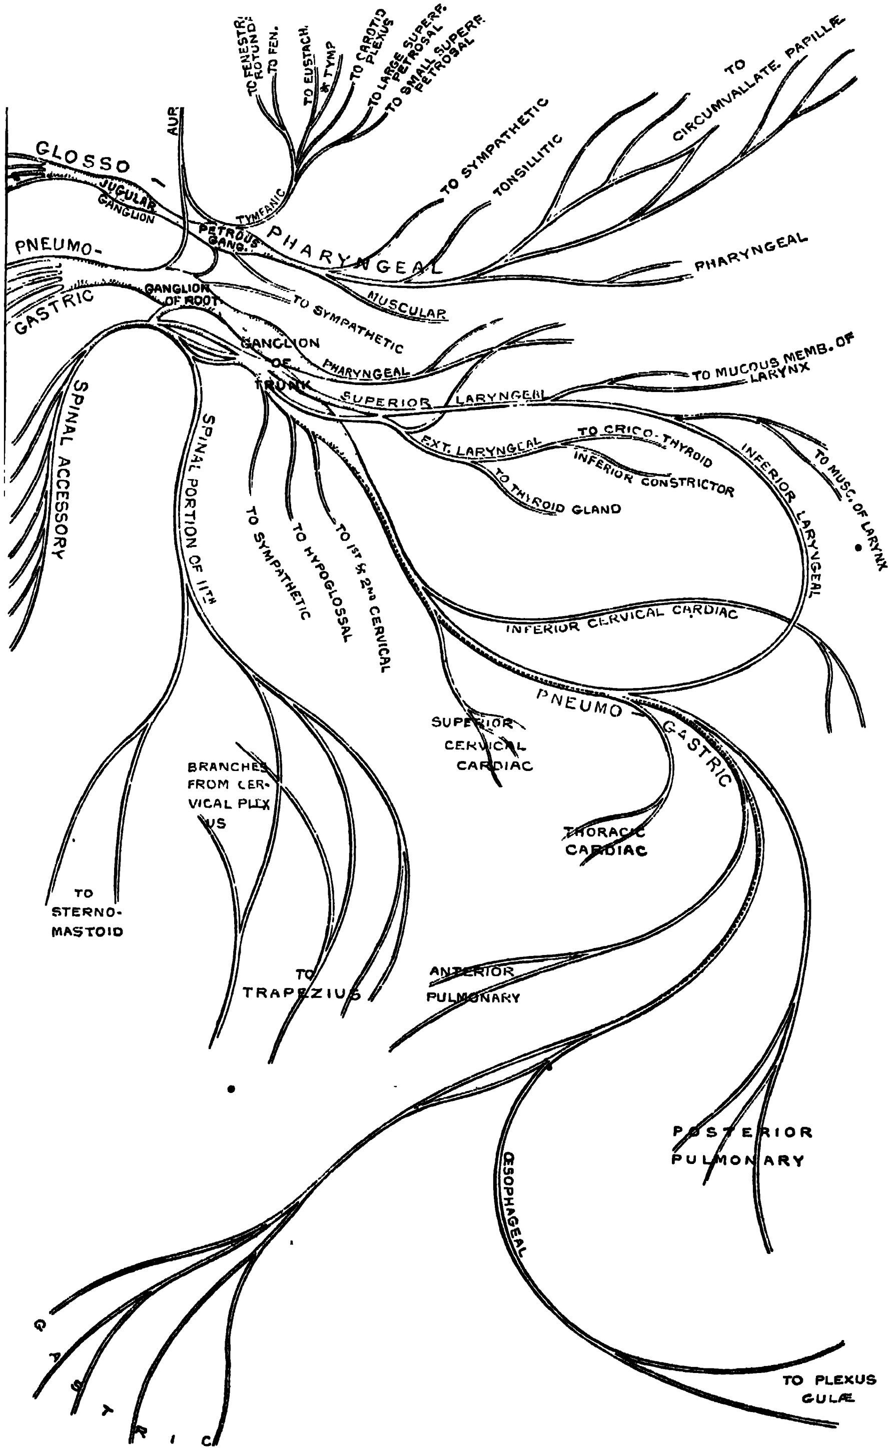
Its *superficial origin* is by three or four filaments, closely connected together, from the upper part of the medulla oblongata, in the groove between the olivary and restiform bodies.

The *sensory* fibres arise from the cells of the jugular and petrous ganglia, which are situated on the trunk of the nerve, and will be presently described. When traced into the medulla, some of the sensory fibres terminate by arborising around the cells of the upper part of a nucleus which lies beneath the ala cinerea in the lower part of the floor of the fourth ventricle. Many of the fibres, however, contribute to form a strand, named the *fasciculus solitarius*, which descends in the medulla. Associated with this strand are numerous nerve-cells, around which the fibres of the fasciculus terminate.

The *motor* fibres take origin from the cells of the *nucleus ambiguus*, which lies some distance from the lower part of the floor of the fourth ventricle in the lateral area of the medulla and is continuous below with the anterior grey cornu of the spinal cord. From this nucleus the fibres are first directed backwards, and then they bend forwards and outwards to join the fibres of the sensory root. The nucleus ambiguus gives origin to the motor branches of the glosso-pharyngeal and vagus, and to the bulbar part of the spinal accessory.

From its superficial origin, the glosso-pharyngeal nerve passes outwards across the flocculus, and leaves the skull at the central part of the jugular foramen, in a separate sheath of the dura mater, external to and in front of the pneumogastric and spinal accessory nerves (fig. 636). In its passage through the jugular foramen, it grooves the lower border of the petrous portion of the temporal bone; and, at its exit from the skull, passes forwards between the jugular vein and internal carotid artery; it descends in front of the latter vessel, and beneath the styloid process and the muscles connected with it, to the lower border of the Stylo-pharyngeus. The nerve now curves inwards, forming an arch on the side of the neck and lying upon the Stylo-pharyngeus and Middle constrictor of the pharynx. It then passes under cover of the Hyo-glossus, and is finally distributed to the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth and tonsil.

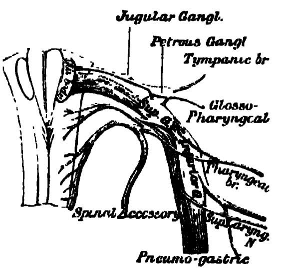
Fig. 783.—Plan of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. (After Flower.)



In passing through the jugular foramen, the nerve presents, in succession, two gangliform enlargements (fig. 784). The superior, the smaller, is called the *jugular ganglion*; the inferior and larger, the *petrous ganglion*, or the *ganglion of Andersch.*

The **jugular ganglion** (ganglion superius) is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is of very small size, and involves only part of the trunk of the nerve. It is usually regarded as a detached portion of the lower ganglion.

FIG. 784.—Origins, ganglia, and communications of the ninth, tenth, and eleventh cranial nerves.



The **petrous ganglion** (ganglion petrosum) is situated in a depression in the lower border of the petrous portion of the temporal bone; it is larger than the superior, and involves the whole of the fibres of the nerve. From this ganglion arise those filaments which connect the glosso-pharyngeal with the pneumogastric and sympathetic nerves.

Branches of communication.—The glosso-pharyngeal nerve communicates with the pneumogastric, sympathetic, and facial.

The branches to the pneumogastric are two filaments which arise from the petrous ganglion, one passing to the auricular branch, and the other to the upper ganglion, of the pneumogastric. The petrous ganglion is connected by a filament with the superior cervical ganglion of the sympathetic.

The branch of communication with the facial perforates the posterior belly of the Digastric. It arises from the trunk of the glosso-pharyngeal below the petrous ganglion, and joins the facial just after the exit of that nerve from the stylo-mastoid foramen.

Branches of distribution.—The branches of distribution of the glosso-pharyngeal are, the tympanic, carotid, pharyngeal, muscular, tonsillar, and lingual.

The **tympanic branch** (Jacobson's nerve, n. tympanicus) arises from the petrous ganglion, and enters a small canal on the under surface of the petrous portion of the temporal bone on the bony ridge which separates the carotid canal from the jugular fossa. It ascends to the tympanum, which it enters by an aperture in the floor of that cavity close to the inner wall, and divides into branches. These form the *plexus tympanicus* and are contained in grooves upon the surface of the promontory. This plexus gives off: (1) the small superficial petrosal nerve; (2) a branch to join the great superficial petrosal nerve; and (3) branches to the tympanic cavity, all of which will be described in connection with the anatomy of the ear.

The **carotid branches** descend along the trunk of the internal carotid artery as far as its commencement, communicating with the pharyngeal branch of the pneumogastric, and with branches of the sympathetic.

The **pharyngeal branches** (rami pharyngei) are three or four filaments which unite, opposite the Middle constrictor of the pharynx, with the pharyngeal branches of the pneumogastric and sympathetic nerves, to form the pharyngeal plexus; branches from this plexus perforate the muscular coat of the pharynx and supply its muscles and mucous membrane.

The **muscular branch** is distributed to the Stylo-pharyngeus.

The **tonsillar branches** (rami tonsillares) supply the tonsil, forming around this body a plexus (*circulus tonsillaris*) from which filaments are distributed to the soft palate and fauces, where they communicate with the palatine nerves.

The **lingual branches** (rami linguales) are two in number: one supplies the circumvallate papillæ and the mucous membrane covering the surface of the base of the tongue; the other perforates the substance, and supplies the mucous membrane and follicular glands of the posterior part of the tongue, and communicates with the lingual nerve.

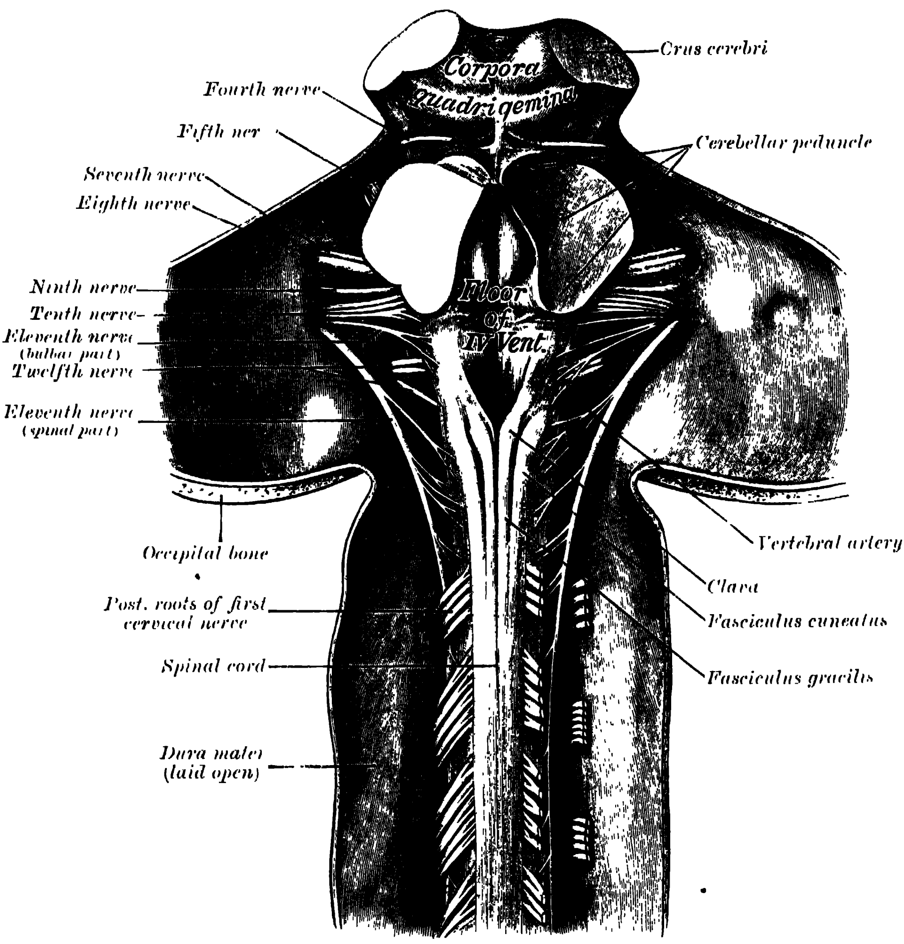
Applied Anatomy.—The exact anatomy of this nerve is still doubtful, and disease in it alone cannot usually be diagnosed.

TENTH NERVE (figs. 783, 785, 786)

The **Tenth** or **Pneumogastric nerve** (n. vagus) has a more extensive distribution than any of the other cranial nerves, since it passes through the neck and thorax to the upper part of the abdomen. It is composed of both motor and sensory fibres. It supplies the organs of voice and respiration with motor and sensory fibres; and the pharynx, œsophagus, stomach, and heart with motor fibres.

The *superficial origin* of the pneumogastric nerve is by eight or ten filaments from the groove between the olivary and restiform bodies, below the glosso-pharyngeal. The *sensory* fibres arise from the cells of the ganglion of the root and the ganglion of the trunk of the nerve, and, when traced into the medulla,

FIG. 785.—Mid- and hind-brains and upper part of spinal cord exposed from behind.

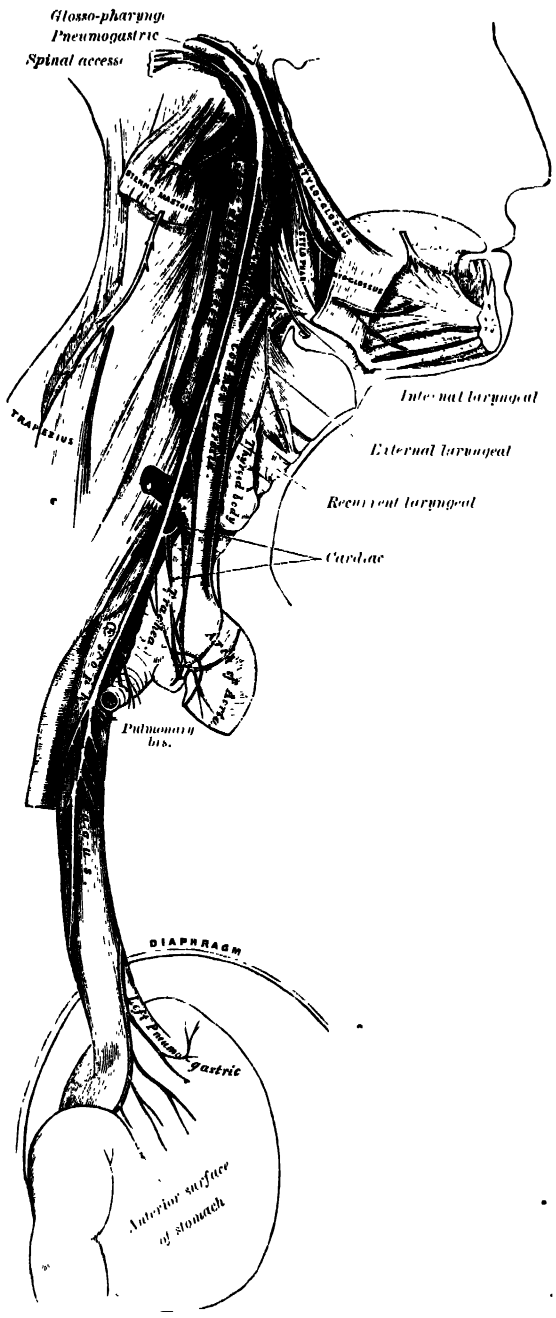


mostly terminate by arborising around the cells of the inferior part of the nucleus which lies beneath the ala cinerea in the lower part of the floor of the fourth ventricle. Some of the sensory fibres of the glosso-pharyngeal nerve have been seen to terminate in the upper part of this nucleus. A few of the sensory fibres of the vagus descend in the fasciculus solitarius and terminate around its cells. The *motor* fibres arise from the cells of the nucleus ambiguus, already referred to in connection with the motor root of the glosso-pharyngeal nerve.

The filaments become united, and form a flat cord, which passes outwards beneath the flocculus to the jugular foramen, through which it emerges from the cranium. In passing through this opening, the pneumogastric is

accompanied by the spinal accessory, and is contained in the same sheath of dura mater with it, a membranous septum separating them from the glosso-pharyngeal which lies in front (fig. 636). The nerve in this situation presents a well-marked ganglionic enlargement, which is called the *ganglion of the root* (ganglion jugulare); to it the accessory part of the spinal accessory nerve is connected by one or two filaments. After its exit from the jugular foramen the nerve is joined by the accessory portion of the spinal accessory, and enlarges into a second gangliform swelling, called the *ganglion of the trunk* (ganglion nodosum); through this the fibres of the accessory portion of the spinal accessory pass unchanged, being principally distributed to the pharyngeal and superior laryngeal branches of the vagus, but some of the filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve and probably also with the cardiac nerves. The vagus nerve passes vertically down the neck within the carotid sheath, lying between the internal carotid artery and internal jugular vein as far as the thyroid cartilage, and then between the same vein and the common carotid artery to the root of the neck. From this downwards, the course of the nerve differs on the two sides of the body.

FIG. 786.—Course and distribution of the ninth, tenth, and eleventh cranial nerves.



On the *right side*, the nerve passes across the subclavian artery between it and the right innominate vein, and descends by the side of the trachea to the back part of the root of the lung, where it spreads out in a plexiform network (*posterior pulmonary plexus*). From the lower part of this two cords descend on the œsophagus, and divide to form, with branches from the opposite nerve, the œsophageal plexus (*plexus gulæ*). Below, these branches are collected into a single cord, which runs along the back part of the œsophagus, enters the abdomen, and is distributed to the posterior surface of the stomach,

joining the left side of the solar plexus, and sending filaments to the splenic plexus and a considerable branch to the cœliac plexus.

On the *left side*, the pneumogastric nerve enters the chest between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the arch of the aorta, and descends behind the root of the left lung, forming the *posterior pulmonary plexus*. From this it runs along the anterior surface of the œsophagus, where it unites with the nerve of the right side in forming the *plexus gulæ*, and is continued to the stomach, distributing branches over its anterior surface; some of these extend over the fundus, and others along the lesser curvature. Filaments from these branches enter the gastro-hepatic omentum, and join the hepatic plexus.

The **ganglion ~~of the root~~** is of a greyish colour, spherical in form, about one sixth of an inch in diameter.

Branches of communication.—To this ganglion the accessory portion of the spinal accessory nerve is connected by several delicate filaments; it also communicates by a twig with the petrous ganglion of the glosso-pharyngeal, with the facial nerve by means of its auricular branch, and with the sympathetic by means of an ascending filament from the superior cervical ganglion.

The **ganglion of the trunk** is a plexiform cord, cylindrical in form, of a reddish colour, and about an inch in length; it involves the whole of the fibres of the nerve. Passing through it is the accessory portion of the spinal accessory nerve, which blends with the pneumogastric below the ganglion.

Branches of communication.—This ganglion is connected with the hypoglossal, the superior cervical ganglion of the sympathetic, and the loop between the first and second cervical nerves.

Branches of distribution.—The branches of the pneumogastric are:

In the jugular fossa	Meningeal. Auricular.
In the neck	Pharyngeal. Superior laryngeal. Recurrent laryngeal. Cervical cardiac.
In the thorax	Thoracic cardiac. Anterior pulmonary. Posterior pulmonary. Œsophageal.
In the abdomen	Gastric.

The **meningeal branch** (ramus meningeus) is a recurrent filament given off from the ganglion of the root in the jugular foramen. It passes backwards, through the jugular foramen, and is distributed to the dura mater covering the posterior fossa of the base of the skull.

The **auricular branch** (ramus auricularis), or nerve of Arnold, arises from the ganglion of the root, and is joined soon after its origin by a filament from the petrous ganglion of the glosso-pharyngeal; it passes outwards behind the ~~jugular vein~~, and enters a small canal on the outer wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the aqueductus Fallopii about one-sixth of an inch above the stylo-mastoid foramen, and here it gives off an ascending branch which joins the facial. The continuation of the nerve reaches the surface by passing through the auricular fissure between the mastoid process and the tympanic plate, and divides into two branches, one of which communicates with the posterior auricular nerve, while the other supplies the integument at the back part of the pinna and the posterior part of the external auditory meatus.

The **pharyngeal branch** (ramus pharyngeus), the principal motor nerve of the pharynx, arises from the upper part of the ganglion of the trunk. It consists principally of filaments from the accessory portion of the spinal accessory; it passes across the internal carotid artery to the upper border of ~~the Middle~~ constrictor, where it divides into numerous filaments, which join with those from the glosso-pharyngeal, sympathetic, and external laryngeal to form the *pharyngeal plexus*. From the plexus, branches are distributed to

the muscles and mucous membrane of the pharynx and the muscles of the soft palate, except the Tensor palati. A minute filament descends and joins the hypoglossal nerve as it winds round the occipital artery.

The **superior laryngeal nerve** (n. laryngeus superior) is larger than the preceding, and arises from the middle of the ganglion of the trunk. In its course it receives a branch from the superior cervical ganglion of the sympathetic. It descends, by the side of the pharynx, behind the internal carotid artery, and divides into two branches, the external and internal laryngeal.

The *external laryngeal branch* (ramus externus), the smaller, descends on the larynx, beneath the Sterno-thyroid, to supply the Crico-thyroid muscle. It gives branches to the pharyngeal plexus and the Inferior constrictor, and communicates with the superior cardiac nerve, behind the common carotid artery.

The *internal laryngeal branch* (ramus internus) descends to the thyro-hyoid membrane, pierces it in company with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. A small branch communicates with the recurrent laryngeal nerve. Of the branches to the mucous membrane some are distributed to the epiglottis, the base of the tongue, and the epiglottic glands; while others pass backwards, in the aryteno-epiglottic fold, to supply the mucous membrane surrounding the superior orifice of the larynx, and that lining the cavity of the larynx as low down as the vocal cord. The filament which joins with the recurrent laryngeal descends beneath the mucous membrane on the inner surface of the thyroid cartilage, where the two nerves become united.

The **inferior or recurrent laryngeal nerve** (n. recurrens), so called from its reflected course, is the motor nerve of the larynx. It arises, on the *right* side, in front of the subclavian artery; winds from before backwards round that vessel, and ascends obliquely to the side of the trachea behind the common carotid, and either in front of or behind the inferior thyroid artery. On the *left* side, it arises in front of the arch of the aorta, and winds from before backwards below the aorta at the point where the obliterated ductus arteriosus is attached, and then ascends to the side of the trachea. The nerve on either side ascends in the groove between the trachea and œsophagus, passes under the lower border of the Inferior constrictor muscle to enter the larynx behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid, and is distributed to all the muscles of the larynx, excepting the Crico-thyroid. It communicates with the superior laryngeal nerve, and gives off a few filaments to the mucous membrane of the lower part of the larynx.

The recurrent laryngeal, as it hooks round the subclavian artery or aorta, gives off several cardiac filaments, which unite with the cardiac branches from the pneumogastric and sympathetic. As it ascends in the neck it gives off œsophageal branches, more numerous on the left than on the right side, which supply the mucous membrane and muscular coat of the œsophagus; tracheal branches to the mucous membrane and muscular fibres of the trachea; and some pharyngeal filaments to the Inferior constrictor of the pharynx.

The **cervical cardiac branches** (rami cardiaci superiores), two or three in number, arise from the pneumogastric, at the upper and lower parts of the neck.

The *superior branches* are small, and communicate with the cardiac branches of the sympathetic. They can be traced to the great or deep cardiac plexus.

The *inferior branch* arises at the lower part of the neck, just above the first rib. That from the right vagus passes in front or by the side of the innominate artery, and communicates with one of the cardiac nerves proceeding to the great or deep cardiac plexus; that from the left runs down across the left side of the arch of the aorta, and joins the superficial cardiac plexus.

The **thoracic cardiac branches** (rami cardiaci inferiores), on the right side, arise from the trunk of the pneumogastric as it lies by the side of the trachea, and from its recurrent laryngeal branch; but on the left side from the recurrent nerve only; passing inwards, they end in the deep cardiac plexus.

The **anterior pulmonary branches** (rami bronchiales anteriores), two or three in number, and of small size, are distributed on the anterior surface of the root of the lung. They join with filaments from the sympathetic, and form the *anterior pulmonary plexus* (plexus pulmonalis anterior).

The posterior pulmonary branches (rami bronchiales posteriores), more numerous and larger than the anterior, are distributed on the posterior surface of the root of the lung; they are joined by filaments from the third and fourth (sometimes also from the first and second) thoracic ganglia of the sympathetic, and form the *posterior pulmonary plexus* (plexus pulmonalis posterior). Branches from this plexus accompany the ramifications of the bronchi through the substance of the lung.

The **œsophageal branches** (rami œsophagei) are given off from the pneumogastric both above and below the pulmonary branches. The lower are more numerous and larger than the upper. They form, together with branches from the opposite nerve, the *œsophageal plexus*. From this plexus filaments are distributed to the back of the pericardium.

The **gastric branches** (rami gastrici) are the terminal filaments of the pneumogastric nerve. The nerve on the right side is distributed to the posterior surface of the stomach, and joins the left side of the cœliac plexus and the splenic plexus. The nerve on the left side is distributed over the anterior surface of the stomach, and along the lesser curvature. It unites with branches of the right nerve and with the sympathetic, some filaments passing through the lesser omentum to the hepatic plexus.

Applied Anatomy.—The trunk of the pneumogastric is rarely injured, but the functions of the nerve may be interfered with by damage to its nucleus of origin in the medulla; by thickening or growth from the meninges or bones, or aneurysm of the basilar artery, before its exit from the skull, injuries such as gunshot or punctured wounds in the neck, or injuries during such operations as ligature of the carotid artery, removal of tuberculous glands or other deep-seated tumours. The pneumogastric may also be compressed by aneurysms of the carotid artery, and its deep origin becomes affected in bulbar paralysis. The symptoms produced by paralysis of the nerve are palpitation, with increased frequency of the pulse, constant vomiting, slowing of the respiration, and a sensation of suffocation.

'Reflexes' on the branches of the vagus are not at all uncommonly met with. The 'ear cough' is perhaps one of the commonest, where a plug of wax in the auditory meatus may by irritating the filaments of Arnold's nerve be responsible for a persistent cough. Syringing the external auditory meatus frequently produces cough, and, in children, vomiting is not uncommon as the result of such a procedure; moreover, in people with weak hearts, syringing the ear has been responsible for a sudden fatal syncope, by reflex irritation of the cardiac branches. Another very common example is the persistent cough which is frequently due to enlarged bronchial glands in children, the irritation of which is referred to the superior laryngeal filaments.

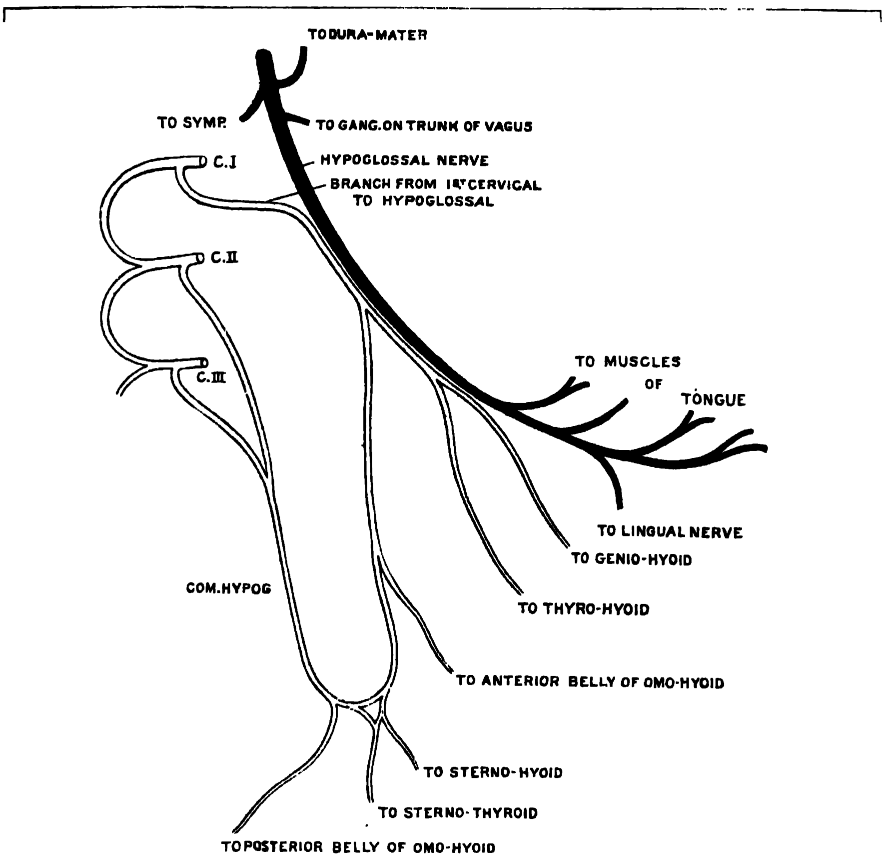
The anatomy of the laryngeal nerves is of considerable importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, reflex spasm of the glottis is the result. When its trunk is pressed upon by, for instance, a goitre or an aneurysm of the upper part of the carotid, there is a peculiar dry, brassy cough. When the nerve is paralysed, there is anæsthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, as the nerve also supplies the cricothyroid muscle, the vocal cords cannot be made tense, and the voice is deep and hoarse. Paralysis may be the result of bulbar paralysis; may be a sequel to diphtheria, when both nerves are usually involved; or it may, though less commonly, be caused by the pressure of tumours or aneurysms, when the paralysis is generally unilateral. Irritation of the recurrent or inferior laryngeal nerves produces spasm of the muscles of the larynx. When both these recurrent nerves are paralysed, the vocal cords are motionless, in the so-called 'cadaveric position'—that is to say, in the position in which they are found in ordinary tranquil respiration; neither closed as in phonation, nor open as in deep inspiratory efforts. When one recurrent nerve is paralysed, the cord of the same side is motionless, while the opposite one crosses the middle line to accommodate itself to the affected one; hence phonation is present, but the voice is altered and weak in timbre. The nerves may be paralysed in bulbar paralysis or after diphtheria, when the paralysis usually affects both sides; or they may be affected by the pressure of aneurysms of the aorta, innominate, or subclavian arteries; by mediastinal tumours; by gummata; or by cancer of the upper part of the œsophagus, when the paralysis is often unilateral. Paralysis of the adductor muscles of the larynx on both sides is quite common, and is usually functional in nature. The voice is reduced to a whisper, but the power of coughing is preserved.

Eleventh Nerve (figs. 783, 785, 786)

The **Eleventh or Spinal Accessory nerve** (n. accessorius) consists of two parts: one, the accessory part to the vagus, and the other the spinal portion.

The **bulbar or accessory part** is the smaller of the two. Its fibres arise from the cells of the *nucleus ambiguus* and emerge as four or five delicate filaments from the side of the medulla, below the roots of the vagus. It passes outwards to the jugular foramen, where it interchanges fibres with the spinal portion or becomes united to it for a short distance; it is also connected, in the foramen, with the ganglion of the root of the vagus by one or two filaments. It then passes through the foramen, and becoming again separated from the spinal portion it is continued over the surface of the ganglion of the trunk of the vagus, being adherent to its surface, and is distributed principally to the pharyngeal and superior laryngeal branches of the pneumogastric. Through the pharyngeal branch it probably supplies the Azygos uvulæ and Levator palati muscles (see page 486). Some few filaments from it are continued into the trunk of the vagus

Fig. 787.– Plan of the hypoglossal nerve.



below the ganglion, to be distributed with the recurrent laryngeal nerve and probably also with the cardiac nerves.

The **spinal portion** is firm in texture, and its fibres arise from the motor cells in the outer part of the anterior horn of the grey matter of the spinal cord as low as the fifth cervical nerve. Passing outwards and backwards through the lateral white column of the cord, they emerge on its surface and unite to form a single trunk, which ascends between the ligamentum denticulatum and the posterior roots of the spinal nerves, enters the skull through the foramen magnum, and is then directed outwards to the jugular foramen, through which it passes, lying in the same sheath of dura mater as the pneumogastric, but separated from it by a fold of the arachnoid. In the jugular foramen, it receives one or two filaments from the accessory portion, or else joins it for a short distance and then separates from it again. At its exit from the jugular

foramen, it runs backwards, either in front of or behind the internal jugular vein, and descends obliquely behind the Digastric and Stylo-hyoid muscles to the upper part of the Sterno-mastoid. It pierces this muscle, and passes obliquely across the posterior triangle, to terminate in the deep surface of the Trapezius. During its passage through the Sterno-mastoid it gives several branches to the muscle, and joins in its substance with branches from the second cervical. In the posterior triangle it joins with the second and third cervical nerves, while beneath the Trapezius it forms a plexus with the third and fourth cervical nerves, and from this plexus fibres are distributed to the muscle.

Applied Anatomy.—The functions of the spinal accessory nerve may be interfered with either by central changes; or at its exit from the skull, by fractures running across the jugular foramen; or in the neck, by inflamed lymphatic glands, &c. The acute wry neck in children is most commonly due to inflamed or suppurating glands, and rapidly subsides with appropriate treatment. Central irritation causes clonic spasm of the Sterno-mastoid and Trapezius muscles, or, as it is termed, spasmodic torticollis. In cases of this affection in which all previous palliative treatment has failed, and the spasms are so severe as to undermine the patient's health, division or excision of a portion of the spinal accessory nerve has been resorted to. This must be done from the anterior border of the Sterno-mastoid muscle. The operation consists in making an incision, three inches in length, from the apex of the mastoid process along the anterior border of the muscle, which is defined and pulled backwards, so as to stretch the nerve, which is then to be sought for beneath the Digastric muscle, about two inches below the apex of the mastoid process. Unfortunately, the operation does not yield a satisfactory or permanent cure, as the spasms tend to recur after an interval, either in the same muscles or in other groups of neck muscles.

In cases where extensive dissections are undertaken for enlarged glands in the posterior triangle of the neck, it is essential that this nerve should be at once sought for and isolated from the mass of inflamed glands so as to maintain its continuity, as otherwise it would be very liable to be divided, with resulting paralysis of the Trapezius.

Twelfth Nerve (figs. 785, 787, 788)

The **Twelfth** or **Hypoglossal nerve** (n. hypoglossus) is the motor nerve of the tongue.

Its fibres arise from the cells of the *hypoglossal nucleus*, which is an upward prolongation of the base of the anterior horn of grey matter of the cord. This nucleus is about three-quarters of an inch in length, and its upper part corresponds with the *trigonum hypoglossi*, which is situated close to the middle line in the lower half of the floor of the fourth ventricle. The lower part of the nucleus extends downwards into the closed part of the medulla, and there lies in relation to the ventro-lateral aspect of the central canal. The fibres run forwards through the entire thickness of the medulla, between its anterior and lateral areas, and emerge in the pre-olivary sulcus between the pyramid and the olivary body.

The filaments of this nerve are collected into two bundles, which perforate the dura mater separately, opposite the anterior condyloid foramen, and unite together after their passage through it. In those cases in which the anterior condyloid foramen in the occipital bone is double, these two portions of the nerve are separated by the small piece of bone which divides the foramen. The nerve descends almost vertically to a point corresponding with the angle of the jaw. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and intimately connected with the pneumogastric nerve; it then passes forwards between the vein and artery, and lower down in the neck becomes superficial below the Digastric muscle. The nerve then loops round the occipital artery, and crosses the external carotid and lingual below the tendon of the Digastric. It passes beneath the tendon of the Digastric, the Stylo-hyoid, and the Mylo-hyoid muscles, lying between the last-named muscle and the Hyo-glossus, and communicates at the anterior border of the Hyo-glossus with the lingual nerve; it is then continued forwards in the fibres of the Genio-hyo-glossus muscle as far as the tip of the tongue, distributing branches to its muscular substance.

Branches of communication.—The branches of communication are, with the

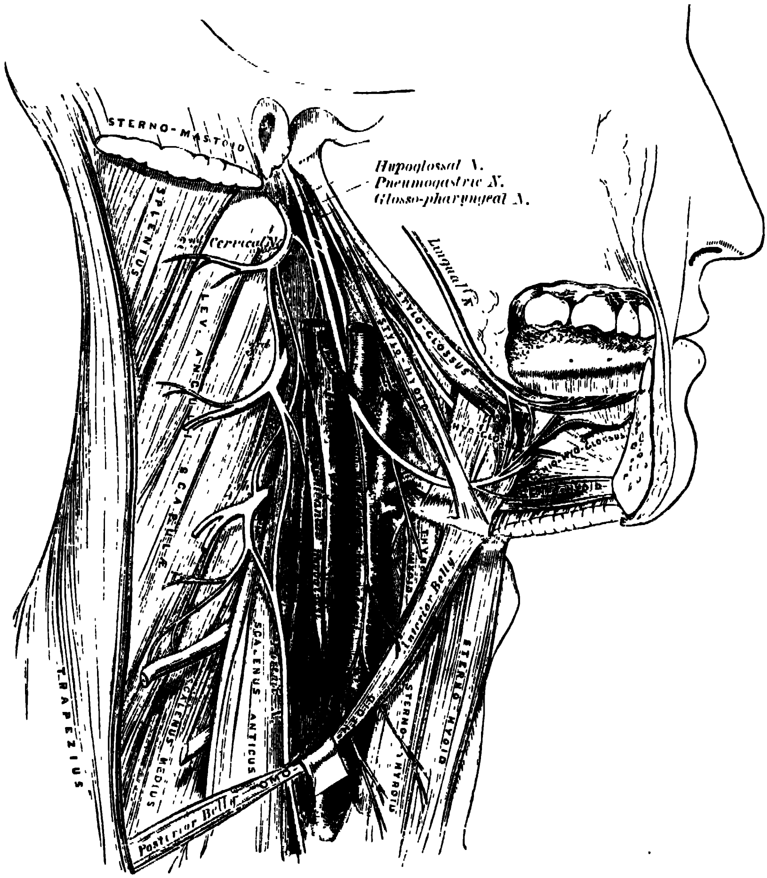
Pneumogastric.	First and second cervical nerves.
Sympathetic.	Lingual.

The communication with the pneumogastric takes place close to the exit of the nerve from the skull, numerous filaments passing between the hypoglossal and the ganglion of the trunk of the pneumogastric through the mass of connective tissue which unites the two nerves. It also communicates with the pharyngeal plexus by a minute filament as it winds round the occipital artery.

The communication with the sympathetic takes place opposite the atlas by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by a filament derived from the loop connecting the first two cervical nerves.

The communication with the lingual takes place near the anterior border of the Hyo-glossus muscle by numerous filaments which ascend upon it.

FIG. 788.—Hypoglossal nerve, cervical plexus, and their branches.



Branches of distribution.—The branches of distribution are, the

Meningeal.	Thyro-hyoid.
Descendens hypoglossi.	Muscular.

Of these branches, the meningeal, descendens hypoglossi, thyro-hyoid, and the muscular branch to the Genio-hyoid, are probably derived mainly from the branch which passes from the loop between the first and second cervical to join the hypoglossal (fig. 787).

Meningeal branches.—As the hypoglossal nerve passes through the anterior condyloid foramen it gives off, according to Luschka, several filaments to the dura mater in the posterior fossa of the base of the skull.

The descendens hypoglossi (ramus descendens) is a long slender branch, which quits the hypoglossal where it turns round the occipital artery. It

descends in front of the sheath of the carotid vessels, giving off a branch to the anterior belly of the Omo-hyoid, and then joins the descendens cervicis (ramus communicans hypoglossi) from the second and third cervical nerves, just below the middle of the neck, to form a loop, the *ansa hypoglossi*. From the convexity of this loop branches pass to supply the Sterno-hyoid, the Sterno-thyroid, and the posterior belly of the Omo-hyoid. According to Arnold, another filament descends in front of the vessels into the chest, and joins the cardiac and phrenic nerves.

The **thyro-hyoid branch** (ramus thyreohyoideus) arises from the hypoglossal near the posterior border of the Hyo-glossus; it runs obliquely across the great cornu of the hyoid bone, and supplies the Thyro-hyoid muscle.

The **muscular branches** are distributed to the Stylo-glossus, Hyo-glossus, Genio-hyoid, and Genio-hyo-glossus muscles. At the under surface of the tongue numerous slender branches pass upwards into the substance of the organ to supply its intrinsic muscles.

Applied Anatomy.—The hypoglossal nerve is an important guide in the operation of ligature of the lingual artery (see page 631). It runs forwards on the Hyo-glossus just above the great cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought for by cutting through the fibres of the Hyo-glossus. In cases where it has been injured on one side of the neck, or in some cases of bulbar paralysis, unilateral paralysis, together with hemiatrophy of the tongue, is the result; the tongue, when protruded, being directed to the paralysed side owing to the unopposed action of the Genio-hyo-glossus of the opposite side. On retraction, the wasted and paralysed side of the tongue rises up higher than the other. The larynx may deviate towards the sound side on swallowing, from the unilateral paralysis of the depressors of the hyoid bone. If the paralysis is bilateral, the tongue lies motionless in the mouth, while articulation and mastication are much interfered with.

THE SPINAL NERVES (NERVI SPINALES)

The **spinal nerves** spring from the spinal cord, and are transmitted through the intervertebral foramina. They number thirty-one pairs, which are grouped as follows:

Cervical, 8;
Thoracic, 12;
Lumbar, 5;
Sacral, 5;
Coccygeal, 1.

The *first cervical nerve* emerges from the vertebral canal between the occipital bone and the atlas, and is therefore called the *suboccipital nerve* (n. suboccipitalis): the eighth issues between the seventh cervical and first thoracic vertebræ.

Nerve roots.—Each nerve is attached to the spinal cord by two roots, an anterior or ventral, and a posterior or dorsal, the latter being characterised by the presence of a ganglion, the *spinal ganglion*.

The **anterior root** (radix anterior) emerges from the anterior surface of the cord as a number of rootlets or fasciculi (fila radicularia), which coalesce to form two bundles near the intervertebral foramen.

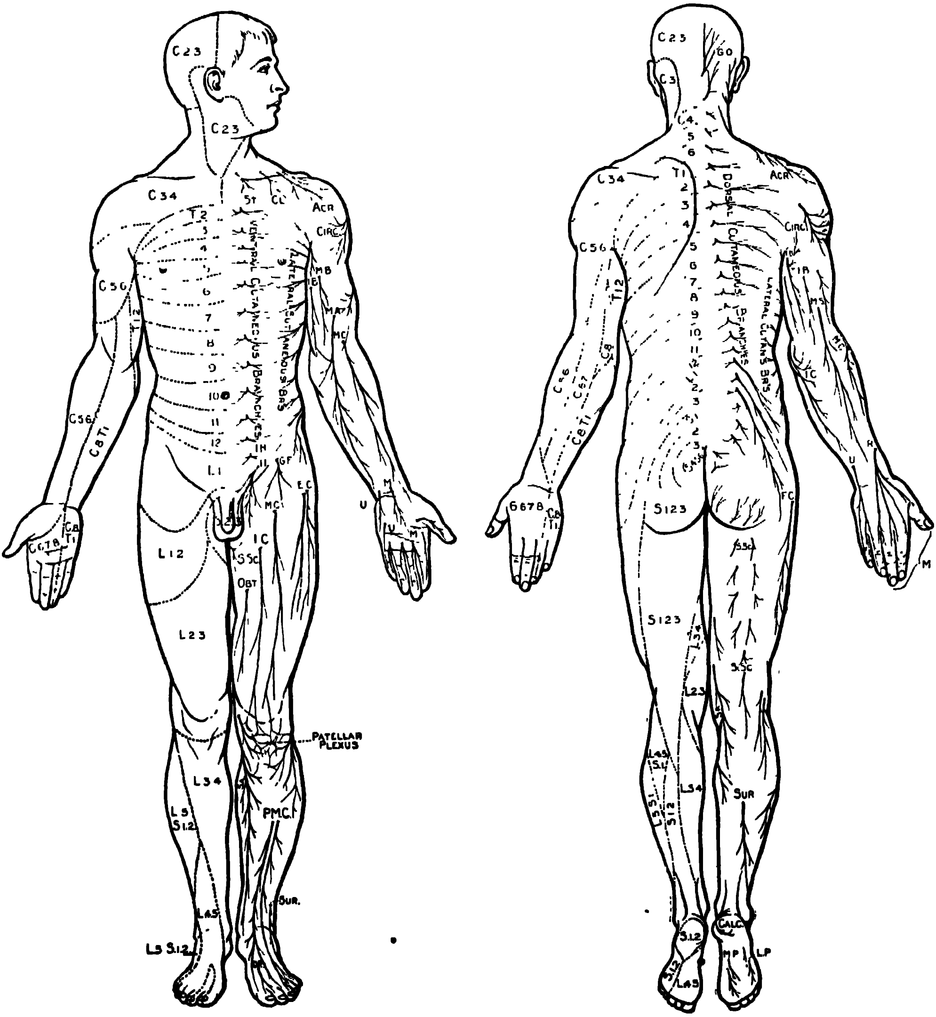
The **posterior root** (radix posterior) is larger than the anterior owing to the greater size and number of its fasciculi; these are attached along the postero-lateral furrow of the spinal cord and unite to form two bundles which join the spinal ganglion. The posterior root of the first cervical nerve is exceptional in that it is smaller than the anterior; it is occasionally wanting.

The **spinal ganglia** (ganglia spinalia) are collections of nerve cells on the posterior roots of the spinal nerves. Each ganglion is oval in shape, reddish in colour, and its size bears a proportion to that of the nerve root on which it is situated; it is bifid internally where it is joined by the two bundles of the posterior nerve root. The ganglia are usually placed in the intervertebral foramina, immediately outside the points where the nerve roots perforate the dura mater, but there are exceptions to this rule; thus the ganglia of the first and second cervical nerves lie on the neural arches of the atlas and axis respectively, those of the sacral nerves are inside the vertebral canal, while

that on the posterior root of the coccygeal nerve is placed within the sheath of dura mater.

Structure.—The ganglia consist chiefly of unipolar nerve cells, and from these the fibres of the posterior root take origin—the single process of each cell dividing after a short course into a central fibre which enters the spinal cord and a peripheral fibre which runs outwards into the spinal nerve. Two other forms of cells are, however, present, viz.: (*a*) the cells of Dogiel, whose axons

FIG. 789.—Distribution of cutaneous nerves.



Ventral aspect *Dorsal aspect*

ramify close to the cell (type II. of Golgi), and are distributed entirely within the ganglion; and (*b*) multipolar cells similar to those found in the sympathetic ganglia.

The ganglion of the first cervical nerve may be absent, while small *aberrant ganglia* consisting of groups of nerve cells are sometimes found on the posterior roots between the spinal ganglia and the cord.

Each nerve root receives a covering from the pia mater, and is loosely invested by the arachnoid membrane, the latter being prolonged as far as the points where the roots pierce the dura mater. The two roots pierce the dura mater separately, each receiving a sheath from this membrane; where the

roots join to form the spinal nerve this sheath is continuous with the epineurium of the nerve.

Size and direction.—The roots of the upper four *cervical* nerves are small, those of the lower four are large. The posterior roots of the cervical nerves bear a proportion to the anterior of three to one, which is greater than in the other regions; their individual filaments are also larger than those of the anterior roots. The posterior root of the first cervical is an exception to this rule, being smaller than the anterior root; in eight per cent. of cases it is wanting. The roots of the first and second cervical nerves are short, and run nearly horizontally outwards to their points of exit from the vertebral canal. From the second to the eighth cervical they are directed obliquely downwards and outwards, the obliquity and length of the roots successively increasing; the distance, however, between the level of attachment of any of these roots to the cord and the points of exit of the corresponding nerves never exceeds the depth of one vertebra.

The roots of the *thoracic* nerves, with the exception of the first, are of small size, and the posterior only slightly exceed the anterior in thickness. They increase successively in length, from above downwards, and in the lower part of the thoracic region descend in contact with the cord for a distance equal to the height of at least two vertebræ before they emerge from the vertebral canal.

The roots of the lower *lumbar* and upper *sacral* nerves are the largest, and their individual filaments the most numerous of all the spinal nerves, while the roots of the *coccygeal* nerve are the smallest.

The roots of the lumbar, sacral, and coccygeal nerves run vertically downwards to their respective exits, and as the spinal cord ends near the lower border of the first lumbar vertebra it follows that the length of the successive roots must rapidly increase. As already mentioned (page 797), the term *cauda equina* is applied to this collection of nerve roots.

From the description given it will be seen that the largest nerve roots, and consequently the largest spinal nerves, are attached to the cervical and lumbar swellings of the cord; these nerves are distributed to the upper and lower limbs.

Points of emergence.—The following table, after Macalister, shows the relations which the places of attachment of the nerves to the cord present to the bodies and spinous processes of the vertebræ:

Level of body of	No. of Nerve	Level of tip of spine of	Level of body of	No. of Nerve	Level of tip of spine of

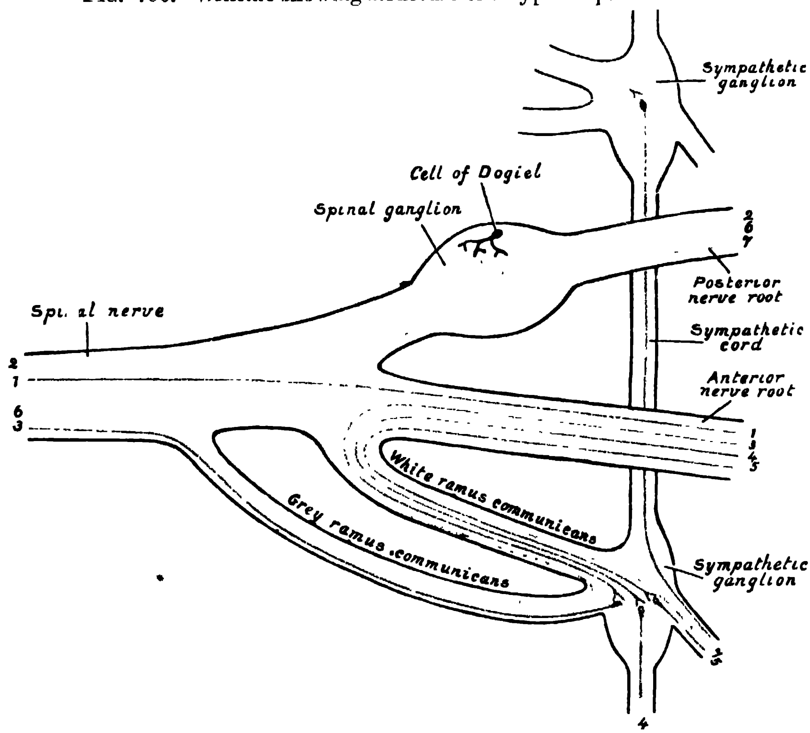
Connections with sympathetic.—Immediately beyond the spinal ganglion, the anterior and posterior nerve roots unite to form the *spinal* nerve which emerges through the intervertebral foramen. Each spinal nerve receives a branch (*grey ramus communicans*) from the adjacent ganglion of the sympathetic cord, while all the thoracic, and the first and second lumbar nerves each

contribute a branch (*white ramus communicans*) to the adjoining sympathetic ganglion. The second, third, and fourth sacral nerves also supply white rami; these branches, however, are not connected with the ganglia of the sympathetic cord, but run directly into the pelvic plexuses of the sympathetic.

Structure.—Each typical spinal nerve contains fibres belonging to two systems, viz. the somatic, and the sympathetic or splanchnic, as well as fibres connecting these systems with each other.

1. The **somatic** fibres are efferent and afferent. The *efferent* fibres originate in the cells of the anterior horn of the spinal cord, and run outwards through the anterior nerve roots to the spinal nerve. They convey impulses to the voluntary muscles, and are continuous from their origin to their peripheral distribution. The *afferent* fibres convey impressions inwards from the skin, &c., and originate in the unipolar nerve cells of the spinal ganglia. The single processes of these cells divide into peripheral and central fibres, and the latter enter the spinal cord through the posterior nerve roots. Many of them are

FIG. 790.—Scheme showing structure of a typical spinal nerve.



1. Somatic efferent. 2. Somatic afferent. 3, 4, 5. Splanchnic efferent. 6, 7. Splanchnic afferent.

continued up the cord to the medulla oblongata, where they end in the nucleus gracilis and nucleus cuneatus, but some form synapses round efferent neurons in the same or opposite side of the cord, completing in this way reflex arcs.

2. The **sympathetic** fibres are also efferent and afferent. The *efferent* fibres originate in the lateral horn of the spinal cord and are conveyed through the anterior nerve root and the white ramus communicans to the corresponding ganglion of the sympathetic chain; here they may end by forming synapses around its cells, or may run through the ganglion to end in another of the chain ganglia or in a more distally placed ganglion in one of the sympathetic plexuses. In all cases they terminate by forming synapses around other nerve cells. From the cells of the chain ganglia other fibres take origin ; some of these run inwards through the grey rami communicantes to join the spinal nerves, along which they are carried to the blood-vessels of the trunk and limbs,* while others pass

* It is generally stated that the sympathetic fibres which run in the spinal nerves are distributed to the Arrectores pilorum muscles and the glands of the skin, but the evidence is not conclusive.

to the viscera, either directly or after interruption in one of the distal ganglia. The *afferent* fibres are derived partly from the unipolar cells (type I.) and partly from the multipolar cells (type III.) of the spinal ganglia. Their peripheral processes are carried outwards through the white rami communicantes, and after passing through one or more sympathetic ganglia (but always without interruption in them) finally terminate in the tissues of the viscera. The central processes of the unipolar cells enter the spinal cord through the posterior nerve root and form synapses around either somatic or sympathetic efferent neurons, thus completing reflex arcs. The dendrites of the multipolar nerve cells form synapses around the cells of type II. (cells of Dogiel) in the spinal ganglia, and by this path the original impulse is transferred from the sympathetic to the somatic system, through which it is conveyed to the sensorium.

Divisions.—After emerging from the intervertebral foramen, each spinal nerve gives off a small *recurrent branch* (ramus meningeus) which re-enters the spinal canal through the intervertebral foramen and supplies the vertebræ and their ligaments, and the blood-vessels of the spinal cord and its membranes. It then splits into a posterior or dorsal, and an anterior or ventral division, each division containing fibres from both nerve roots.

POSTERIOR PRIMARY DIVISIONS OF THE SPINAL NERVES

The **posterior primary divisions** are as a rule smaller than the anterior. They are directed backwards and, with the exceptions of those of the first cervical, the fourth and fifth sacral, and the coccygeal, divide into internal and external branches (rami mediales et laterales) for the supply of the muscles and skin of the posterior part of the trunk.

Cervical Nerves

The **posterior division of the first cervical or suboccipital nerve** is larger than the anterior division, and emerges above the posterior arch of the atlas and beneath the vertebral artery. It enters the suboccipital triangle and supplies the muscles which bound this space, viz. the Rectus capitis posticus major, the Obliquus superior, and the Obliquus inferior; it gives branches also to the Rectus capitis posticus minor and the Complexus. A filament from the branch to the Obliquus inferior joins the second cervical nerve.

The nerve also occasionally gives off a cutaneous branch which accompanies the occipital artery to the scalp, and communicates with the great and small occipital nerves.

The **posterior division of the second cervical nerve** is much larger than the anterior division, and is the greatest of all the posterior cervical divisions. It emerges between the posterior arch of the atlas and the lamina of the axis, below the Inferior oblique. It supplies a twig to this muscle, receives a communicating filament from the first cervical, and then divides into a large internal and a small external branch.

The *internal* branch, called from its size the *great occipital nerve* (n. occipitalis major) ascends obliquely inwards between the Obliquus inferior and the Complexus, and pierces the latter muscle and the Trapezius near their attachments to the occipital bone. It is now joined by a filament from the posterior division of the third cervical and, ascending on the back of the head with the occipital artery, divides into branches which communicate with the small occipital nerve and supply the skin of the scalp as far forward as the vertex of the skull. It gives off muscular branches to the Complexus, and occasionally a twig to the back of the pinna. The *external* branch supplies filaments to the Splenius, Trachelo-mastoid and Complexus, and is often joined by the corresponding branch of the third cervical.

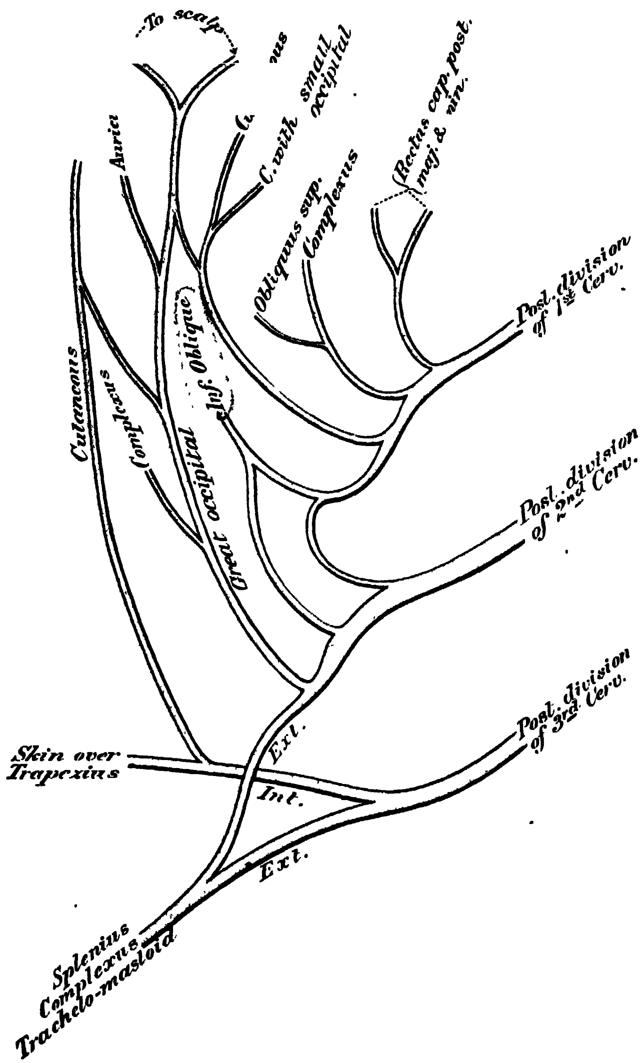
The **posterior division of the third cervical** is intermediate in size between those of the second and fourth. Its *internal branch* runs between the Complexus and Semispinalis, and piercing the Splenius and Trapezius, ends in the skin. While under the Trapezius it gives off a branch called the *third*

occipital nerve (n. occipitalis tertius) which pierces the Trapezius and ends in the skin of the lower part of the back of the head. It lies to the inner side of the great occipital and communicates with it. The *external* branch often joins that of the second.

The posterior division of the suboccipital, and the inner branches of the posterior primary divisions of the second and third cervical nerves are sometimes joined by communicating loops to form the *posterior cervical plexus* (Cruveilhier) (fig. 791).

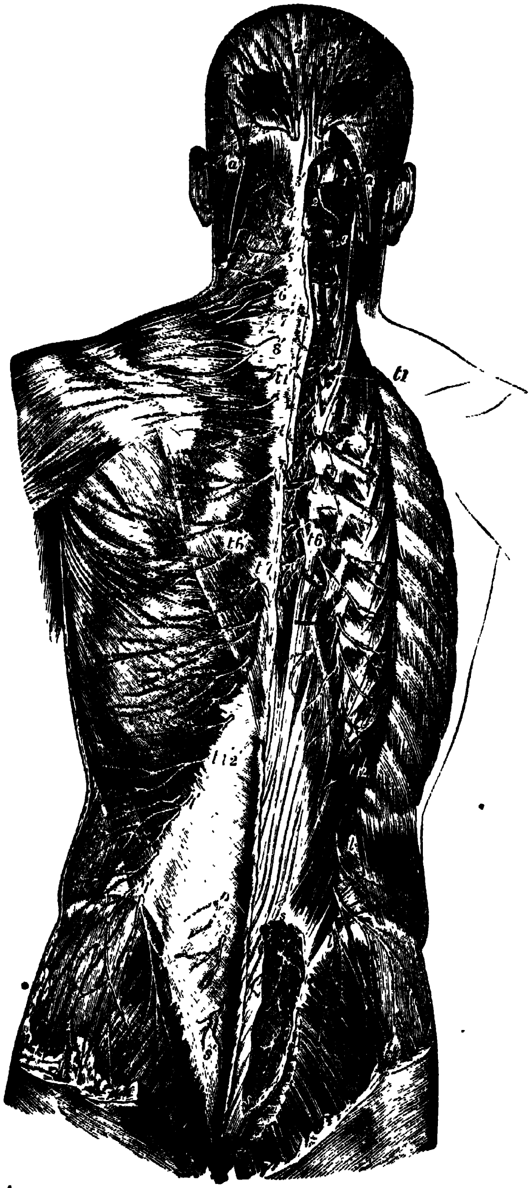
The **posterior divisions of the lower five cervical nerves** divide into internal and external branches. The *internal* branches of the fourth

FIG. 791.—Plan of the posterior divisions of the upper cervical nerves.



and fifth run between the Semispinalis and Complexus, and, having reached the spinous processes, pierce the Splenius and Trapezius to end in the skin. Sometimes the internal branch of the fifth fails to reach the skin. The internal branches of the lower three nerves are small, and end in the Semispinalis, Multifidus spinæ, Complexus and Interspinales. The *external* branches of the lower five nerves supply the Cervicalis ascendens, Transversalis colli, and Trachelo-mastoid.

FIG. 792.—Superficial and deep distribution of the posterior divisions of the spinal nerves (after Hirschfeld and Leveillé). On the left side the cutaneous branches are represented lying on the superficial layer of muscles. On the right side the superficial muscles have been removed, the Splenius capitis and Complexus divided in the neck, and the Erector spinæ divided and partly removed in the back, so as to expose the posterior divisions of the spinal nerves near their origin.



a, *a*. Small occipital nerve from the cervical plexus. 1. External muscular branches of the first cervical nerve, and union by a loop with the second. 2. Placed on the Rectus capitis posticus major muscle, marks the great occipital nerve (2′), passing round the short muscles and piercing the Complexus: the external branch is seen to the outside. 3. External branch from the posterior division of the third nerve. 3′. Its internal branch, sometimes called the third occipital. 4′ to 8′. The internal branches of the several corresponding nerves on the left side. The external branches of these nerves, proceeding to muscles, are displayed on the right side. *t* 1 to *t* 6 and thence to *t* 12. External muscular branches of the posterior divisions of the 12 thoracic nerves on the right side. *t* 1′ to *t* 6′. The internal cutaneous branches of the six upper thoracic nerves on the left side. *t* 7′ to *t* 12′. External branches of the six lower thoracic nerves. *l*, *l*. External branches from the posterior divisions of several lumbar nerves on the right side, piercing the muscles, the lower descending over the gluteal region. *l′*, *l′*. The same, more superficially, on the left side. *s*, *s*. The issue and union by loops of the posterior divisions of four sacral nerves on the right side. *s′*, *s′*. Some of those distributed to the skin on the left side.

Thoracic Nerves (fig. 792)

The *internal* branches of the **posterior divisions of the upper six thoracic nerves** run inwards between the Semispinalis dorsi and Multifidus spinæ, which they supply; they then pierce the Rhomboidei and Trapezius and reach the skin by the sides of the spinous processes. The internal branches of the **lower six** are distributed chiefly to the Multifidus spinæ and Longissimus dorsi; occasionally they give off filaments to the skin near the middle line.

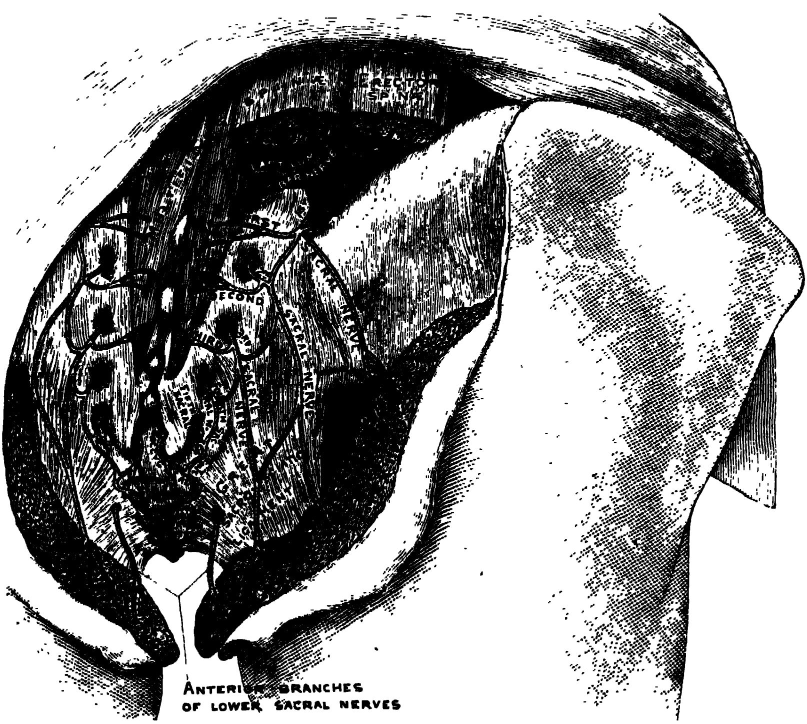
The *external branches* increase in size from above downwards. They run through or beneath the Longissimus dorsi to the interval between it and the Ilio-costalis, and supply these muscles; the lower five or six also give off cutaneous branches which pierce the Serratus posticus inferior and Latissimus dorsi in a line with the angles of the ribs. The external branches of a variable number of the upper thoracic nerves also give filaments to the skin.

The internal cutaneous branches of the posterior primary divisions of the thoracic nerves descend for some distance close to the spinous processes before reaching the skin, while the external branches travel downwards for a considerable distance—it may be as much as the breadth of four ribs—before they become superficial; the branch from the twelfth thoracic, for instance, reaches the skin only a little way above the iliac crest.*

Lumbar Nerves

The *internal branches* of the **posterior divisions of the lumbar nerves** pass inwards close to the articular processes of the vertebræ and end in the Multifidus spinæ.

Fig. 793.—The posterior primary divisions of the sacral nerves.



The *external branches* supply the Erector Spinæ. The upper three give off cutaneous nerves which pierce the aponeurosis of the Latissimus dorsi at the outer border of the Erector spinæ and descend across the posterior part of the iliac crest to the skin of the buttock, some of their twigs running as far as the level of the great trochanter.

* Consult in this connection an article on the cutaneous branches of the posterior primary divisions of the spinal nerves, by H. M. Johnston, *Journal of Anatomy and Physiology*, vol. xliii.

Sacral Nerves

The **posterior divisions of the sacral nerves** (fig. 793) are small, and diminish in size from above downwards; they emerge, except the last, through the posterior sacral foramina. The *upper three* are covered at their points of exit by the Multifidus spinæ, and divide into internal and external branches.

The *internal* branches are small, and end in the Multifidus spinæ.

The *external* branches join with one another and with the last lumbar and fourth sacral to form loops on the posterior surface of the sacrum. From these loops branches run to the posterior surface of the great sacro-sciatic ligament and form a second series of loops under the Gluteus maximus. From this second series cutaneous branches, two or three in number, pierce the Gluteus maximus along a line drawn from the posterior superior iliac spine to the tip of the coccyx; they supply the skin over the posterior part of the buttock.

The posterior divisions of the *lower two* sacral nerves are small and lie below the Multifidus spinæ. They do not divide into internal and external branches, but unite with each other and with the posterior division of the coccygeal nerve to form loops on the back of the sacrum; filaments from these loops supply the skin over the coccyx.

Coccygeal Nerve

The **posterior division of the coccygeal nerve** does not divide into an internal and an external branch, but receives, as already stated, a communicating branch from the last sacral; it is lost in the skin over the back of the coccyx.

ANTERIOR PRIMARY DIVISIONS OF THE SPINAL NERVES

The **anterior primary divisions of the spinal nerves** (rami anteriores) supply the antero-lateral parts of the trunk, and the limbs; they are for the most part larger than the posterior divisions. In the thoracic region they run independently of one another, but in the cervical, lumbar, and sacral regions they unite near their origins to form plexuses.

CERVICAL NERVES (NN. CERVICALES)

The **anterior primary divisions of the cervical nerves,** with the exception of the first, pass outwards between the anterior and posterior Inter-transverse muscles, lying on the grooved upper surfaces of the transverse processes, and emerge between the muscles attached to the anterior and posterior tubercles of these. The *anterior primary division of the first or sub-occipital nerve* issues from the vertebral canal above the posterior arch of the atlas and runs forwards round the lateral aspect of its superior articular process, internal to the vertebral artery. In most cases it descends internal to and in front of the Rectus lateralis, but in some cases it pierces the muscle.

The anterior primary divisions of the *upper four cervical nerves* unite to form the *cervical plexus*, and each receives a grey ramus communicans from the superior cervical ganglion of the sympathetic cord. Those of the *lower four cervical*, together with the greater part of the first thoracic, form the *brachial plexus*. They each receive a grey ramus communicans, those for the fifth and sixth being derived from the middle, and those for the seventh and eighth from the lowest, cervical ganglion of the sympathetic.

Cervical Plexus (Plexus Cervicalis)

The **cervical plexus** (fig. 794) is formed by the anterior primary divisions of the upper four cervical nerves; each nerve, except the first, divides into an upper and a lower branch, and the branches unite to form three loops. It is situated opposite the upper four cervical vertebræ, in front of the Levator anguli scapulæ and Scalenus medius, and covered by the Sterno-mastoid.

Its branches are divided into two groups, *superficial* and *deep*, and are here

given in tabular form; the figures following the names indicate the nerves from which the different branches take origin:

Superficial	Ascending		Small occipital	2, C.
			Great auricular	2, 3, C.
	Transverse		Superficial or transverse cervical	2, 3, C.
	Descending or Supraclavicular		Sternal, Clavicular, Acromial	3, 4, C.
Deep	Internal	Communicating	With hypoglossal	1, 2, C.
			,, vagus	1, 2, C.
			,, sympathetic	1, 2, 3, 4, C.
		Muscular	Rectus lateralis	1, C.
			Anterior recti	1, 2, C.
			Communicantes hypoglossi	2, 3, C.
			Phrenic	3, 4, 5, C.
	External	Communicating	with Spinal accessory	2, 3, 4, C.
		Muscular	Sterno-mastoid	2, C.
			Trapezius	3, 4, C.
			Levator anguli scapulæ	3, 4, C.
			Scalenus medius	3, 4, C.

Superficial Branches of the Cervical Plexus (fig. 795)

The **small occipital** (n. occipitalis minor) arises from the second cervical nerve, sometimes also from the third; it curves round the posterior border of the Sterno-mastoid, and ascends along the posterior border of the muscle. Near the cranium it perforates the deep fascia, and is continued upwards along the side of the head behind the ear, supplying the integument and communicating with the great occipital, the great auricular, and the posterior auricular branch of the facial. The small occipital varies in size, and is sometimes duplicated.

It gives off an *auricular branch*, which supplies the integument of the upper and back part of the auricle, communicating with the mastoid branch of the great auricular. This branch is occasionally derived from the great occipital nerve.

The **great auricular** (n. auricularis magnus) is the largest of the ascending branches. It arises from the second and third cervical nerves, winds round the posterior border of the Sterno-mastoid, and, after perforating the deep fascia, ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into facial, auricular, and mastoid branches.

The *facial branches* are distributed to the integument of the face over the parotid gland; others penetrate the substance of the gland, and communicate with the facial nerve.

The *auricular branches* ascend to supply the integument of the back of the pinna, except at its upper part, communicating with the auricular branches of the facial and pneumogastric nerves. A filament pierces the pinna to reach its outer surface, where it is distributed to the lobule and lower part of the concha.

The *mastoid branch* communicates with the small occipital and with the posterior auricular branch of the facial, and is distributed to the integument behind the ear.

The **superficial** or **transverse cervical** (n. cutaneus colli) arises from the second and third cervical nerves, turns round the posterior border of the Sterno-mastoid about its middle, and, passing obliquely forwards beneath the external jugular vein to the anterior border of the muscle, perforates the deep cervical fascia, and divides beneath the Platysma into two branches, which are distributed to the antero-lateral parts of the neck.

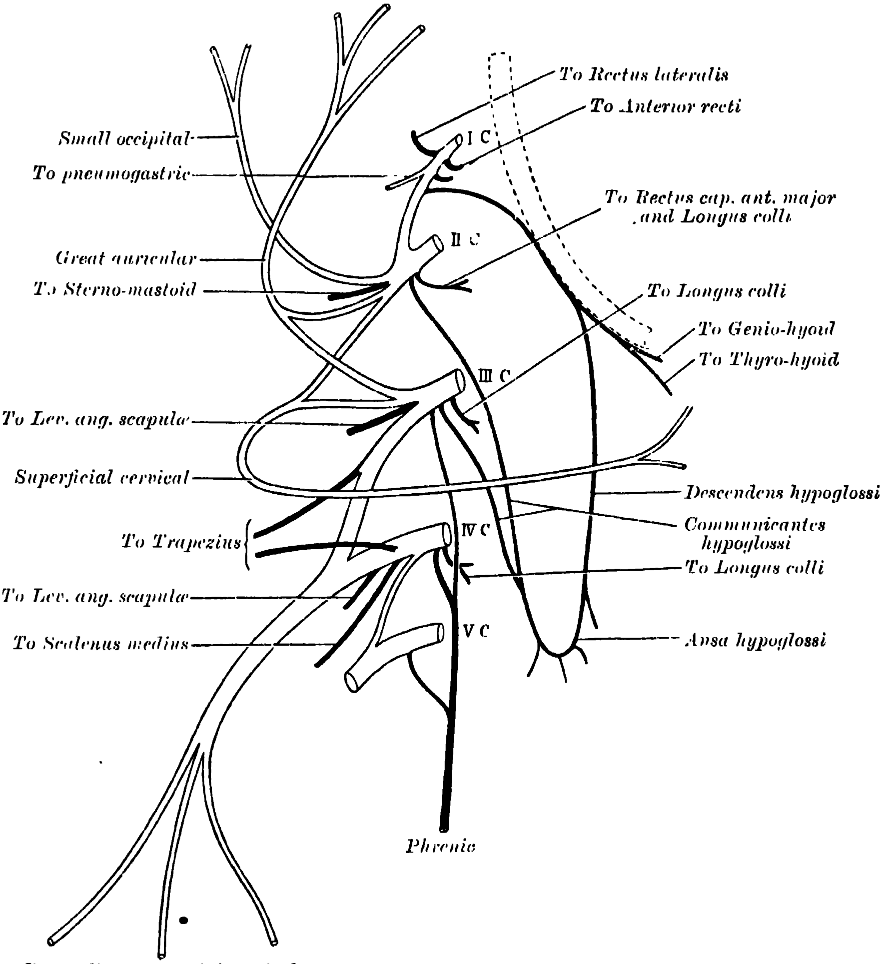
The *ascending branch* gives a filament which accompanies the external jugular vein; it then passes upwards to the submaxillary region, and divides into branches, some of which form a plexus with the cervical branches of the facial

nerve beneath the Platysma; others pierce that muscle, and are distributed to the integument of the upper half of the neck, at its fore part, as high as the chin.

The *descending branch* (occasionally represented by two or more filaments) pierces the Platysma, and is distributed to the integument of the side and front of the neck, as low as the sternum.

The **descending** or **supraclavicular nerves** (nn. supraclaviculares) arise from the third and fourth cervical nerves: emerging beneath the posterior border of the Sterno-mastoid, they descend in the posterior triangle of the neck beneath the Platysma and deep cervical fascia. Near the clavicle they

FIG. 794.—Plan of cervical plexus.



perforate the fascia and Platysma to become cutaneous, and are arranged, according to their position, into three groups.

The *inner* or *sternal branches* (nn. supraclaviculares anteriores) cross obliquely over the external jugular vein and the clavicular and sternal attachments of the Sterno-mastoid, and supply the integument as far as the median line. They furnish one or two filaments to the sterno-clavicular joint.

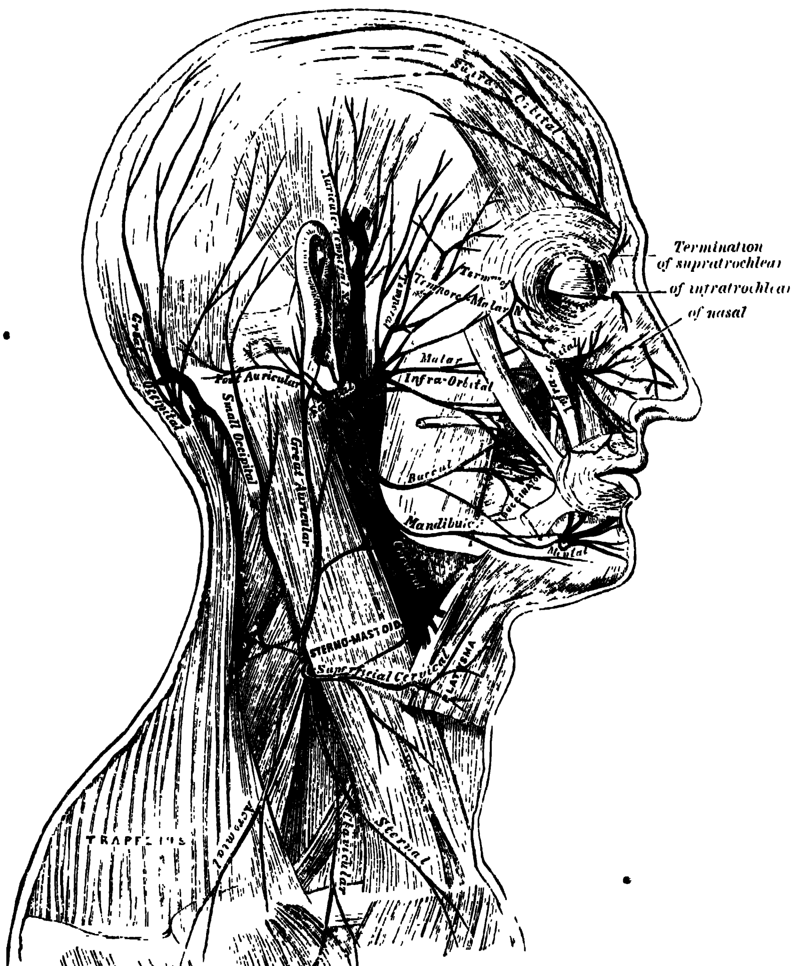
The *middle* or *clavicular branches* (nn. supraclaviculares medii) cross the clavicle, and supply the integument over the Pectoral and Deltoid muscles, communicating with the cutaneous branches of the upper intercostal nerves.

The *external* or *acromial branches* (nn. supraclaviculares posteriores) pass obliquely across the outer surface of the Trapezius and the acromion, and supply the integument of the upper and back part of the shoulder.

Deep Branches of the Cervical Plexus. Internal Series

The **communicating branches** consist of several filaments, which pass from the loop between the first and second cervical nerves to the pneumogastric, hypoglossal, and sympathetic. The branch to the hypoglossal ultimately leaves that nerve as a series of branches, viz. the descendens hypoglossi, the nerve to the Thyro-hyoid and the nerve to the Genio-hyoid (see page 940). A communicating branch also passes from the fourth to the fifth cervical, while each of the first four cervical nerves receives a grey ramus communicans from the superior cervical ganglion of the sympathetic.

Fig. 795.—The nerves of the scalp, face, and side of the neck.



Muscular branches supply the Anterior recti and Rectus lateralis muscles; they proceed from the first cervical nerve, and from the loop formed between it and the second.

The **communicantes hypoglossi** (fig. 794) consist usually of two filaments, one derived from the second, and the other from the third cervical. These filaments usually join to form the *descendens cervicis*, which passes downwards on the outer side of the internal jugular vein, crosses in front of the vein a little below the middle of the neck, and forms a loop (*ansa hypoglossi*) with the descendens hypoglossi in front of the sheath of the carotid vessels (see page 941). Occasionally, the loop is formed within the sheath.

The phrenic (n. phrenicus), or *internal respiratory nerve of Bell*, arises chiefly from the fourth cervical nerve, but receives a filament from the third and a branch from the fifth; the fibres from the fifth nerve occasionally come through the nerve to the Subclavius. It descends to the root of the neck, running obliquely across the front of the Scalenus anticus, and beneath the Sterno-mastoid, the posterior belly of the Omo-hyoid, and the transversalis colli and suprascapular vessels. It next passes over the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the chest, crosses the internal mammary artery near its origin. Within the chest, it descends nearly vertically in front of the root of the lung, and then between the pericardium and the mediastinal portion of the pleura, to the Diaphragm, where it divides into branches, which separately pierce that muscle, and are distributed to its under surface. In the thorax it is accompanied by a branch of the internal mammary artery, the arteria comes nervi phrenici.

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The *right nerve* is situated more deeply, and is shorter and more vertical in direction than the left; it lies on the outer side of the right innominate vein and superior vena cava.

The *left nerve* is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the opposite side. At the root of the neck it is crossed by the thoracic duct; in the superior mediastinum it is placed between the left common carotid and left subclavian arteries, and crosses in front of the vagus on the left side of the arch of the aorta.

Each nerve supplies filaments to the pericardium and pleura, and at the root of the neck is joined by a filament from the sympathetic, and, occasionally, by one from the ansa hypoglossi. Branches have been described as passing to the peritoneum.

From the *right nerve*, one or two filaments pass to join in a small ganglion with phrenic branches of the solar plexus; and branches from this ganglion are distributed to the hepatic plexus, the suprarenal capsule, and inferior vena cava. From the *left nerve*, filaments pass to join the phrenic plexus of the sympathetic, but without any ganglionic enlargement.

Deep Branches of the Cervical Plexus. External Series

Communicating branches.—The deep branches of the external series of the cervical plexus communicate with the spinal accessory nerve, in the substance of the Sterno-mastoid muscle, in the posterior triangle, and beneath the Trapezius.

Muscular branches are distributed to the Sterno-mastoid, Trapezius, Levator anguli scapulæ, and Scalenus medius.

The branch for the Sterno-mastoid is derived from the second cervical; the Trapezius and Levator anguli scapulæ receive branches from the third and fourth. The Scalenus medius is supplied sometimes by the third, sometimes by the fourth, and occasionally by both nerves.

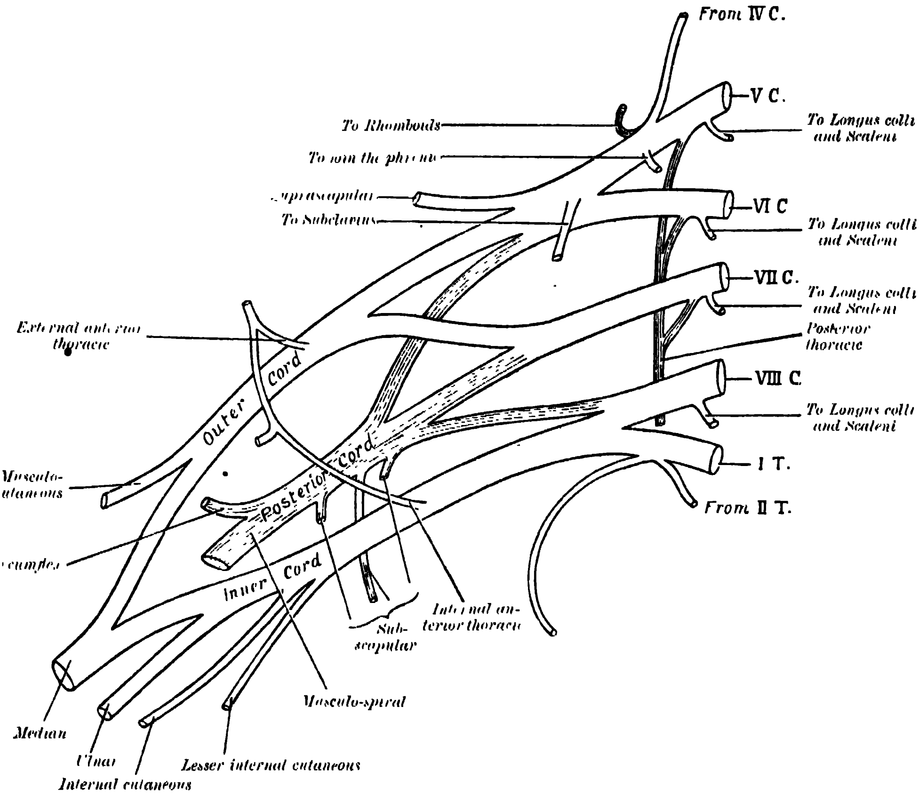
Applied Anatomy.—Pains referred to the terminal branches of the cervical plexus are not uncommon in caries of the cervical spine, where pain may be felt radiating over the occiput, if the disease is situated high up in the spine.

The Brachial Plexus (Plexus Brachialis)

The **brachial plexus** (fig. 796) is formed by the union of the anterior primary divisions of the lower four cervical nerves and the greater part of the anterior primary division of the first thoracic nerve; a fasciculus from the fourth cervical nerve usually contributes and frequently one from the second thoracic nerve. It extends from the lower part of the side of the neck to the axilla. The nerves which form the plexus are nearly equal in size, but their mode of communication is subject to some variation, so that no one plan can be given as applying

to every case. The following is, however, the most constant arrangement. The fifth and sixth cervical unite soon after their exit from the intervertebral foramina to form a common trunk. The eighth cervical and first thoracic also unite to form one trunk, while the seventh cervical runs out alone. Three trunks are thus formed, an upper one, formed by the junction of the fifth and sixth cervical nerves; a middle one, consisting of the seventh cervical nerve; and a lower one, formed by the junction of the eighth cervical and first thoracic nerves. As they pass beneath the clavicle, each of these three trunks divides into two divisions, an *anterior* and a *posterior*.* The anterior divisions of the upper

FIG. 796.—Plan of brachial plexus.



and middle trunks then unite to form a cord, which is situated on the outer side of the middle part of the axillary artery, and is called the *outer cord* of the brachial plexus. The anterior division of the lower trunk passes down on the inner side of the axillary artery in the middle of the axilla, and forms the *inner cord* of the brachial plexus. The posterior divisions of all three trunks unite to form the *posterior cord* of the brachial plexus, which is situated behind the second portion of the axillary artery.

Relations.—*In the neck*, the brachial plexus lies in the posterior triangle, being covered by the skin, Platysma, and deep fascia: it is crossed by the descending superficial cervical nerves, the posterior belly of the Omo-hyoid, the external jugular vein, and the Transversalis colli artery. When the posterior scapular artery arises from the third part of the subclavian, it usually passes between the roots of the plexus. The plexus emerges from between the Anterior and Middle scalenus muscles; its upper part lies above the third part of the subclavian artery, while the trunk formed by the union of the eighth cervical and first thoracic is placed behind the artery; it next passes behind the clavicle,

* The posterior division of the lower trunk is very much smaller than the others, and is frequently derived entirely from the eighth cervical nerve.

the Subclavius muscle and suprascapular vessels, and lies upon the first serration of the Serratus magnus, and the Subscapularis. *In the axilla* it is placed on the outer side of the first portion of the axillary artery; it surrounds the second part of the artery, one cord lying upon the outer side of that vessel, one on the inner side, and one behind it; and at the lower part of the axillary space gives off its terminal branches to the upper extremity.

Branches of communication.—The brachial plexus communicates with the cervical plexus by a branch from the fourth to the fifth nerve, and with the phrenic nerve by a branch from the fifth cervical, which joins that nerve on the Scalenus anticus. Close to their exit from the intervertebral foramina the fifth and sixth cervical nerves are joined by filaments from the middle cervical ganglion of the sympathetic, the seventh and eighth cervical by twigs from the inferior ganglion, and the first thoracic nerve by a branch from the first thoracic ganglion.

Branches of distribution.—The branches of the brachial plexus may be arranged into two groups, viz. those given off above and those below the clavicle.

SUPRACLAVICULAR BRANCHES

Communicating	with phrenic	5 C.
	with sympathetic	5, 6, 7, 8 C, 1 T.
Muscular to	Rhomboids (posterior scapular)	5 C.
	Supraspinatus, Infraspinatus (suprascapular)	5, 6 C.
	Subclavius . . Thoracic Longus	5, 6 C.
	~~Serratus~~ magnus (posterior thoracic)	5, 6, 7 C.
	Longus colli	5, 6, 7, 8 C.
	Scaleni	5, 6, 7, 8 C.

The **communicating branch** with the phrenic is derived from the fifth cervical nerve or from the loop between the fifth and sixth; it joins the phrenic on the Scalenus anticus. The communications with the sympathetic have already been referred to.

The unnamed **muscular branches** supply the Longus colli, Scaleni, and Subclavius. Those for the Longus colli and Scaleni arise from the four lower cervical nerves at their exit from the intervertebral foramina.

The nerve to the Subclavius is a small filament, which arises from the fifth cervical at its point of junction with the sixth nerve; it descends in front of the third part of the subclavian artery and the lower trunk of the plexus, to the muscle, and is usually connected by a filament with the phrenic nerve.

The **posterior scapular** (n. dorsalis scapulæ), or nerve to the Rhomboids, arises from the fifth cervical, pierces the Scalenus medius, and passes beneath the Levator anguli scapulæ, which it occasionally supplies, to the Rhomboid muscles.

The **posterior thoracic** (n. thoracalis longus), or *external respiratory of Bell* (fig. 801) supplies the Serratus magnus, and is remarkable for the length of its course. It usually arises by three roots from the fifth, sixth, and seventh cervical nerves; but the root from the seventh nerve may be absent. The roots from the fifth and sixth nerves pierce the Scalenus medius, while that from the seventh nerve emerges from in front of the muscle. The nerve passes down behind the brachial plexus and the axillary vessels, resting on the outer surface of the Serratus magnus. It extends along the side of the chest to the lower border of that muscle, supplying filaments to each of its digitations.

The **suprascapular** (n. suprascapularis) (fig. 802) arises from the trunk formed by the fifth and sixth cervical nerves; running obliquely outwards beneath the Trapezius and the Omo-hyoid, it enters the supraspinous fossa through the suprascapular notch, below the transverse or suprascapular ligament; it then passes beneath the Supraspinatus muscle, and curves round the external border of the spine of the scapula to the infraspinous fossa. In the supraspinous fossa it gives off two branches to the Supraspinatus muscle, and an articular filament to the shoulder-joint; and in the infraspinous fossa it gives off two branches to the Infraspinatus muscle, besides some filaments to the shoulder-joint and scapula.

Infraclavicular Branches

The infraclavicular branches are derived from the three cords of the brachial plexus. The fasciculi of which they are composed may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

Outer cord .	Musculo-cutaneous .	5, 6 C.
	External anterior thoracic	5, 6, 7 C.
	Outer head of median .	6, 7 C.
Inner cord	Internal anterior thoracic	8 C, 1 T.
	Internal cutaneous .	8 C, 1 T.
	Lesser internal cutaneous	(8 C) 1 T.
	Ulnar	8 C, 1 T.
	Inner head of median .	8 C, 1 T.
Posterior cord	Upper subscapular .	5, 6 C.
	Middle ,, . .	5, 6, 7 C.
	Lower ,, . .	5, 6 C.
	Circumflex . . .	5, 6 C.
	Musculo-spiral . .	(5) 6, 7, 8 C (1 T).

These branches may be arranged according to the regions they supply:

To the chest	Internal and external anterior thoracic.
To the shoulder	Subscapulars. Circumflex.
To the arm, forearm, and hand	Musculo-cutaneous. Internal cutaneous. Lesser internal cutaneous. Median. Ulnar. Musculo-spiral.

The **anterior thoracic nerves** (nn. thoracales anteriores) (fig. 801), two in number, supply the Pectoral muscles.

The *external anterior thoracic*, the larger of the two, arises from the outer cord of the brachial plexus, through which its fibres may be traced to the fifth, sixth, and seventh cervical nerves. It passes inwards, across the axillary artery and vein, pierces the costo-coracoid membrane, and is distributed to the under surface of the Pectoralis major. It sends down a communicating filament which joins the internal nerve, and forms with it a loop in front of the first part of the axillary artery.

The *internal anterior thoracic* arises from the inner cord, and through it from the eighth cervical and first thoracic. It passes behind the first part of the axillary artery, curves forwards between the axillary artery and vein, and joins with the filament from the external nerve. It then passes to the under surface of the Pectoralis minor muscle, where it divides into a number of branches, which supply the muscle. Some two or three branches pass through the muscle to supply the Pectoralis major.

The **subscapular nerves** (nn. subscapulares), three in number, supply the Subscapularis, Teres major, and Latissimus dorsi muscles. The fasciculi of which they are composed may be traced to the fifth, sixth, and seventh cervical nerves.

The *upper* or *short subscapular*, the smallest, enters the upper part of the Subscapularis muscle; this nerve is frequently represented by two branches.

The *lower subscapular* enters the axillary border of the Subscapularis, and terminates in the Teres major. The latter muscle is sometimes supplied by a separate branch.

The *middle* or *long subscapular*, the largest of the three, follows the course of the subscapular artery, along the posterior wall of the axilla to the Latissimus dorsi, in which it may be traced as far as the lower border of the muscle.

The **circumflex** (n. axillaris) (fig. 802) supplies some of the muscles and part of the integument of the shoulder, and gives a branch to the shoulder-joint. It arises from the posterior cord of the brachial plexus, in common

with the musculo-spiral nerve, and its fibres may be traced through the posterior cord to the fifth and sixth cervical nerves. It is at first placed behind the axillary artery, between it and the Subscapularis muscle, and passes downwards and outwards to the lower border of that muscle. It then winds backwards, in company with the posterior circumflex artery, through a quadrilateral space bounded above by the Subscapularis, below by the Teres major, internally by the long head of the Triceps, and externally by the surgical neck of the humerus, and divides into two branches.

FIG. 797.—Cutaneous nerves of right upper extremity. Anterior view.

The *upper branch* winds round the surgical neck of the humerus, beneath the Deltoid, with the posterior circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off cutaneous branches, which pierce the muscle and ramify in the integument covering its lower part.

The *lower branch*, at its origin, distributes filaments to the Teres minor and the back part of the Deltoid. Upon the filament to the former muscle an oval enlargement usually exists. The nerve then pierces the deep fascia, and supplies the integument over the lower two-thirds of the posterior part of the Deltoid, as well as that covering the long head of the Triceps.

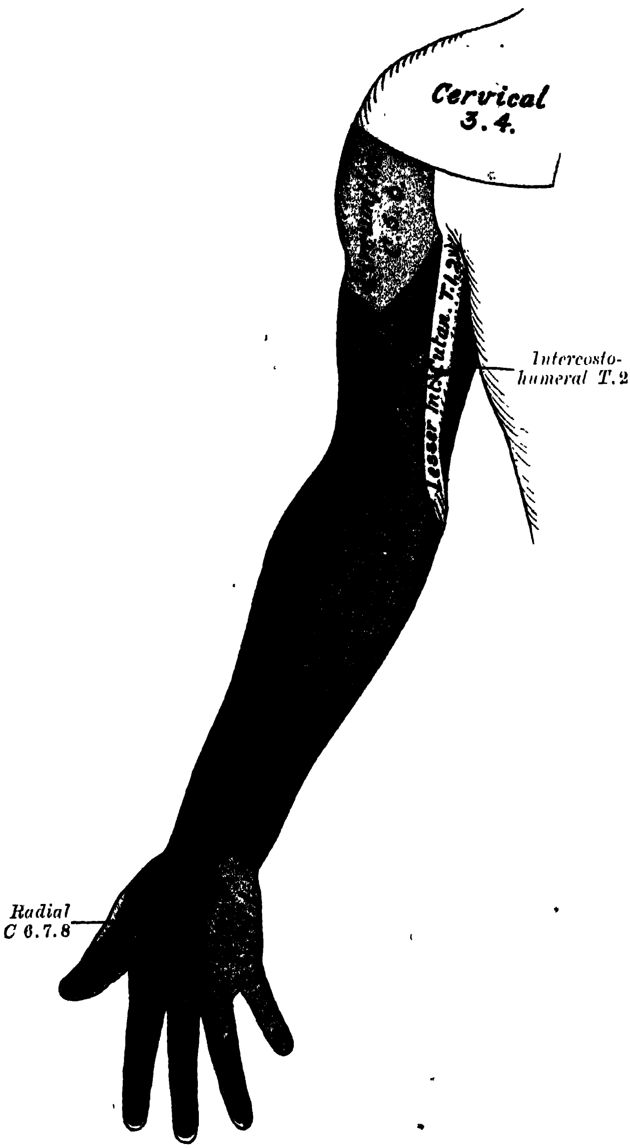
The circumflex nerve, before its division, gives off an articular filament which enters the shoulder-joint below the Subscapularis.

The **musculo-cutaneous** (n. musculocutaneus) (fig. 801) arises from the outer cord of the brachial plexus, opposite the lower border of the Pectoralis minor, its fibres being derived from the fifth and sixth cervical nerves. It perforates the Coraco-brachialis muscle and passes obliquely between the Biceps and Brachialis anticus, to the outer side of the arm; a little above the elbow it becomes cutaneous by perforating the deep fascia on the outer side of the tendon of the Biceps. In its course through the arm it supplies the Coraco-brachialis, Biceps, and the greater part of the Brachialis anticus. The branch to the Coraco-brachialis is given off from the nerve close to its origin, and in some instances, especially in early life, as a separate filament from the outer cord of the plexus; it is derived from the seventh nerve, and is by some anatomists regarded as a separate nerve, more or less closely incorporated with the musculo-cutaneous. The branches to the Biceps and Brachialis anticus are given off after the musculo-cutaneous has pierced the Coraco-brachialis. The nerve also sends a small branch to the bone, which enters the nutrient foramen with the accompanying artery, while the branch supplying the Brachialis anticus gives a filament to the elbow joint.

The cutaneous portion of the nerve (n. cutaneus antibrachii lateralis) passes behind the median cephalic vein, and divides, opposite the elbow-joint, into an anterior and a posterior branch.

The *anterior branch* descends along the radial border of the forearm to the wrist, and supplies the integument over the outer half of its anterior surface. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the back of the wrist, and supply the carpus. The nerve then passes downwards to the ball of the thumb, where it terminates in cutaneous filaments. It communicates with a branch from the radial nerve, and with the palmar cutaneous branch of the median.

FIG. 798.—Segmental distribution of the cutaneous nerves of the right upper extremity. Anterior view.



The *posterior branch* passes downwards, along the back part of the radial side of the forearm, to the wrist. It supplies the integument of the lower two-thirds of the forearm, communicating with the radial nerve and the external cutaneous branch of the musculo-spiral.

The musculo-cutaneous nerve presents frequent irregularities. It may adhere for some distance to the median and then pass outwards, beneath the Biceps, instead of through the Coraco-brachialis. Frequently some of the fibres of the median run for some distance in the musculo-cutaneous and then leave it to join their proper trunk. Less frequently the reverse is the case, and the median sends a branch to join the musculo-cutaneous. Instead of piercing the Coraco-brachialis the nerve may pass under it or through the Biceps. Occasionally it gives a filament to the Pronator teres, and it has been seen to supply the back of the thumb when the radial nerve was absent.

The **internal cutaneous** (n. cutaneus antibrachii medialis) (fig. 801) arises from the inner cord in common with the ulnar and internal head of the median, and, at its commencement, lies on the inner side of the axillary artery. It derives its fibres from the eighth cervical and first thoracic nerves. It gives off, near the axilla, a filament, which pierces the fascia and supplies the integument covering the Biceps muscle, nearly as far as the elbow. This filament lies a little external to the common trunk, from which it arises. The nerve then passes down the inner side of the arm on the inner side of the brachial artery, pierces the deep fascia with the basilic vein, about the middle of the upper arm, and, becoming cutaneous, divides into two branches, an anterior and a posterior.

The *anterior branch*, the larger of the two, passes usually in front of, but occasionally behind, the median basilic vein. It then descends on the anterior surface of the ulnar side of the forearm, distributing filaments to the integument as far as the wrist, and communicating with the palmar cutaneous branch of the ulnar nerve.

The *posterior branch* passes obliquely downwards on the inner side of the basilic vein, in front of the internal epicondyle of the humerus, to the back of the forearm, and descends on the posterior surface of its ulnar side as far as the wrist, distributing filaments to the integument. It communicates with the lesser internal cutaneous, the lower external cutaneous branch of the musculo-spiral, and the dorsal branch of the ulnar nerve.

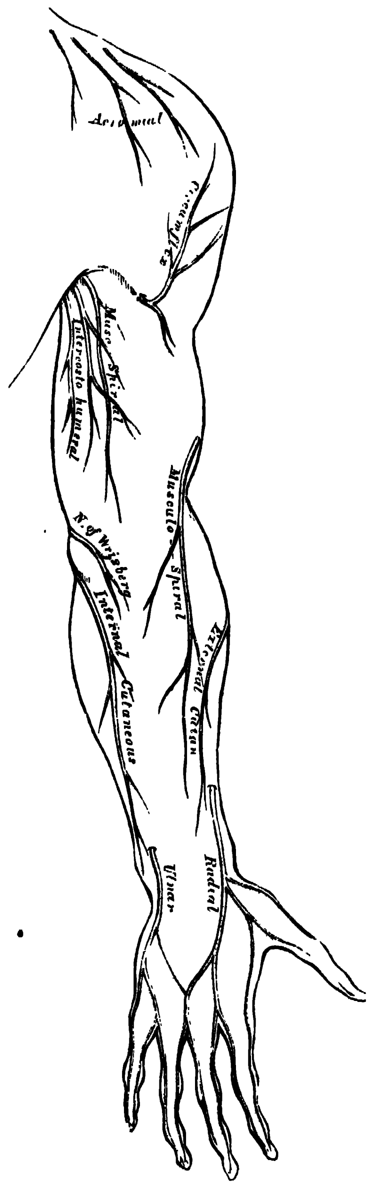


FIG. 799.—Cutaneous nerves of right upper extremity. Posterior view.

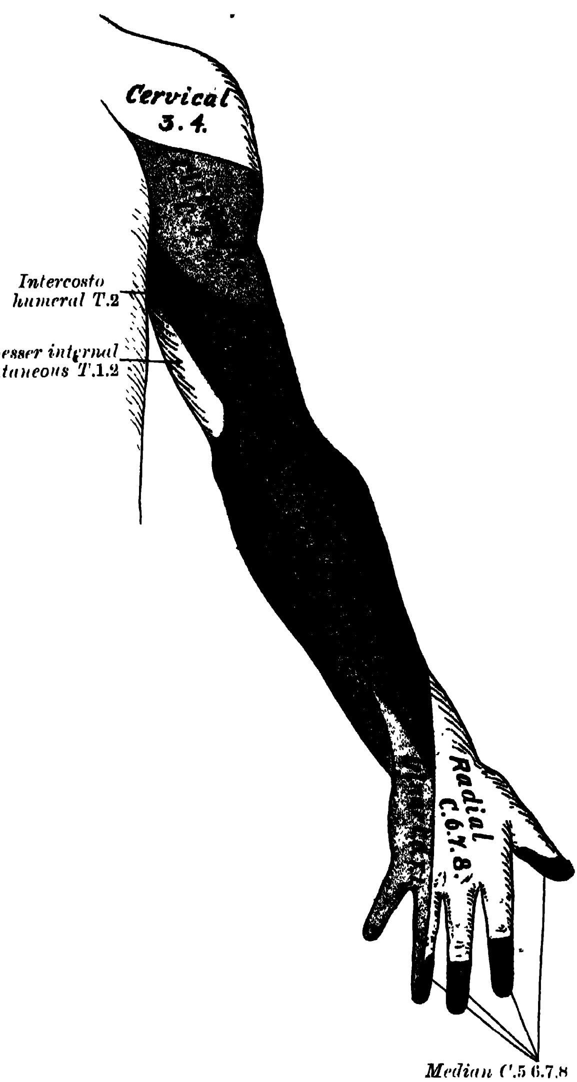
The **lesser internal cutaneous** (n. cutaneus brachii medialis), or nerve of Wrisberg, is distributed to the integument on the inner side of the arm (fig. 801). It is the smallest of the branches of the brachial plexus, and arising from the inner cord receives its fibres from the first thoracic nerve, and sometimes from the eighth cervical. It passes through the axillary space, at first lying behind, and then on the inner side of the axillary vein, and communicates with the intercosto-humeral nerve (lateral cutaneous branch of the second thoracic). It descends along the inner side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the integument of the back part of the lower third of the arm, extending as far as the elbow, where some filaments are lost in the integument in front of the inner epicondyle, and others over the olecranon. It communicates with the posterior branch of the internal cutaneous nerve.

In some cases the nerve of Wrisberg and intercosto-humeral are connected by two or three filaments, which form a plexus at the back part of the axilla. In other cases, the intercosto-humeral is of large size, and takes the place of the nerve of Wrisberg, receiving merely a filament of communication from the brachial plexus, which represents the latter nerve; in a few cases, this filament is wanting.

The **median** (n. medianus) (fig. 801) extends along the middle of the arm and forearm to the hand. It arises by two roots, one from the outer and one from the inner cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front or on the outer side of that vessel. Its fibres are derived from the sixth, seventh, and eighth cervical and first thoracic nerves. As it descends through the arm, it lies at first on the outer side of the brachial artery, crosses that vessel in the middle of its course, usually in front of, but occasionally behind it, and lies on its inner side

at the bend of the elbow, where it is situated beneath the bicipital fascia, and is separated from the elbow-joint by the Brachialis anticus. *In the forearm* it passes between the two heads of the Pronator teres and crosses the ulnar artery, but is separated from this vessel by the deep head of the Pronator teres. It descends beneath the Flexor sublimis digitorum, lying on the Flexor profundus digitorum, to within two inches above the anterior annular ligament of the wrist; here it becomes more superficial, and is situated between the tendons of the Flexor sublimis digitorum and Flexor carpi radialis. In this situation it lies beneath, and rather to the radial side of, the tendon of the Palmaris longus, and is covered by the integument and fascia. It then passes beneath the anterior annular ligament into the palm of the hand. In its course through the forearm it is accompanied by a branch of the anterior interosseous artery.

Fig. 800.—Segmental distribution of the cutaneous nerves of the right upper extremity. Posterior view.



Branches. — With the exception of the nerve to the Pronator teres, which sometimes arises above the elbow-joint, the median nerve gives off no branches in the arm. As it passes in front of the elbow, it supplies one or two articular twigs to the joint. *In the forearm* its branches are, muscular, anterior interosseous, and palmar cutaneous.

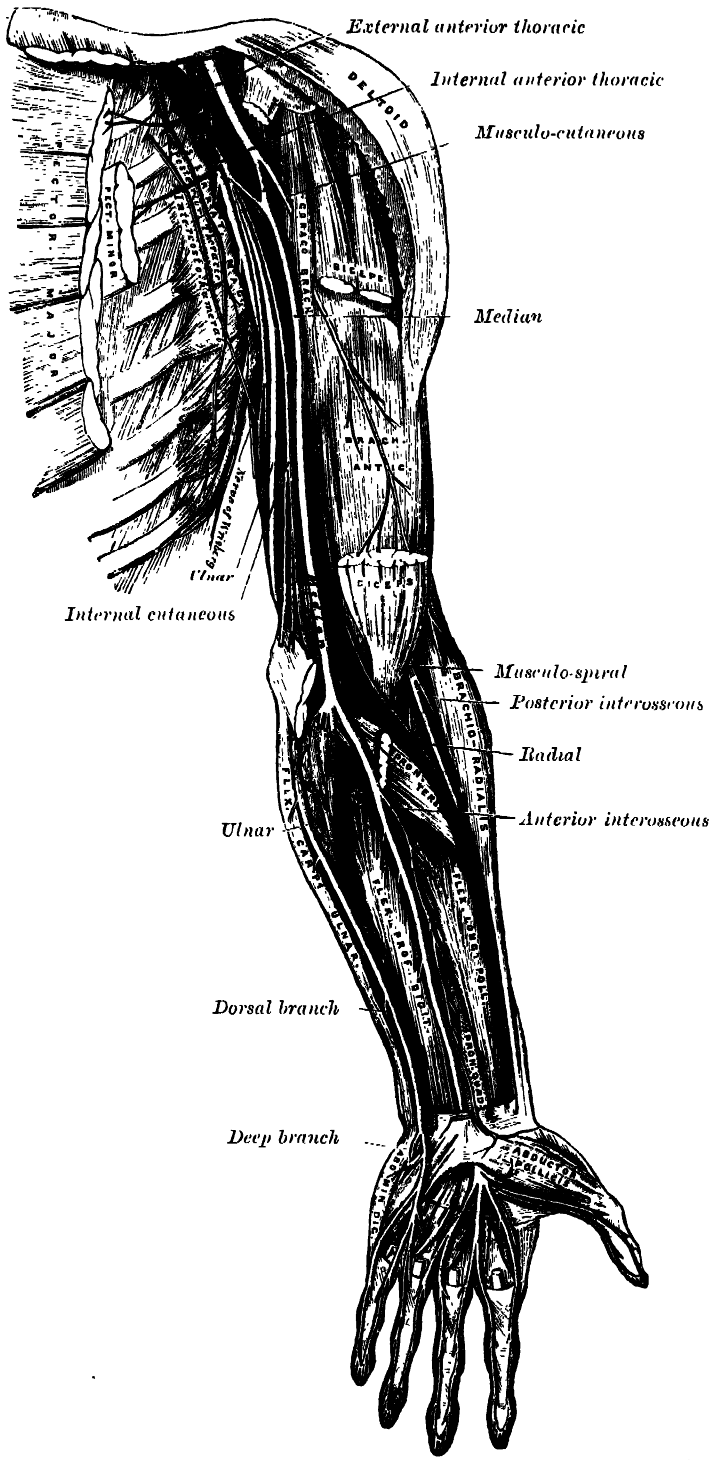
The *muscular branches* are derived from the nerve near the elbow and supply all the superficial muscles on the front of the forearm, except the Flexor carpi ulnaris.

The *anterior interosseous* (n. interosseus antibrachii volaris) supplies the deep muscles on the front of the forearm, except the inner half of the Flexor profundus digitorum. It accompanies the anterior interosseous artery along the interosseous membrane, in the interval between the Flexor longus pollicis and Flexor profundus digitorum, supplying the whole of the former and the outer half of the latter, and terminates below in the Pronator quadratus and wrist-joint.

The *palmar cutaneous branch* (ramus cutaneus palmaris) arises from the median nerve at the lower part of the forearm. It pierces the fascia above the annular ligament, and, descending over that ligament, divides into two branches; the outer supplies the skin over the ball of the thumb, and communicates with the anterior cutaneous branch of the musculo-cutaneous

nerve; the inner supplies the integument of the palm of the hand, communicating with the palmar cutaneous branch of the ulnar.

FIG. 801.—Nerves of the left upper extremity.



In the palm of the hand, the median nerve is covered by the integument and palmar fascia, and crossed by the superficial palmar arch. It rests upon the tendons of the Flexor muscles. In this situation it becomes enlarged, somewhat flattened, of a reddish colour, and divides into two branches. Of these, the *external* supplies a muscular branch to some of the muscles of the thumb, and digital branches to the thumb and radial side of the index finger; the *internal* supplies digital branches to the contiguous sides of the index and middle, and of the middle and ring fingers.

The *branch to the muscles of the thumb* is a short nerve, which divides to supply the Abductor, the Opponens, and the superficial head of the Flexor brevis pollicis; the remaining muscles of this group are supplied by the ulnar nerve.

The *digital branches* are five in number. The *first* and *second* pass along the borders of the thumb, the external branch communicating with branches of the radial nerve. The *third* passes along the radial side of the index finger, and gives a filament to the First lumbrical. The *fourth* subdivides to supply the adjacent sides of the index and middle fingers, and sends a branch to the Second lumbrical. The *fifth* supplies the adjacent sides of the middle and ring fingers, and communicates with a branch from the ulnar nerve.

Each digital nerve, opposite the base of the first phalanx, gives off a dorsal branch, which joins the dorsal digital nerve from the radial, and runs along the side of the dorsum of the finger, to end in the integument over the last phalanx. At the end of the finger, the digital nerve divides into a palmar and a dorsal branch, the former of which supplies the extremity of the finger, and the latter ramifies round and beneath the nail. The digital nerves, as they run along the fingers, are placed superficial to the digital arteries.

The **ulnar** (n. ulnaris) (fig. 801) is placed along the inner or ulnar side of the upper limb, and is distributed to the muscles and integument of the forearm and hand. It arises from the inner cord of the brachial plexus, in common with the inner head of the median and the internal cutaneous nerve, and derives its fibres from the eighth cervical and first thoracic nerves. It is smaller than the median, and lies at first behind it, but diverges from it in its course down the arm. At its origin it lies to the inner side of the axillary artery, and bears the same relation to the brachial artery as far as the middle of the arm. Here it pierces the internal intermuscular septum, runs obliquely across the internal head of the Triceps, and descends to the groove between the internal epicondyle and the olecranon, accompanied by the inferior profunda artery. *At the elbow*, it rests upon the back of the inner epicondyle, and passes into the forearm between the two heads of the Flexor carpi ulnaris. *In the forearm*, it descends in a perfectly straight course along the ulnar side, lying upon the Flexor profundus digitorum, its upper half being covered by the Flexor carpi ulnaris, its lower half lying on the outer side of the muscle, covered by the integument and fascia. In the upper third of its course, it is separated from the ulnar artery by a considerable interval, but in the rest of its extent lies close to the inner side of the artery. *At the wrist* the ulnar nerve crosses the annular ligament on the outer side of the pisiform bone, to the inner side of and a little behind the ulnar artery, and immediately beyond this bone divides into two branches, the superficial and deep palmar.

The branches of the ulnar nerve are:

In the forearm	Articular (elbow). Muscular. Palmar cutaneous. Dorsal cutaneous. Articular (wrist).	In the hand	Superficial palmar. Deep palmar.

The *articular branches* to the elbow-joint consist of several small filaments. They arise from the nerve as it lies in the groove between the inner epicondyle and olecranon.

The *muscular branches*, two in number, arise from the trunk of the nerve near the elbow: one supplies the Flexor carpi ulnaris; the other, the inner half of the Flexor profundus digitorum.

The *palmar cutaneous* (ramus cutaneus palmaris) arises from the ulnar nerve about the middle of the forearm, and runs downwards, on the ulnar artery, giving off some filaments to the vessel. Just above the annular

ligament, it perforates the deep fascia and ends in the integument of the palm, communicating with the palmar branch of the median nerve.

The *dorsal cutaneous branch* (ramus dorsalis manus) arises about two inches above the wrist; it passes backwards beneath the Flexor carpi ulnaris, perforates the deep fascia, and, running along the ulnar side of the back of the wrist and hand, divides into branches: one of these supplies the inner side of the little finger; a second supplies the adjacent sides of the little and ring fingers; a third joins the branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers, and assists in supplying them; a fourth is distributed to the metacarpal region of the hand, communicating with a branch of the radial nerve.

On the little finger the dorsal digital branches extend only as far as the base of the terminal phalanx, and on the ring finger as far as the base of the second phalanx; the more distal parts of these digits are supplied by dorsal branches derived from the palmar digital branches of the ulnar.

The *superficial palmar branch* (ramus superficialis) supplies the Palmaris brevis, and the integument on the inner side of the hand, and terminates in two digital branches, which are distributed, one to the ulnar side of the little finger, the other to the adjoining sides of the little and ring fingers, the latter communicating with a branch from the median. The digital branches are distributed to the fingers in the same manner as the digital branches of the median.

The *deep palmar branch* (ramus profundus), accompanied by the deep branch of the ulnar artery, passes between the Abductor and Flexor brevis minimi digiti; it then perforates the Opponens minimi digiti and follows the course of the deep palmar arch beneath the flexor tendons. At its origin it supplies the muscles of the little finger. As it crosses the deep part of the hand, it supplies all the Interossei and the two inner Lumbricales; it ends by supplying the Adductores transversus et obliquus pollicis and the inner head of the Flexor brevis pollicis. It also sends articular filaments to the wrist-joint.

It will be remembered that the inner part of the Flexor profundus digitorum is supplied by the ulnar nerve; the two inner Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. In like manner the outer part of the Flexor profundus and the two outer Lumbricales are supplied by the median nerve. Brooks stated that in twelve instances out of twenty-one he found that the Third lumbrical received a twig from the median nerve, in addition to its branch from the ulnar.

The **musculo-spiral** (n. radialis) (fig. 802), the largest branch of the brachial plexus, supplies the muscles of the back part of the arm and forearm, and the integument of the same parts, as well as that of the back of the hand. It arises from the posterior cord of the brachial plexus, of which it may be regarded as the continuation. Its fibres are derived from the sixth, seventh, and eighth cervical nerves, and sometimes also from the fifth cervical and first thoracic nerves. At its commencement it is placed first behind the axillary and then behind the upper part of the brachial artery, passing down in front of the tendons of the Latissimus dorsi and Teres major. It winds round from the inner to the outer side of the humerus in the musculo-spiral groove with the superior profunda artery, between the internal and external heads of the Triceps muscle. It pierces the external intermuscular septum, and descends between the Brachialis anticus and Brachio-radialis to the front of the external epicondyle, where it divides into the radial and posterior interosseous nerves.

The branches of the musculo-spiral nerve are:

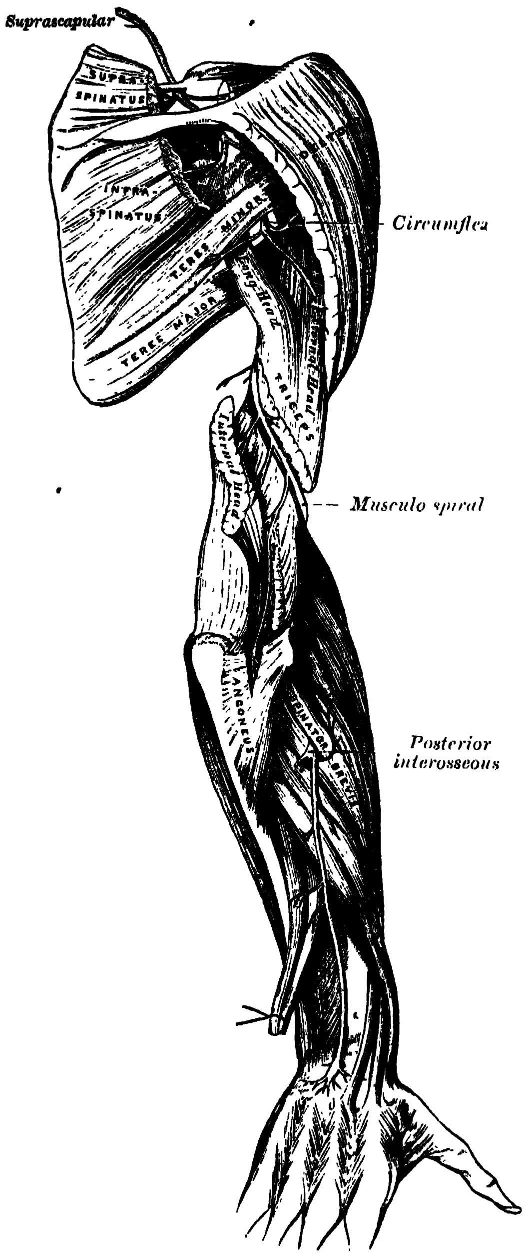
Muscular.	Radial.
Cutaneous.	Posterior interosseous.

The *muscular branches* are derived from the nerve, at the inner side, back part, and outer side of the arm respectively; they supply the Triceps, Anconeus, Brachio-radialis, Extensor carpi radialis longior, and Brachialis anticus.

The internal muscular branches supply the inner and middle heads of the Triceps muscle. That to the inner head of the Triceps is a long, slender filament, which lies close to the ulnar nerve as far as the lower third of the arm, and is therefore frequently spoken of as the *ulnar collateral*.

The posterior muscular branch, of large size, arises from the nerve in the groove between the Triceps and the humerus. It divides into branches, which supply the inner and outer heads of the Triceps and the Anconeus muscles. The branch for the latter muscle is a long, slender filament, which descends in the substance of the inner head of the Triceps to the Anconeus.

Fig. 802.—The suprascapular, circumflex, and musculo-spiral nerves.



The external muscular branches supply the Brachio-radialis, Extensor carpi radialis longior, and (usually) the outer part of the Brachialis anticus.

The *cutaneous branches* are three in number, one internal and two external.

The internal cutaneous branch arises in the axillary space, with the inner muscular branch. It is of small size, and passes through the axilla to the inner side of the arm, supplying the integument on its posterior aspect nearly as far as the olecranon. In its course it crosses beneath the intercosto-humeral, with which it communicates.

The two external cutaneous branches perforate the outer head of the Triceps at its attachment to the humerus. The *upper* and smaller one passes to the front of the elbow, lying close to the cephalic vein, and supplies the integument of the lower half of the arm on its anterior aspect. The *lower* branch pierces the deep fascia below the insertion of the Deltoid, and passes down along the outer side of the arm and elbow, and then along the back part of the radial side of the forearm to the wrist, supplying the integument in its course, and joining, near its termination, with the posterior cutaneous branch of the musculo-cutaneous nerve.

The **radial** (ramus superficialis n. radialis) passes along the front of the radial side of the forearm to the commencement of its lower third. It lies at first a little to the outer side of the radial artery, concealed beneath the Brachio-radialis. In the middle third of the forearm, it lies beneath the same muscle, in close relation with the outer side of the artery. It quits the artery about three inches above the wrist, passes beneath the tendon of the Brachio-radialis, and, piercing the deep fascia at the outer border of the forearm, divides into two branches.

The external branch, the smaller of the two, supplies the integument of the radial side and ball of the thumb, joining with the anterior branch of the musculo-cutaneous nerve.

The internal branch communicates, above the wrist, with the posterior cutaneous branch from the musculo-cutaneous, and, on the back of the hand, with the dorsal cutaneous branch of the ulnar nerve. It then divides into four digital nerves, which are distributed as follows: the first supplies the ulnar side of the thumb; the second, the radial side of the index finger; the third, the adjoining sides of the index and middle fingers; and the fourth, the adjacent borders of the middle and ring fingers.* The latter nerve communicates with a filament from the dorsal branch of the ulnar nerve.

The **posterior interosseous** (n. interosseus antibrachii dorsalis) winds to the back of the forearm round the outer side of the radius, passes between the two planes of fibres of the Supinator brevis, and is prolonged downwards between the superficial and deep layer of muscles, to the middle of the forearm. Considerably diminished in size, it descends on the interosseous membrane, beneath the Extensor longus pollicis, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the ligaments and articulations of the carpus. It supplies all the muscles on the radial side and posterior aspect of the forearm, excepting the Anconeus, Brachio-radialis, and Extensor carpi radialis longior.

Applied Anatomy.—The brachial plexus may be injured by falls from a height on to the side of the head and shoulder, whereby the nerves of the plexus are violently stretched; the fifth cervical nerve sustains the greatest amount of injury, and the subsequent paralysis may be confined to the muscles supplied by this nerve, viz. the Deltoid, Biceps, Brachialis anticus, and Brachio-radialis, with sometimes the Supra- and Infraspinatus and the Supinator brevis. The position of the limb, under such conditions, is characteristic: the arm hangs by the side and is rotated inwards; the forearm is extended and pronated. The arm cannot be raised from the side; all power of flexion of the elbow is lost, as is also supination of the forearm. This is known as Erb's paralysis, and a very similar condition is occasionally met with in new-born children, either from injury to the fifth nerve from the pressure of forceps used in effecting delivery, or from traction of the head in breech presentations. A second variety of partial palsy of the brachial plexus is known as the Klumpke paralysis. In this it is the eighth cervical and first thoracic nerves that are injured, either before or after they have joined to form the lower trunk. Atrophy follows in the intrinsic muscles of the hand, and in the flexors of the fingers and wrists; the thenar and hypothenar eminences waste and flatten; the fingers cannot be spread out or approximated, on account of the paralysis of the Interossei, and become clawed. The injury to the nerves may follow direct violence, or a gunshot wound.

The brachial plexus may also be injured by violent traction on the arm, or by efforts at reducing a dislocation of the shoulder-joint; and the amount of paralysis will depend upon the amount of injury to the constituent nerves. When the entire plexus is involved, the whole of the upper extremity will be paralysed and anæsthetic. In these cases the injury appears to be rather a tearing away of the roots of the nerves from their origin in the spinal cord, than a solution of continuity in the nerves themselves. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as 'crutch paralysis.' In these cases the musculo-spiral seems most frequently to be the nerve chiefly implicated; the ulnar nerve suffers next in frequency. The median and musculo-spiral nerves often suffer from 'sleep palsies,' paralysis from pressure coming on while the patient is profoundly asleep under the influence of alcohol or some narcotic.

Paralysis of the *posterior thoracic nerve* throws the Serratus magnus out of action, and may occur in porters in whom the nerve is exposed to injury in the shoulder as it crosses the posterior triangle of the neck. The lower angle of the scapula is drawn inwards towards the middle line, by the unopposed action of the Rhomboids and Levator anguli scapulæ, and tends to project out backwards when the arm is held horizontally forwards. The arm cannot be raised above the horizontal unless the lower angle of the scapula is pushed outwards for the patient.

The *circumflex nerve*, on account of its course round the surgical neck of the humerus, is liable to be torn in fractures of this part of the bone, and in dislocations of the shoulder-joint; paralysis of the Deltoid, anæsthesia of the skin covering that muscle, and the formation of adhesions in the shoulder-joint in consequence of injury to its trophic nerves, result. According to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it. Paralysis

* According to Hutchinson, the digital nerve to the thumb reaches only as high as the root of the nail: the one to the forefinger as high as the middle of the second phalanx: and the one to the middle and ring fingers not higher than the first phalangeal joint.—*London Hos. Gaz.* vol. iii. p. 319.

of the Deltoid renders abduction of the arm to the horizontal level impossible. The associated paralysis of the Teres minor is not easily demonstrated.

Hilton takes the circumflex nerve as an illustration of a law which he lays down, that 'the same trunks of nerves whose branches supply the groups of muscles moving a joint, furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source.' In this way he explains the fact that an inflamed joint becomes rigid.

The *median nerve* is liable to injury in wounds of the forearm. When it is paralysed, there is loss of flexion of the second phalanges of all the fingers, and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and little fingers is effected by that portion of the Flexor profundus digitorum which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the Interossei. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. There is loss in the power of pronating the forearm ; the Brachio-radialis has the power of bringing the forearm into a position of mid-pronation, but beyond this no further pronation can be effected. The wrist can be flexed, if the hand is first adducted, by the action of the Flexor carpi ulnaris. There is loss or impairment of sensation on the palmar surfaces of the thumb, index, middle, and outer half of ring fingers, and on the dorsal surfaces of the same fingers over the last two phalanges ; except in the thumb, where the loss of sensation would be limited to the back of the last phalanx. In old cases the unopposed action of the Interossei produces backward dislocation of the interphalangeal joints. The thumb is extended and adducted to the index, cannot be flexed or abducted, and cannot be apposed to any one of the fingers; in consequence an 'ape-like' hand is produced. In order to expose the median nerve, for the purpose of uniting the divided ends, supposing the injury to be just above the wrist, an incision should be made along the radial side of the tendon of the Palmaris longus, which serves as a guide to the nerve.

The *ulnar nerve* is also liable to be injured in wounds of the forearm. When paralysed, there is impaired power of ulnar flexion, and upon an attempt being made to flex the wrist, the hand is drawn to the radial side from paralysis of the Flexor carpi ulnaris: there is inability to spread out the fingers from paralysis of the Interossei, and for the same reason the fingers, especially the ring and little fingers, cannot be flexed at the metacarpo-phalangeal joints or extended at the interphalangeal joints, and the hand assumes a claw shape from the action of the opposing muscles ; there is loss of power of flexion in the little and ring fingers ; and there is inability to adduct the thumb. The muscles of the hypothenar eminence become wasted. Sensation is lost, or impaired, in the skin supplied by the nerve. In order to expose the nerve in the lower part of the forearm, an incision should be made along the outer border of the tendon of the Flexor carpi ulnaris, and the nerve will be found lying on the ulnar side of the ulnar artery.

The *musculo-spiral nerve* is probably more frequently injured than any other nerve of the upper extremity. In consequence of its close relationship to the humerus, as it lies in the musculo-spiral groove, it is often torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be contused against the bone by kicks or blows, or to be divided by wounds of the arm. When paralysed, the hand is flexed at the wrist and lies flaccid. This is known as *wrist-drop*. The fingers are also flexed, and on an attempt being made to extend them, the last two phalanges only will be extended, through the action of the Interossei ; the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but is possible to a certain extent if the forearm be flexed so as to allow of the action of the Biceps. The power of extension of the forearm is lost on account of paralysis of the Triceps, if the injury to the nerve has taken place near its origin. In cases due to pressure, sensation is hardly affected ; severe injury to the nerve occasions anæsthesia over the area supplied by the radial nerve, and, if the lesion be high up, on the outer side of the upper arm and the back of the forearm (external and internal cutaneous branches) as well.

The nerve is best exposed by making an incision along the inner border of the Brachio-radialis, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in this structure indicating the border of the muscle is to be defined, and the deep fascia divided in this line. By now raising the Brachio-radialis, the nerve will be found lying between it and the Brachialis anticus. The muscles supplied by the posterior interosseous branch of the musculo-spiral nerve are also particularly liable to be affected in chronic lead poisoning.

THORACIC NERVES (NN. THORACALES)

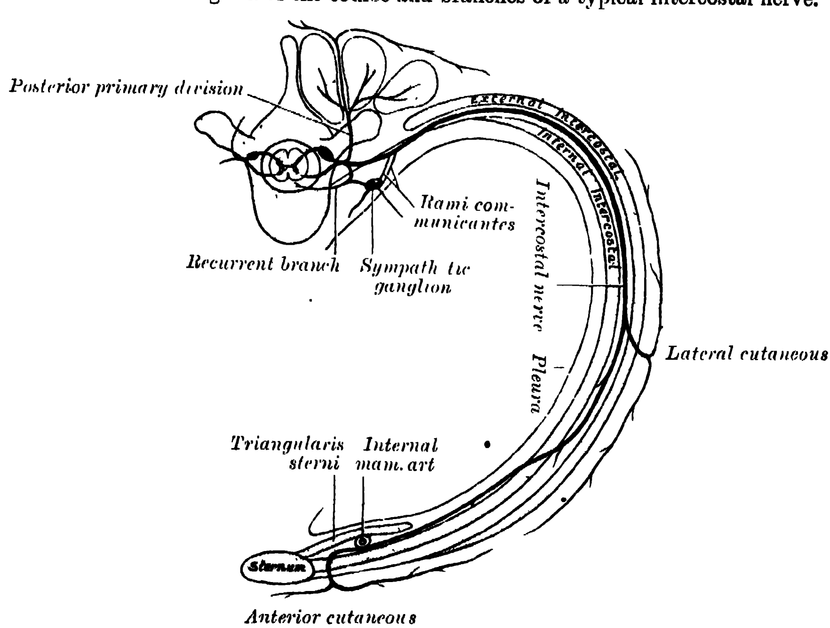
The anterior primary divisions of the thoracic nerves are twelve in number on either side. Eleven of them are situated between the ribs, and are therefore termed *intercostal* ; the twelfth lies below the last rib. Each nerve is connected

with the adjoining ganglion of the sympathetic by one or two filaments. The intercostal nerves are distributed chiefly to the parietes of the thorax and abdomen, and differ from the anterior divisions of the other spinal nerves, in that each pursues an independent course, i.e. there is no plexus formation. The first two nerves supply fibres to the upper limb in addition to their thoracic branches; the next four are limited in their distribution to the parietes of the thorax; the five lower supply the parietes of the chest and abdomen. The twelfth thoracic is distributed to the abdominal wall and the skin of the buttock.

The **first thoracic nerve.**—The anterior division of the first thoracic nerve divides into two branches; one, the larger, leaves the thorax in front of the neck of the first rib, and enters into the formation of the brachial plexus; the other and smaller branch runs along the first intercostal space, forming the *first intercostal nerve*, and terminates on the front of the chest, by forming the first anterior cutaneous nerve of the thorax. Occasionally this anterior cutaneous branch is wanting. The first intercostal nerve as a rule gives off no lateral cutaneous branch; but sometimes a small branch is given off, to communicate with the intercosto-humeral. It frequently receives a connecting twig from the second thoracic nerve, which passes upwards over the neck of the second rib.

The **upper thoracic nerves.**—The anterior divisions of the second, third, fourth, fifth, and sixth thoracic nerves, and the small branch from the first thoracic, are confined to the parietes of the thorax, and are named *thoracic intercostal nerves*. They pass forwards (fig. 803) in the intercostal spaces below the intercostal vessels. At the back of the chest they lie between the pleura and the posterior intercostal membranes, but soon pierce the latter and run between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the Internal intercostal muscles, and, running

FIG. 803.—Diagram of the course and branches of a typical intercostal nerve.



amidst their fibres as far as the costal cartilages, they gain the inner surfaces of the muscles and lie between them and the pleura. Near the sternum, they cross in front of the internal mammary artery and Triangularis sterni muscle, pierce the Internal intercostal muscles, the anterior intercostal membranes, and Pectoralis major muscle, and supply the integument of the front of the chest and over the mammary gland, forming the anterior cutaneous nerves (rami cutanei anteriores) of the thorax; the branch from the second nerve is joined with the supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments supply the Intercostals, the Infracostales, the Levatores costarum, the Serratus posticus superior, and the Triangularis sterni muscles. At the front of the chest some of these branches cross the costal cartilages from one intercostal space to another.

Lateral cutaneous nerves (rami cutanei laterales).—These are derived from the intercostal nerves, midway between the vertebræ and sternum; they pierce the External intercostal and Serratus magnus muscles, and divide into anterior and posterior branches.

The *anterior branches* (rami anteriores) are reflected forwards to the side and the fore part of the chest, supplying the integument of the chest and mamma; those of the fifth and sixth nerves supply the upper digitations of the External oblique.

The *posterior branches* (rami posteriores) are reflected backwards, to supply the integument over the scapula and over the Latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve is of large size, and does not divide, like the other nerves, into an anterior and a posterior branch. It is named, from its origin and distribution, the *intercosto-humeral* nerve (n. intercostobrachialis) (fig. 801). It pierces the External intercostal muscle and the Serratus magnus, crosses the axilla to the inner side of the arm, and joins with a filament from the nerve of Wrisberg. It then pierces the fascia, and supplies the skin of the upper half of the inner and back part of the arm, communicating with the internal cutaneous branch of the musculo-spiral nerve. The size of this nerve is in inverse proportion to the size of the other cutaneous nerves, especially the nerve of Wrisberg. A second intercosto-humeral nerve is frequently given off from the third intercostal. It supplies filaments to the armpit and inner side of the arm.

The **lower thoracic nerves.**—The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh thoracic nerves are continued anteriorly from the intercostal spaces into the abdominal wall; hence these nerves are named *thoracico-abdominal intercostal nerves.* They have the same arrangement as the upper ones as far as the anterior extremities of the intercostal spaces, where they pass behind the costal cartilages, and between the Internal oblique and Transversalis muscles, to the sheath of the Rectus, which they perforate. They supply the Rectus muscle, and terminate in branches which become subcutaneous near the linea alba. These branches are named the *anterior cutaneous nerves* of the abdomen. They are directed outwards as far as the lateral cutaneous nerves and supply the integument of the front of the belly. The lower intercostal nerves supply the Intercostal and Abdominal muscles—the last three send branches to the Serratus posticus inferior—and, about the middle of their course, give off lateral cutaneous branches. These pierce the External intercostal muscles and the External oblique, in the same line as the lateral cutaneous nerves of the thorax, and divide into anterior and posterior branches, which are distributed to the integument of the abdomen and back; the anterior branches supply the digitations of the External oblique muscle, and extend downwards and forwards nearly as far as the margin of the Rectus: the posterior branches pass backwards to supply the skin over the Latissimus dorsi.

The anterior division of the **last thoracic** is larger than the others; it runs along the lower border of the last rib, often gives a communicating branch to the first lumbar nerve, and passes under the external arcuate ligament of the Diaphragm. It then runs in front of the Quadratus lumborum, perforates the Transversalis, and passes forwards between it and the Internal oblique, to be distributed in the same manner as the lower intercostal nerves. It communicates with the ilio-hypogastric branch of the lumbar plexus, and gives a branch to the Pyramidalis muscle.

The *lateral cutaneous branch of the last thoracic* is remarkable for its large size. It does not divide into an anterior and a posterior branch like the lateral cutaneous branches of the intercostal nerves, but perforates the Internal and External oblique muscles, passes downwards over the crest of the ilium in front of the iliac branch of the ilio-hypogastric (fig. 811), and is distributed to the integument of the front part of the gluteal region, some of its filaments extending as low down as the trochanter major.

Applied Anatomy.—The lower seven thoracic nerves and the ilio-hypogastric from the first lumbar nerve supply the skin of the abdominal wall. They run downwards and inwards fairly equidistant from each other. The sixth and seventh supply the skin over the 'pit of the stomach'; the eighth corresponds to about the position of the middle linea transversa; the tenth to the umbilicus; and the ilio-hypogastric supplies the skin over the pubis and external abdominal ring. In many diseases affecting the nerve-trunks at or near their origins, the pain is referred to their peripheral terminations. Thus, in Pott's disease of the spine, children will often be brought to the surgeon suffering from pain in the belly. This is due to the fact that the nerves are irritated at the seat of disease as they issue from the spinal canal. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied round the abdomen, and in these cases the situation of the sense of constriction may serve to localise the disease in the spinal column. In other cases where the bone disease is more extensive, and two or more nerves are involved, a more general, diffused pain in the abdomen is felt.

Again, it must be borne in mind that the same nerves which supply the skin of the abdomen supply also the planes of muscle which constitute the greater part of the abdominal wall. Hence, it follows that any irritation applied to the peripheral terminations of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be over-estimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more rapid response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

Again, the nerves supplying the abdominal muscles and skin, derived from the lower intercostal nerves, are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in laceration of the abdominal viscera and in acute peritonitis, the muscles of the belly wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

Inflammation of the ganglia on one or more of any of the posterior nerve-roots is the cause of *shingles* * or herpes zoster, in which there is a painful eruption of groups of cutaneous vesicles corresponding to the distribution of the nerves derived from the affected ganglia. It is commonest in the intercostal nerves; the eruption is often preceded and followed, as well as accompanied, by girdle pains, and in old people these may be prolonged and serious in character. Herpes is the analogue on the sensory side to anterior poliomyelitis (page 810) on the motor side of the nervous system.

LUMBO-SACRAL PLEXUS

The anterior primary divisions of the lumbar, sacral and coccygeal nerves form the lumbo-sacral plexus, the first lumbar nerve being frequently joined by a branch from the twelfth thoracic. For descriptive purposes this plexus is usually divided into three parts—the lumbar, sacral and pudendal plexuses.

LUMBAR NERVES (NN. LUMBALES)

The **anterior primary divisions of the lumbar nerves** increase in size from above downwards. They are joined, near their origins, by *grey rami communicantes* from the lumbar ganglia of the sympathetic cord. These rami consist of long, slender branches which accompany the lumbar arteries round the sides of the vertebral bodies, beneath the Psoas magnus. Their arrangement is somewhat irregular: one ganglion may give rami to two lumbar nerves, or one lumbar nerve may receive rami from two ganglia. The first and second, and sometimes the third and fourth lumbar nerves are each connected with the lumbar part of the sympathetic cord by a *white ramus communicans*. The nerves pass obliquely outwards behind the Psoas magnus, or between its fasciculi, distributing filaments to it and the Quadratus lumborum. The first

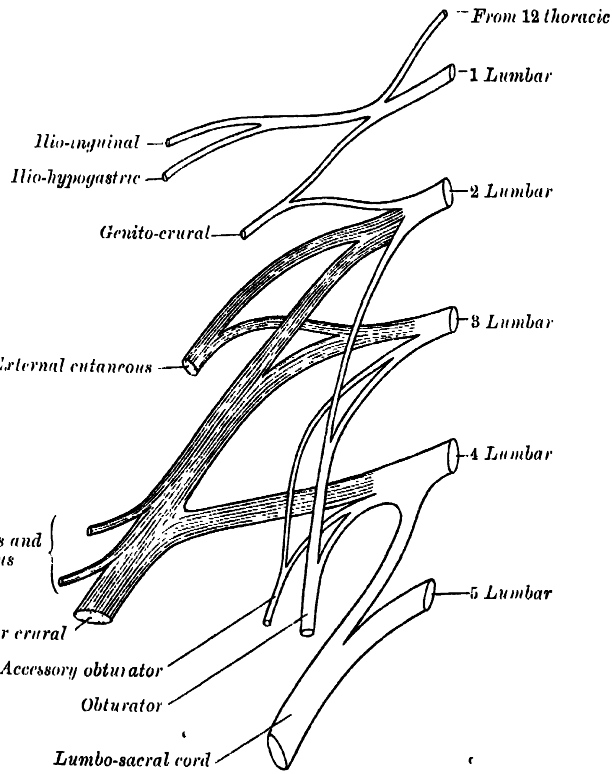
* From Lat. *cingulum*, a belt.

three and the greater part of the fourth are connected together in this situation by anastomotic loops, and form the *lumbar plexus*. The smaller part of the fourth joins with the fifth to form the *lumbo-sacral cord* (truncus lumbosacralis), which assists in the formation of the sacral plexus. The fourth nerve is named the *nervus furcalis*, from the fact that it is subdivided between the two plexuses.*

Lumbar Plexus (Plexus lumbalis)

The **lumbar plexus** (fig. 804) is formed by the loops of communication between the anterior divisions of the first three and the greater part of the fourth lumbar nerves. The plexus is narrow above, and the first lumbar often receives a branch from the last thoracic nerve; it is broad below, where it is joined to the sacral plexus by the lumbo-sacral cord. It is situated in the posterior part of the Psoas magnus, in front of the transverse processes of the lumbar vertebræ.

Fig. 804.—Plan of lumbar plexus.

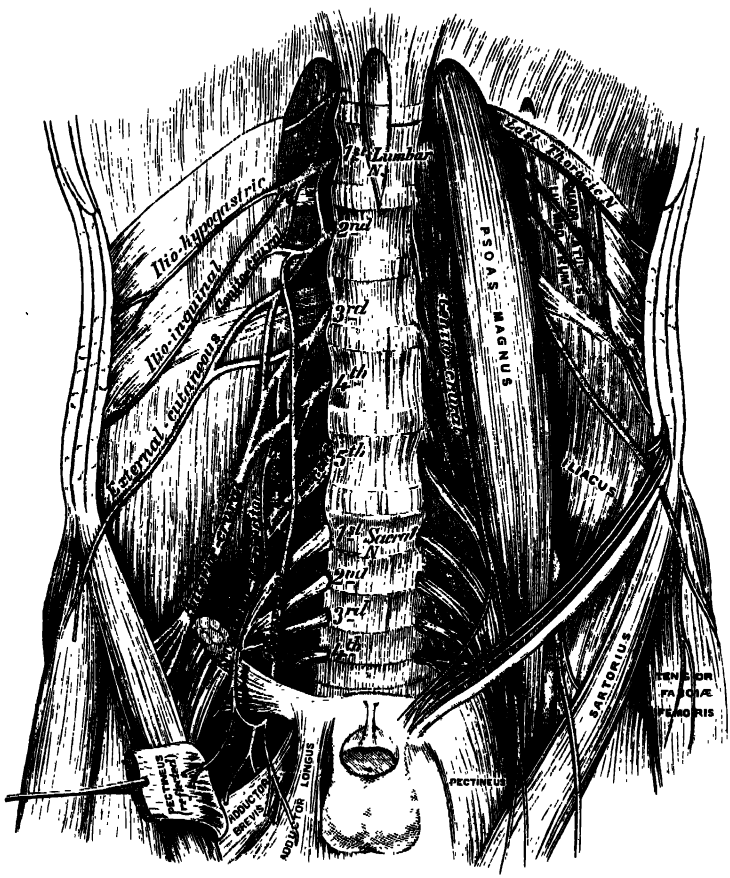


The mode in which the plexus is arranged varies in different subjects. It differs from the brachial plexus in not forming an intricate interlacement, but the several nerves of distribution arise from one or more of the spinal nerves, somewhat in the following manner: the first lumbar nerve frequently receives a twig from the last thoracic, and divides into an upper and lower branch; the upper and larger branch subdivides into the ilio-hypogastric and ilio-inguinal; the lower and smaller branch unites with a branch of the second lumbar to form

* In most cases the fourth lumbar is the *nervus furcalis*; but this arrangement is frequently departed from. The third is occasionally the lowest nerve which enters the lumbar plexus, giving at the same time some fibres to the sacral plexus, and thus forming the nervus furcalis; or both the third and fourth may be furcal nerves. When this occurs, the plexus is termed *high* or *pre-fixed*. More frequently the fifth nerve is divided between the lumbar and sacral plexuses, and constitutes the nervus furcalis; and when this takes place, the plexus is distinguished as a *low* or *post-fixed* plexus. These variations necessarily produce corresponding modifications in the sacral plexus.

the genito-crural nerve. The remainder of the second nerve, and the third and fourth nerves, divide into ventral and dorsal divisions. The ventral division of the second unites with the ventral divisions of the third and fourth nerves to form the obturator nerve. The dorsal divisions of the second and third nerves divide into two branches, a smaller branch from each uniting to form the external cutaneous nerve, and a larger branch from each joining with the dorsal division of the fourth lumbar nerve to form the anterior

FIG. 805.—The lumbar plexus and its branches.



crural nerve. The accessory obturator, when it exists, is formed by the union of two small branches given off from the third and fourth nerves.

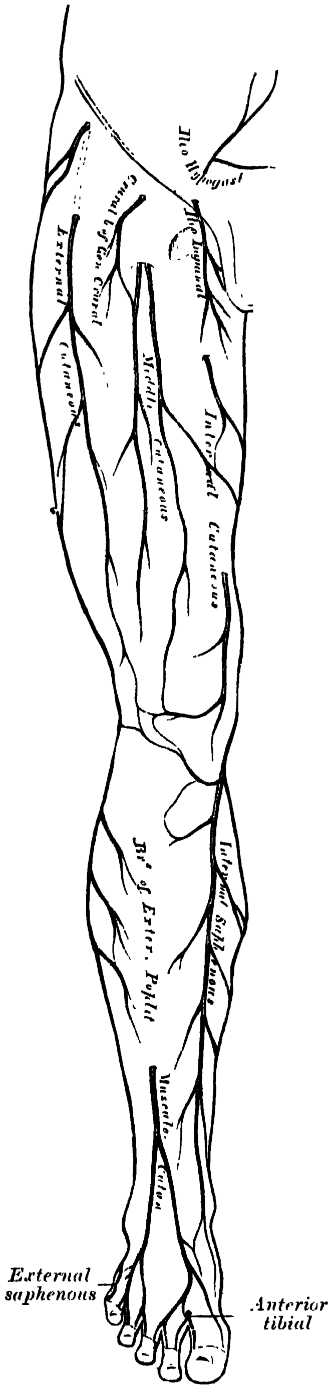
The branches of the lumbar plexus may therefore be arranged as follows :

Ilio-hypogastric	1 L.
Ilio-inguinal	1 L.
Genito-crural	1, 2 L.
	Dorsal divisions.
External cutaneous	2, 3, L.
Anterior crural	2, 3, 4 L.
	Ventral divisions.
Obturator	2, 3, 4 L.
Accessory obturator	3, 4 L.

The **ilio-hypogastric** (n. iliohypogastricus) arises from the first lumbar nerve. It emerges from the outer border of the Psoas muscle at its upper

part, and crosses obliquely in front of the Quadratus lumborum to the crest of the ilium. It then perforates the Transversalis muscle at its posterior part, near the crest of the ilium, and divides between it and the Internal oblique into two branches, iliac and hypogastric.

Fig. 806.—Cutaneous nerves of lower extremity. Front view.



The *iliac branch* (ramus cutaneus lateralis) pierces the Internal and External oblique muscles immediately above the crest of the ilium, and is distributed to the integument of the gluteal region, behind the lateral cutaneous branch of the last thoracic nerve (fig. 811). The size of the nerve bears an inverse proportion to that of the lateral cutaneous branch of the last thoracic nerve.

The *hypogastric branch* (ramus cutaneus anterior) (fig. 806) continues onwards between the Internal oblique and Transversalis muscles. It then pierces the Internal oblique, and becomes cutaneous by perforating the aponeurosis of the External oblique, about an inch above, and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The ilio-hypogastric nerve communicates with the last thoracic and ilio-inguinal nerves.

The **ilio-inguinal** (n. ilioinguinalis), smaller than the preceding, arises with it from the first lumbar nerve. It emerges from the outer border of the Psoas just below the ilio-hypogastric, and, passing obliquely across the Quadratus lumborum and Iliacus muscles, perforates the Transversalis, near the fore part of the crest of the ilium, and communicates with the ilio-hypogastric nerve between that muscle and the Internal oblique. The nerve then pierces the Internal oblique, distributing filaments to it, and, accompanying the spermatic cord through the external abdominal ring, is distributed to the integument of the upper and inner part of the thigh, to the skin over the root of the penis and upper part of the scrotum in the male, and to the skin covering the mons Veneris and labium majus in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases, a branch from the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent.

The **genito-crural** (n. genitofemoralis) arises from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas, and emerges from its inner border, close to the vertebral column, opposite the disc between the third and fourth lumbar vertebræ; it then descends on the

surface of the Psoas muscle, under cover of the peritoneum, and divides into a genital and a crural branch. Occasionally the two branches emerge separately through the substance of the Psoas.

FIG. 807.—Segmental distribution of cutaneous nerves of right lower extremity. Front view.

The *genital branch* (n. spermaticus externus) passes outwards on the Psoas magnus, and pierces the fascia transversalis, or passes through the internal abdominal ring; it then descends along the back part of the spermatic cord to the scrotum, supplies, in the male, the Cremaster muscle, and gives a few filaments to the skin of the scrotum. In the female, it accompanies the round ligament, and is lost upon it.

The *crural branch* (n. lumboinguinalis) descends on the external iliac artery, sending a few filaments round it, and, passing beneath Poupart's ligament to the thigh, enters the sheath of the femoral vessels, lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

A few filaments from this nerve may be traced on to the femoral artery; they are derived from the nerve as it passes beneath Poupart's ligament.

The **external cutaneous** (n. cutaneus femoris lateralis) arises from the second and third lumbar nerves. It emerges from the outer border of the Psoas muscle about its middle, and crosses the Iliacus muscle obliquely, towards the anterior superior spine of the ilium. It then passes under Poupart's ligament and over the Sartorius muscle into the thigh, where it divides into two branches, an anterior and a posterior.

The *anterior branch* descends in an aponeurotic canal formed in the fascia lata, becomes superficial about four inches below Poupart's ligament, and divides into branches which are distributed to the integument along the anterior and outer part of the thigh, as far down as the knee. The terminal filaments of this nerve frequently communicate with the middle and internal cutaneous, and with the patellar branch of the long saphenous, forming with them the *patellar plexus*.

The *posterior branch* pierces the fascia lata, and subdivides into

filaments which pass backwards across the outer and posterior surface of the thigh, supplying the integument from the level of the great trochanter to the middle of the thigh.

The **obturator** (n. obturatorius) supplies the Obturator externus and the Adductor muscles of the thigh, the articulations of the hip and knee, and occasionally part of the integument of the thigh and leg. It arises from the second, third, and fourth lumbar nerves. Of these, the branch from the third is the largest, while that from the second is often very small. It descends through the inner fibres of the Psoas muscle, and emerges from its inner border near the brim of the pelvis; it then passes behind the external iliac vessels which separate it from the ureter, and runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen. Here it enters the thigh, and divides into an anterior and a posterior branch, which are separated at first by some of the fibres of the Obturator externus (fig. 545), and lower down by the Adductor brevis.

The *anterior branch* (ramus anterior) (fig. 808) passes down in front of the Adductor brevis, being covered by the Pectineus and Adductor longus; at the lower border of the latter muscle it communicates with the internal cutaneous and internal saphenous branches of the anterior crural, forming a kind of plexus. It then descends upon the femoral artery, to which it is finally distributed. The nerve, near the obturator foramen, gives off an articular branch to the hip-joint. Behind the Pectineus, it distributes muscular branches to the Adductor longus and Gracilis, and usually to the Adductor brevis, and in rare cases to the Pectineus, and receives a communicating branch from the accessory obturator nerve when that nerve is present.

Occasionally the communicating branch to the internal cutaneous and internal saphenous nerves is continued down, as a cutaneous branch, to the thigh and leg. When this is so, it emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the inner side of the knee, where it pierces the deep fascia, communicates with the long saphenous nerve, and is distributed to the integument of the inner side of the leg as low down as its middle. When this communicating branch is small, its place is taken by the internal cutaneous nerve.

The *posterior branch* (ramus posterior) pierces the anterior part of the Obturator externus, sending branches to supply this muscle; it then passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches, which supply the Adductor magnus, and the Adductor brevis when the latter does not receive a branch from the anterior division of the nerve. It also gives off an articular filament to the knee-joint.

The *articular branch for the knee-joint* is sometimes absent; it either perforates the lower part of the Adductor magnus, or passes through the opening which transmits the femoral artery, and enters the popliteal space; it then descends upon the popliteal artery, as far as the back part of the knee-joint, where it perforates the posterior ligament, and is distributed to the synovial membrane. It gives filaments to the artery in its course.

The **accessory obturator** (n. obturatorius accessorius) (fig. 805) is present in about 29 per cent. of cases. It is of small size, and arises by separate filaments from the third and fourth lumbar nerves. It descends along the inner border of the Psoas muscle, crosses the ascending ramus of the pubis, and passes under the outer border of the Pectineus muscle, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its under surface; another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. When this nerve is absent, the hip-joint receives two branches from the obturator nerve. Occasionally it is very small and becomes lost in the capsule of the hip-joint.

The **anterior crural** (n. femoralis) (figs. 805, 808) is the largest branch of the lumbar plexus. It supplies muscular branches to the Iliacus, Pectineus, and all the muscles on the front of the thigh, except the Tensor fasciæ femoris; cutaneous filaments to the front and inner side of the thigh, and to the leg and foot; and articular branches to the hip and knee. It arises from the second, third, and fourth lumbar nerves. It descends through the fibres

of the Psoas, emerging from the muscle at the lower part of its outer border, and passes down between it and the Iliacus behind the fascia iliaca; it then runs beneath Poupart's ligament, into the thigh, where it becomes somewhat flattened, and divides into an anterior and a posterior part. Under Poupart's ligament it is separated from the femoral artery by a portion of the Psoas.

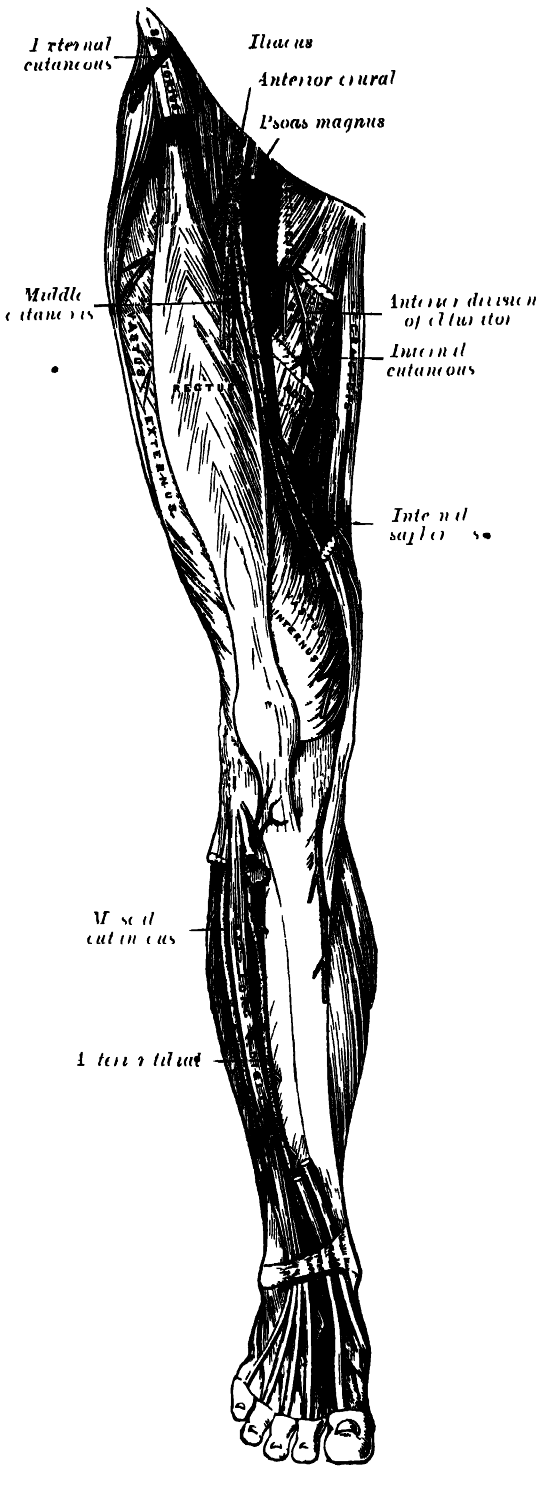


Fig. 808.—Nerves of the right lower extremity. Front view.

Within the abdomen the anterior crural nerve gives off from its outer side some small branches to the Iliacus, and a branch to the femoral artery which is distributed upon the upper part of that vessel. The origin of this branch varies: it occasionally arises higher than usual, or it may arise lower down in the thigh.

In the thigh the following branches are given off:

From the Anterior Division.

Middle cutaneous.
Internal cutaneous.
Muscular.

From the Posterior Division.

Long saphenous.
Muscular.
Articular.

The *middle cutaneous nerve* (fig. 806) pierces the fascia lata (and generally the Sartorius) about three inches below Poupart's ligament, and divides into two branches (rami cutanei anteriores) which descend in immediate proximity along the fore part of the thigh, to supply the integument as low as the front of the knee. Here they communicate with the internal cutaneous nerve and the patellar branch of the internal saphenous, to form the patellar plexus. In the upper part of the thigh the outer division of the middle cutaneous communicates with the crural branch of the genito-crural nerve.

The *internal cutaneous nerve* passes obliquely across the upper part of the

sheath of the femoral artery, and divides in front, or at the inner side of that vessel, into two branches, an anterior and a posterior or internal.

The *anterior branch* runs downwards on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches: one supplies the integument as low down as the inner side of the knee; the other crosses to the outer side of the patella, communicating in its course with the patellar branch of the long saphenous nerve.

The *posterior* or *internal branch* descends along the inner border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with the long saphenous nerve, and gives off several cutaneous branches. It then passes down to supply the integument of the inner side of the leg. Beneath the fascia lata, at the lower border of the Adductor longus, it joins to form a plexiform network (*subsartorial plexus*) with branches of the long saphenous and obturator nerves (fig. 808). When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the internal branch of the internal cutaneous is small, and terminates in the plexus, occasionally giving off a few cutaneous filaments.

The internal cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the integument of the inner side of the thigh, accompanying the long saphenous vein. One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh; a third pierces the fascia at its lower third.

Muscular branches of the anterior division.—The *nerve to the Pectineus* arises from the anterior crural immediately below Poupart's ligament, and passes inwards behind the femoral sheath to enter the anterior surface of the muscle; it is often duplicated. The *nerve to the Sartorius* arises in common with the middle cutaneous.

The *long* or *internal saphenous nerve* (n. saphenus) is the largest cutaneous branch of the anterior crural. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies in front of it, beneath the aponeurotic covering of Hunter's canal, as far as the opening in the lower part of the Adductor magnus. It then quits the artery, and descends vertically along the inner side of the knee beneath the Sartorius, pierces the fascia lata, opposite the interval between the tendons of the Sartorius and Gracilis, and becomes subcutaneous. The nerve then passes along the inner side of the leg, accompanied by the internal saphenous vein, descends behind the internal border of the tibia, and, at the lower third of the leg, divides into two branches: one continues its course along the margin of the tibia, terminating at the inner ankle; the other passes in front of the ankle, and is distributed to the integument along the inner side of the foot, as far as the ball of the great toe, communicating with the internal branch of the musculo-cutaneous nerve.

Branches.—The long saphenous nerve, about the middle of the thigh, gives off a communicating branch which joins the subsartorial plexus.

At the inner side of the knee it gives off a large *patellar branch* (ramus infrapatellaris) which pierces the Sartorius and fascia lata, and is distributed to the integument in front of the patella. This nerve communicates above the knee with the anterior branch of the internal cutaneous and with the middle cutaneous; below the knee, with other branches of the long saphenous; and, on the outer side of the joint, with branches of the external cutaneous nerve, forming a plexiform network, the *plexus patellæ*. The patellar branch is occasionally small, and terminates by joining the internal cutaneous, which supplies its place in front of the knee.

Below the knee, the branches of the long saphenous nerve are distributed to the integument of the front and inner side of the leg, communicating with the cutaneous branches from the internal cutaneous, or from the obturator nerve.

The *muscular branches of the posterior division* supply the four parts of the Quadriceps extensor muscle.

The *branch to the Rectus femoris* enters the under surface of the muscle high up, sending off a small filament to the hip-joint.

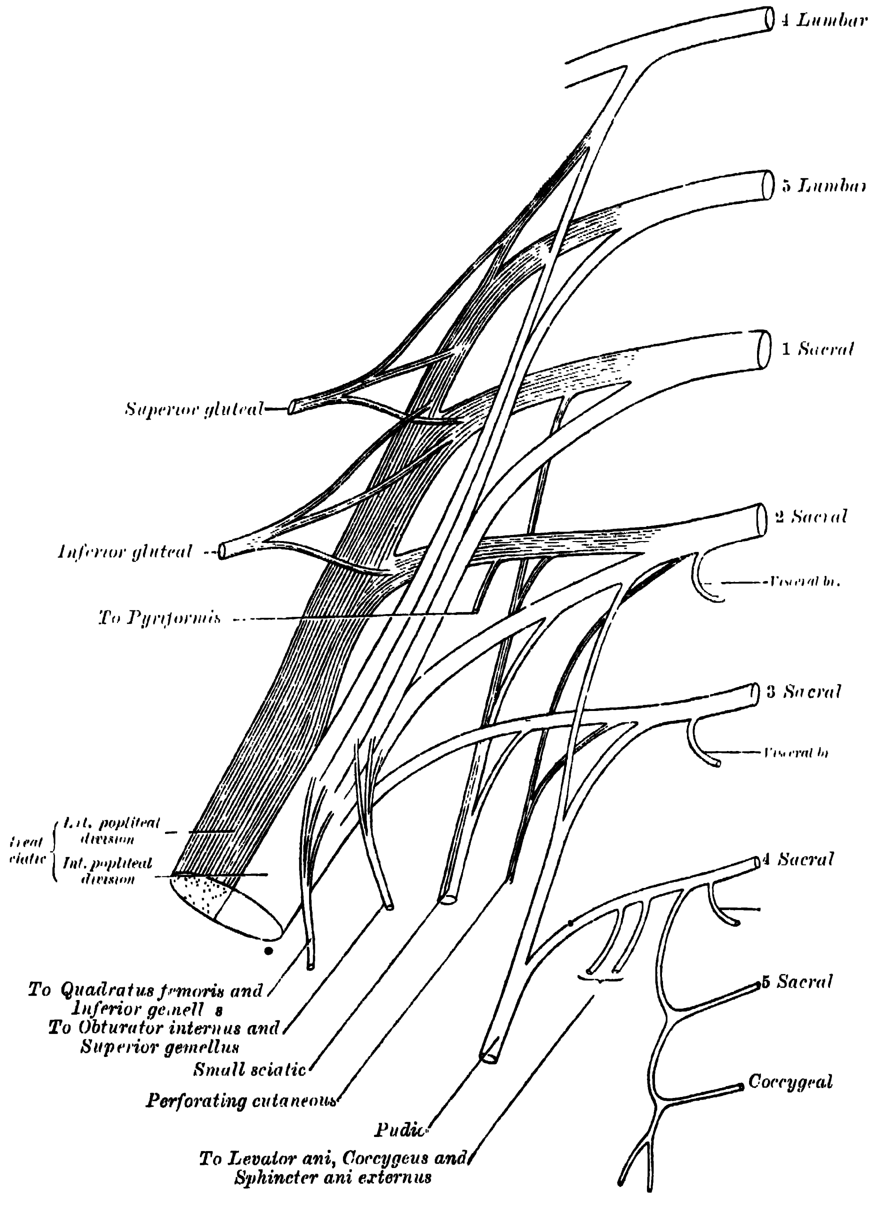
The *branch to the Vastus externus*, of large size, follows the course of the descending branch of the external circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint.

The ***branch to the Vastus internus*** is a long filament running down on the outer side of the femoral vessels in company with the internal saphenous nerve. It enters the muscle about its middle, and gives off a filament, which can usually be traced downwards, on the surface of the muscle, to the knee-joint.

The *branches to the Crureus* are two or three in number, and enter the muscle on its anterior surface about the middle of the thigh; a filament from one of these descends through the muscle to the Subcrureus and the knee-joint.

The *articular branch to the hip-joint* is derived from the nerve to the Rectus.

FIG. 809.—Plan of sacral and pudendal plexuses.



The ***articular branches to the knee-joint*** are three in number. One, a long, slender filament, is derived from the nerve to the Vastus externus; it penetrates the capsular ligament of the joint on its anterior aspect. Another is derived from the nerve to the Vastus internus. It can usually be traced downwards

on the surface of this muscle to near the joint; it then penetrates the muscular fibres, and accompanies the deep branch of the anastomotica magna artery, pierces the capsular ligament of the joint on its inner side, and supplies the synovial membrane. The third branch is derived from the nerve to the Crureus.

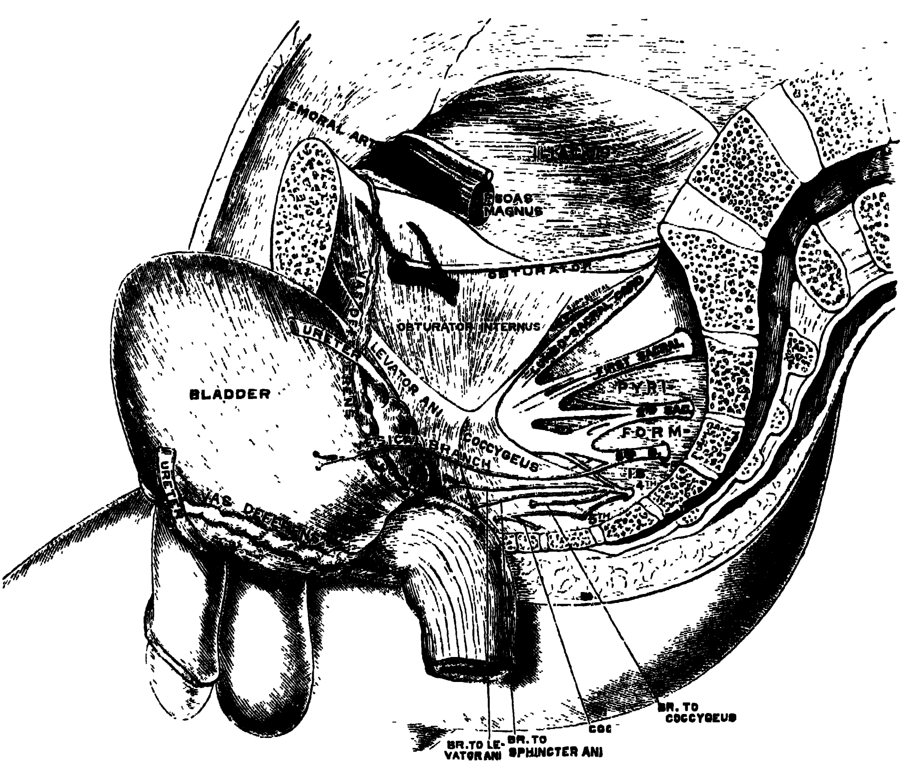
SACRAL AND COCCYGEAL NERVES (NN. SACRALES ET COCCYGEUS)

The **anterior primary divisions of the sacral and coccygeal nerves** form the sacral and pudendal plexuses. The anterior divisions of the upper four sacral nerves enter the pelvis through the anterior sacral foramina, that of the fifth between the sacrum and coccyx, while that of the coccygeal nerve curves forwards below the rudimentary transverse process of the first piece of the coccyx. The first and second sacral are large; the third, fourth, and fifth diminish progressively from above downwards. Each nerve receives a *grey ramus communicans* from the corresponding ganglion of the sympathetic cord, while from the third, and frequently from the second and fourth sacral nerves *white rami communicantes* are given to the pelvic plexuses of the sympathetic.

Sacral Plexus (Plexus Sacralis)

The **sacral plexus** (fig. 809) is formed by the lumbo-sacral cord, the anterior primary division of the first, and portions of the anterior primary divisions of the second and third sacral nerves.

Fig. 810.—Side view of pelvis, showing sacral nerves.



The lumbo-sacral cord comprises the whole of the anterior primary division of the fifth and a part of that of the fourth lumbar nerves; it appears at the inner margin of the Psoas magnus and runs downwards over the pelvic brim to join the first sacral nerve. The third sacral nerve divides into an upper and

a lower branch, the former entering the sacral and the latter the pudendal plexus.

The nerves forming the sacral plexus converge towards the lower part of the great sacro-sciatic foramen, and unite to form a flattened band, from the anterior and posterior surfaces of which several branches arise. The band itself is continued as the great sciatic nerve, which splits on the back of the thigh into the internal and external popliteal nerves; these two nerves sometimes arise separately from the plexus, and in all cases their independence can be shown by dissection.

Relations.—The sacral plexus lies on the back of the pelvis between the Pyriformis and the pelvic fascia (fig. 810); in front of it are the internal iliac vessels, the ureter and the pelvic colon. The gluteal vessels run between the lumbo-sacral cord and the first sacral nerve, and the sciatic vessels between the second and third sacral nerves.

All the nerves entering the plexus, with the exception of the third sacral, split into ventral and dorsal divisions, and the nerves arising from these are as follows:

	Ventral divisions.	Dorsal divisions.
Nerve to Quadratus femoris and Inferior gemellus	4, 5 L, 1 S.	
Nerve to Obturator internus and Superior gemellus	5 L, 1, 2 S.	
Nerve to Pyriformis		(1) 2 S.
Superior gluteal		4, 5 L, 1 S.
Inferior gluteal		5 L, 1, 2 S.
Small sciatic	2, 3 S	1, 2 S.
Great sciatic: Internal popliteal	4, 5 L, 1, 2, 3 S.	
Great sciatic: External popliteal		4, 5 L, 1, 2 S.

The **nerve to the Quadratus femoris and Inferior gemellus** arises from the ventral divisions of the fourth and fifth lumbar and first sacral nerves: it leaves the pelvis through the great sacro-sciatic foramen, below the Pyriformis, and runs down in front of the great sciatic nerve, the Gemelli and the tendon of the Obturator internus, and enters the anterior surfaces of the muscles; it gives an articular branch to the hip-joint.

The **nerve to the Obturator internus** arises from the ventral divisions of the fifth lumbar and first and second sacral nerves: it leaves the pelvis through the great sacro-sciatic foramen below the Pyriformis muscle, crosses the ischial spine, re-enters the pelvis through the small sacro-sciatic foramen, and ends, after entering the pelvic surface of the muscle, in the Obturator internus. The branch to the Gemellus superior enters the upper part of the posterior surface of the muscle.

The **nerve to the Pyriformis** arises from the dorsal division of the second, or the dorsal divisions of the first and second, sacral nerves, and enters the anterior surface of the muscle: this nerve may be double.

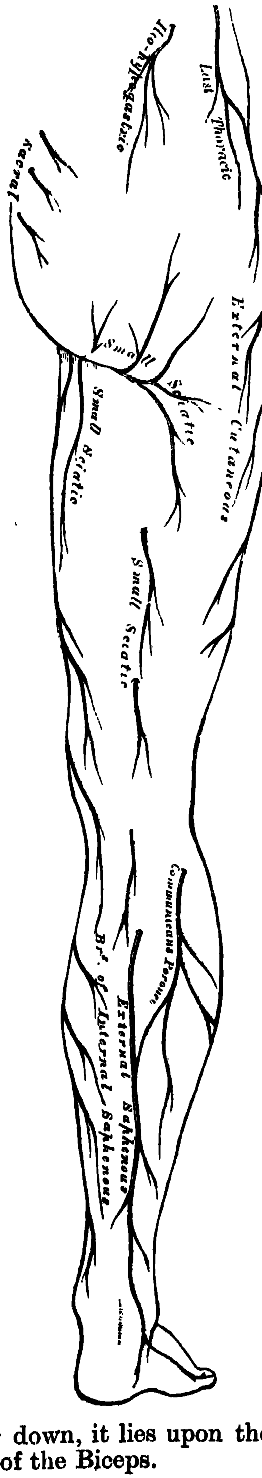
The **superior gluteal** (n. glutæus superior) arises from the dorsal divisions of the fourth and fifth lumbar and first sacral nerves: it leaves the pelvis through the great sacro-sciatic foramen above the Pyriformis, accompanied by the gluteal vessels, and divides into a superior and an inferior branch. The *superior* branch accompanies the upper branch of the deep division of the gluteal artery and ends in the Gluteus minimus. The *inferior* branch runs with the lower branch of the gluteal artery across the Gluteus minimus; it gives filaments to the Gluteus medius and Gluteus minimus, and ends in the Tensor fasciæ femoris.

The **inferior gluteal** (n. glutæus inferior) arises from the dorsal divisions of the fifth lumbar and first and second sacral nerves: it leaves the pelvis through the great sacro-sciatic foramen, below the Pyriformis, and divides into branches which enter the deep surface of the Gluteus maximus.

The **small sciatic** (n. cutaneus femoris posterior) is distributed to the skin of the perinæum and posterior surface of the thigh and leg. It arises partly from the ventral and partly from the dorsal divisions of the first, second, and third sacral nerves, and issues from the pelvis through the great sacro-sciatic foramen below the Pyriformis. It then descends beneath the Gluteus maximus with the sciatic artery, and runs down the back of the thigh beneath

the fascia lata, and over the long head of the Biceps to the back of the knee: here it pierces the fascia and accompanies the external saphenous vein to about the middle of the back of the leg, its terminal twigs communicating with the external saphenous nerve.

FIG. 811.—Cutaneous nerves of right lower extremity. Posterior view.



Its branches are all cutaneous, and are grouped as follows: gluteal, perineal, and femoral.

The *gluteal branches*, three or four in number, turn upwards round the lower border of the Gluteus maximus, and supply the skin covering the lower and outer part of that muscle.

The *perineal branches* (rami perineales) are distributed to the skin at the upper and inner side of the thigh. One branch, longer than the rest, the *inferior pudendal*, curves forwards below and in front of the ischial tuberosity, pierces the fascia lata, and runs forwards beneath the superficial fascia of the perinæum to the skin of the scrotum in the male, and of the labium majus in the female. It communicates with the inferior hæmorrhoidal and superficial perinæal nerves.

The *femoral branches* consist of numerous filaments derived from both sides of the nerve, and are distributed to the skin covering the back and inner side of the thigh, the popliteal space, and the upper part of the back of the leg.

The **great sciatic** (n. ischiadicus) (fig. 813) supplies nearly the whole of the integument of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nerve in the body, measuring three-quarters of an inch in breadth, and is the continuation of the flattened band of the sacral plexus. It passes out of the pelvis through the great sacro-sciatic foramen, below the Pyriformis muscle. It descends between the great trochanter of the femur and the tuberosity of the ischium, along the back part of the thigh to about its lower third, where it divides into two large branches, the *internal* and *external popliteal nerves*. This division may take place at any point between the sacral plexus and the lower third of the thigh. When it occurs at the plexus, the external popliteal nerve usually pierces the Pyriformis.

As the nerve descends along the back of the thigh, it rests upon the posterior surface of the ischium, the nerve to the Quadratus femoris, and the external rotator muscles of the thigh, in company with the small sciatic nerve and artery, and is covered by the Gluteus maximus; lower down, it lies upon the Adductor magnus, and is covered by the long head of the Biceps.

The *branches* of the nerve, before its division, are articular and muscular.

The *articular branches* arise from the upper part of the nerve ; they supply the hip-joint, perforating the posterior part of its fibrous capsule. These branches are sometimes derived from the sacral plexus.

FIG. 812.—Segmental distribution of the cutaneous nerves of the right lower extremity. Posterior view.

Posterior tibial S. 1.2

The *muscular branches* are distributed to the flexors of the leg : viz. the Biceps, Semitendinosus, and Semimembranosus, and to the Adductor magnus. The nerve to the short head of the Biceps comes from the external popliteal part of the great sciatic, while the other muscular branches arise from the internal popliteal portion, as may be seen in those cases where the two popliteal nerves emerge separately on the buttock.

The **internal popliteal** (n. tibialis), the larger of the two terminal branches of the great sciatic, arises from the anterior branches of the last two lumbar and first three sacral nerves. It descends along the back part of the thigh, through the middle of the popliteal space, to the lower part of the Popliteus muscle, where it passes with the popliteal artery beneath the arch of the Soleus, and becomes the posterior tibial. It is overlapped by the hamstring muscles above, and then becomes more superficial, and lies to the outer side of, and some distance from, the popliteal vessels ; opposite the knee-joint, it is in close relation with the vessels, and crosses to the inner side of the artery. Below, it is overlapped by the Gastrocnemius.

The branches of this nerve are, articular, muscular, and a cutaneous branch, the *communicans tibialis*.

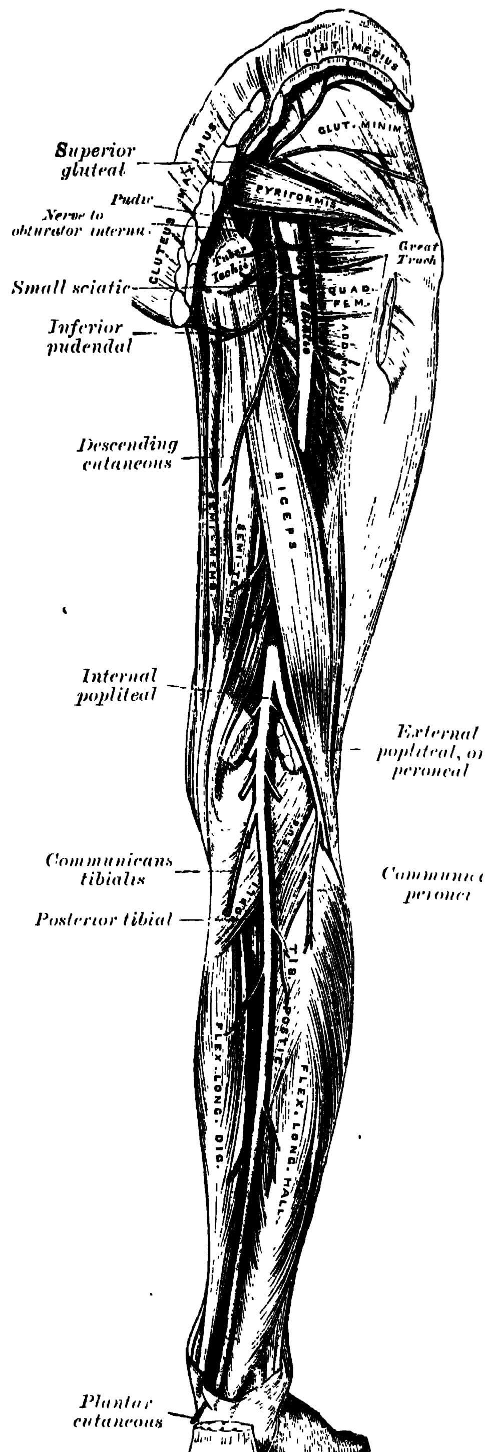
The *articular branches*, usually three in number, supply the knee-joint ; two of these accompany the superior and inferior internal articular arteries ; and a third, the azygos articular artery.

The *muscular branches*, four or five in number, arise from the nerve as it lies between the two heads of the Gastrocnemius muscle ; they supply that muscle, and the Plantaris, Soleus, and Popliteus. The branch which supplies the Popliteus turns round the lower border and is distributed to the deep surface of the muscle.

The *communicans tibialis* (n. cutaneus suræ medialis) descends between the two heads of the Gastrocnemius muscle, and, about the middle of the back of the leg, pierces the deep fascia, and joins a communicating branch (*communicans peronei*) from the external popliteal nerve to form the external, or short, saphenous nerve (fig. 811).

The *external saphenous* (n. suralis), formed by the communicating branches of the internal and external popliteal nerves, passes downwards and outwards near the outer margin of the tendo Achillis, lying close to

Fig. 813.—Nerves of the right lower extremity.* Posterior view.



the external saphenous vein, to the interval between the external malleolus and the os calcis. It winds round the outer malleolus, and is distributed to the integument along the outer side of the foot and little toe, communicating on the dorsum of the foot with the musculo-cutaneous nerve. In the leg, its branches communicate with those of the small sciatic.

The **posterior tibial** (fig. 813), the direct continuation of the internal popliteal nerve, commences at the lower border of the Popliteus muscle, and passes along the back part of the leg with the posterior tibial vessels to the interval between the inner malleolus and the heel, where it divides beneath the internal annular ligament of the ankle into the *internal* and *external plantar nerves.* It lies upon the deep muscles of the leg, and is covered in the upper part by the muscles of the calf, lower down by the skin and the superficial and deep fasciæ. In the upper part of its course, it lies to the inner side of the posterior tibial artery; but it soon crosses that vessel, and lies to its outer side as far as the ankle. In the lower third of the leg, it is placed parallel with the inner margin of the tendo Achillis.

The *branches of the posterior tibial nerve* are muscular, internal calcanean, and articular.

The *muscular branches* arise either separately or by a common trunk from the upper part of the nerve. They supply the Soleus, Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles; the branch to the last muscle accompanies the peroneal artery. The branch from the posterior tibial nerve to the Soleus enters the deep surface of the muscle, while that from the internal popliteal enters the superficial surface.

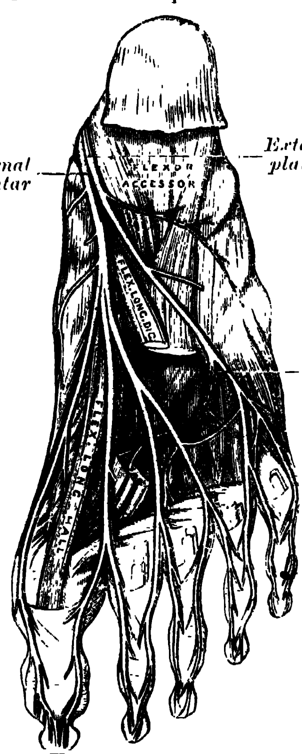
The *internal calcanean branch* (ramus calcaneus medialis) perforates the internal annular ligament, and supplies the integument of the heel and inner side of the sole of the foot.

* N.B.—In this diagram the communicans tibialis and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.

The *articular branch* is given off just above the bifurcation of the nerve, and supplies the ankle-joint.

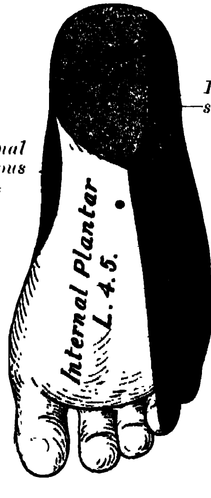
The **internal plantar** (n. plantaris medialis) (fig. 814), the larger of the two terminal branches of the posterior tibial, accompanies the internal plantar artery along the inner side of the foot. From its origin at the inner ankle it passes beneath the Abductor hallucis, and then forwards between this muscle and the Flexor brevis digitorum; it divides opposite the bases of the metatarsal bones into four digital branches, and communicates with the external plantar nerve.

FIG. 814.—The plantar nerves.



Branches.—In its course, the internal plantar nerve gives off *cutaneous branches*, which pierce the plantar fascia, and supply the integument of the sole of the foot; *muscular branches*, which supply the Abductor hallucis and Flexor brevis digitorum; *articular branches* to the articulations of the tarsus and metatarsus; and *four digital branches*. The first (innermost) branch becomes cutaneous about the middle of the sole, between the Abductor hallucis and Flexor brevis digitorum; the three outer branches pass between the divisions of the plantar fascia in the clefts between the toes. They are distributed in the following manner: the *first* supplies the inner border of the great toe, and sends a filament to the Flexor brevis hallucis muscle; the *second* bifurcates, to supply the adjacent sides of the great and second toes, sending a filament to the First lumbricalis;* the *third digital branch* supplies the adjacent sides of the second and third toes; the *fourth* supplies the corresponding sides of the third and fourth toes, and receives a communicating branch from the external plantar nerve. Each digital nerve gives off cutaneous and articular filaments; and opposite the last phalanx sends a dorsal branch, which supplies the structures around the nail, the continuation of the nerve being distributed to the ball of the toe. It will be observed that these digital branches are precisely similar in their distribution to those of the median nerve in the hand.

FIG. 815.—Cutaneous distribution of plantar nerves.



The **external plantar** (n. plantaris lateralis), the smaller of the two, completes the nervous supply to the structures of the sole of the foot, being distributed to the little toe and outer half of the fourth, as well as to most of the deep muscles, its distribution being similar to that of the ulnar in the hand. It passes obliquely forwards with the external plantar artery to the outer side of the foot, lying between the Flexor brevis digitorum and Flexor accessorius; and, in the interval between the former muscle and the Abductor

* Consult article by Brooks, *Journal of Anat. and Physiol.*, vol. xxi.

minimi digiti, divides into a superficial and a deep branch. Before its division, it supplies the Flexor accessorius and Abductor minimi digiti.

The *superficial branch* (ramus superficialis) separates into two digital nerves: one, the smaller of the two, supplies the outer side of the little toe, the Flexor brevis minimi digiti, and the two Interosseous muscles of the fourth metatarsal space; the other and larger digital branch supplies the adjoining sides of the fourth and fifth toes, and communicates with the internal plantar nerve.

The *deep branch* (ramus profundus) accompanies the external plantar artery on the deep surface of the tendons of the Flexor muscles and the Adductor obliquus hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the three outer Lumbricales, the Adductor obliquus hallucis, and the Adductor transversus hallucis.

The **external popliteal** or **peroneal** (n. peronæus communis) (fig. 813), about one-half the size of the internal popliteal, is derived from the dorsal branches of the last two lumbar and first two sacral nerves. It descends obliquely along the outer side of the popliteal space to the head of the fibula, close to the inner margin of the Biceps muscle. It is easily felt beneath the skin behind the head of the fibula, at the inner side of the tendon of the Biceps. It lies between the tendon of the Biceps and outer head of the Gastrocnemius muscle, winds round the neck of the fibula, between the Peroneus longus and the bone, and divides beneath the muscle into the anterior tibial and musculo-cutaneous nerves.

The *branches of the external popliteal nerve*, previous to its division, are articular and cutaneous.

The *articular branches* are three in number; two of these accompany the superior and inferior external articular arteries to the outer side of the knee. The upper one occasionally arises from the great sciatic nerve before its bifurcation. The third (*recurrent*) articular nerve is given off at the point of division of the external popliteal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anticus muscle to the front of the knee, which it supplies.

The *cutaneous branches*, two or three in number, supply the integument along the back part and outer side of the leg: one of these, larger than the rest, the *communicans peronei* (ramus anastomoticus peronæus), arises near the head of the fibula, crosses the external head of the Gastrocnemius to the middle of the leg, and joins with the communicans tibialis to form the external saphenous. The communicans peronei is occasionally continued down as a separate branch as far as the heel.

The **anterior tibial** (n. peronæus profundus) (fig. 808) commences at the bifurcation of the peroneal nerve, between the fibula and upper part of the Peroneus longus, passes obliquely forwards beneath the Extensor longus digitorum to the fore part of the interosseus membrane, and comes into relation with the anterior tibial artery above the middle of the leg; it then descends with the artery to the front of the ankle-joint, where it divides into an external and an internal branch. It lies at first on the outer side of the anterior tibial artery, then in front of it, and again on its outer side at the ankle-joint.

The *branches of the anterior tibial nerve*, in its course through the leg, are *muscular* to the Tibialis anticus, Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis muscles, and an *articular branch* to the ankle-joint.

The *external terminal branch* passes outwards across the tarsus, beneath the Extensor brevis digitorum, and, having become enlarged like the posterior interosseus nerve at the wrist, supplies the Extensor brevis digitorum. From the enlargement three minute *interosseous branches* are given off, which supply the tarsal joints and the metatarso-phalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the Second dorsal interosseous muscle.

The *internal branch*, the continuation of the nerve, accompanies the dorsalis pedis artery along the inner side of the dorsum of the foot, and, at the first interosseous space, divides into two branches, which supply the adjacent sides of the great and second toes, communicating with the innermost branch of the musculo-cutaneous nerve. Before it divides it gives off to the first space an *interosseous branch* which supplies the metatarso-phalangeal joint of the great toe and sends a filament to the First dorsal interosseous muscle.

The **musculo-cutaneous** (n. peronæus superficialis) (fig. 808) supplies the muscles on the fibular side of the leg, and the integument over the greater part of the dorsum of the foot. It passes forwards between the Peronei and the Extensor longus digitorum, pierces the deep fascia at the lower third of the leg, on its front and outer side, and divides into two branches. This nerve, in its course between the muscles, gives off muscular branches to the Peronei longus and brevis, and cutaneous filaments to the integument of the lower part of the leg.

The *internal branch of the musculo-cutaneous nerve* passes in front of the ankle-joint, and divides into two branches, one of which supplies the inner side of the great toe, the other, the adjacent sides of the second and third toes. It also supplies the integument of the inner ankle and inner side of the foot, communicating with the internal saphenous nerve, and joining with the anterior tibial nerve, between the great and second toes.

The *external branch*, the smaller, passes along the outer side of the dorsum of the foot, and divides into two branches, the inner being distributed to the contiguous sides of the third and fourth toes, the outer to the opposed sides of the fourth and fifth toes. It also supplies the integument of the outer ankle and outer side of the foot, communicating with the short saphenous nerve.

The branches of the musculo-cutaneous nerve supply all the toes excepting the outer side of the little toe, and the adjoining sides of the great and second toes, the former being supplied by the external saphenous, and the latter by the internal branch of the anterior tibial. It frequently happens, however, that some of the outer branches of the musculo-cutaneous are absent, their places being then taken by branches of the external saphenous nerve.

Pudendal Plexus (Plexus Pudendus)

The **pudendal plexus** (fig. 809) is not sharply marked off from the sacral plexus, and as a consequence some of the branches which spring from it may arise in conjunction with those of the sacral plexus. It lies on the posterior wall of the pelvis, and is usually formed by branches from the anterior primary divisions of the second and third sacral nerves, the whole of the anterior primary divisions of the fourth and fifth sacral nerves and the coccygeal nerve.

It gives off the following branches :

Perforating cutaneous	2. 3 S.
Pudic	2, 3, 4 S.
Visceral	3, 4 S.
Muscular	4, S.
Ano-coccygeal	4, 5, S. and Cocc.

The **perforating cutaneous** usually arises from the posterior surface of the second and third sacral nerves. It pierces the lower part of the great sacro-sciatic ligament, and winding round the inferior border of the Gluteus maximus supplies the skin covering the inner and lower parts of that muscle.

The perforating cutaneous nerve may arise from the pudic or it may be absent: in the latter case its place may be taken by a branch from the small sciatic nerve or by a branch from the third and fourth, or fourth and fifth, sacral nerves.

The **pudic** (n. pudendus) derives its fibres from the ventral branches of the second, third, and fourth sacral nerves. It leaves the pelvis, below the Pyriformis, through the great sacro-sciatic foramen. It then crosses the spine of the ischium, and re-enters the pelvis through the small sacro-sciatic foramen. It accompanies the pudic vessels upwards and forwards along the outer wall of the ischio-rectal fossa, being contained in a sheath of the obturator fascia, termed *Alcock's canal*, and divides into two terminal branches, viz. the perineal nerve, and the dorsal nerve of the penis or clitoris. Before its division it gives off the inferior hæmorrhoidal nerve.

The *inferior hæmorrhoidal nerve* is occasionally derived separately from the sacral plexus. It passes across the ischio-rectal fossa, with its accompanying vessels, towards the lower end of the rectum, and is distributed to the Sphincter ani externus and to the integument round the anus. Branches of this nerve

communicate with the inferior pudendal and superficial perineal nerves at the fore part of the perinæum.

The *perineal nerve*, the inferior and larger of the two terminal branches of the pudic, is situated below the pudic artery. It accompanies the superficial perineal artery in the perinæum and divides into cutaneous and muscular branches.

The cutaneous branches (superficial perineal) are two in number, posterior and anterior. The *posterior* or *external branch* pierces the base of the triangular ligament of the urethra, and passes forwards along the outer side of the urethral triangle in company with the superficial perineal artery; it is distributed to the skin of the scrotum. It communicates with the inferior hæmorrhoidal, the inferior pudendal, and the other superficial perineal nerve. The *anterior* or *internal branch* also pierces the base of the triangular ligament, and passes forwards nearer to the middle line, to be distributed to the inner and back part of the scrotum. Both these nerves supply the labium majus in the female.

The muscular branches are distributed to the Transversus perinæi, Accelerator urinæ, Erector penis, and Compressor urethræ. A distinct branch given off from the nerve to the Accelerator urinæ, pierces this muscle, and supplies the corpus spongiosum, ending in the mucous membrane of the urethra. This is the *nerve to the bulb*.

The *dorsal nerve of the penis* is the deepest division of the pudic nerve; it accompanies the pudic artery along the ramus of the ischium; it then runs forwards along the inner margin of the ramus of the pubis, between the superficial and deep layers of the triangular ligament. Piercing the superficial layer it gives a branch to the corpus cavernosum, and passes forwards, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, on to the dorsum of the penis, along which it is carried as far as the glans on which it ends.

In the female the dorsal nerve is very small, and supplies the clitoris.

The **visceral branches** arise from the third and fourth, and sometimes from the second, sacral nerves and are distributed to the bladder and rectum and, in the female, to the vagina; they communicate with the pelvic plexuses of the sympathetic.

The **muscular branches** are derived from the fourth sacral, and supply the Levator ani, Coccygeus, and Sphincter ani externus. The branches to the Levator ani and Coccygeus enter their pelvic surfaces; that to the Sphincter ani externus (perineal branch) reaches the ischio-rectal fossa by piercing the Coccygeus or by passing between it and the Levator ani. Cutaneous filaments from this branch supply the skin between the anus and the coccyx.

Ano-coccygeal branches (nn. anicoccygei).—The fifth sacral nerve receives a communicating filament from the fourth, and unites with the coccygeal nerve to form what is known as the *coccygeal plexus* (plexus coccygeus). From this plexus the ano-coccygeal nerves take origin: they consist of a few fine filaments which pierce the great sacro-sciatic ligament to supply the skin in the region of the coccyx.

Applied Anatomy.—The lumbar plexus passes through the Psoas magnus, and therefore in psoas abscess any or all of its branches may be irritated, causing severe pain in the part to which the irritated nerves are distributed. The genito-crural nerve is the one which is most frequently implicated. This nerve is also of importance as it is concerned in one of the principal superficial reflexes employed in the investigation of diseases of the spinal cord. If the skin over the inner side of the thigh just below Poupart's ligament, the part supplied by the crural branch of the genito-crural nerve, be gently tickled in a male child, the testicle will be noticed to be drawn upwards, through the action of the Cremaster muscle, supplied by the genital branch of the same nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The anterior crural nerve is in danger of being injured in fractures of the true pelvis, since the fracture most commonly takes place through the ascending ramus of the pubis, at or near the point where this nerve crosses the bone. It is also liable to be injured in fractures and dislocations of the femur, and is likely to be pressed upon, and its functions impaired, by some tumours growing in the pelvis. Moreover, on account of its superficial position, it is exposed to injury in wounds and stabs in the groin. It is also likely to be affected in cases of infantile paralysis. When this nerve is paralysed, the patient is

unable to flex his hip completely, on account of the paralysis of the Iliacus; or to extend the knee on the thigh, on account of paralysis of the Quadriceps extensor cruris; there is complete paralysis of the Sartorius, and partial paralysis of the Pectineus. There is loss of sensation down the front and inner side of the thigh, except in that part supplied by the crural branch of the genito-crural, and by the ilio-inguinal. There is also loss of sensation down the inner side of the leg and foot as far as the ball of the great toe.

The obturator nerve is rarely paralysed alone, but occasionally in association with the anterior crural. The principal interest attached to it is in connection with its supply to the knee; pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient does not complain of pain in that articulation, but on the inner side of the knee, or in the knee-joint itself, both these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing occurs in sacro-iliac disease: pain is complained of in the knee-joint, or on its inner side. The obturator nerve is in close relationship with the sacro-iliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Further, in cancer of the ilio-pelvic colon, and even in cases where masses of hardened fæces are impacted in this portion of the gut, pain is complained of in the knee. The left obturator nerve lies beneath the pelvic colon, and is readily pressed upon and irritated when disease exists in this part of the intestine. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. The hernial protrusion as it passes out through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is paralysed, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles. Rotation outwards of the thigh is impaired from paralysis of the Obturator externus. Sometimes there is loss of sensation in the upper half of the inner side of the thigh.

The great sciatic nerve is liable to be pressed upon by various forms of pelvic tumour, giving rise to pain along its trunk, to which the term sciatica is applied. Tumours growing from the pelvic viscera, especially advanced cancer of the rectum, aneurysms of some of the branches of the internal iliac artery, calculus in the bladder when of large size, accumulation of fæces in the rectum, may all cause pressure on the nerve inside the pelvis, and give rise to sciatica. Outside the pelvis violent movements of the hip-joint, exostoses or other tumours growing from the margin of the sacro-sciatic foramen, may also give rise to the same condition. Most cases of sciatica, however, are due to neuritis of the sciatic nerve from exposure to cold, and it occurs more often in men than in women, in the latter half of life, and often in association with rheumatism, gout, or diabetes mellitus. The inflamed nerve is often sensitive to pressure, particularly in certain 'tender spots' (e.g. near the posterior iliac spine, at the sciatic notch, about the middle of the back of the thigh, in the popliteal space, below the head of the fibula, behind the malleoli, on the dorsum of the foot), and pain is felt whenever extension of the leg is attempted, and the nerve is stretched. Paralysis of the sciatic nerve is rarely complete; when the lesion occurs high up there is palsy of the Biceps, Semimembranosus, and Semitendinosus, and of the muscles below the knee. If the lesion be lower down, there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, which is supplied by the small sciatic, and in the upper half of the inner side of the leg, when the communicating branch of the obturator is large (see page 974). Lesions of the external popliteal nerve cause paralysis of the Tibialis anticus, the Peronei, the long Extensors of the toes, and the short Extensor on the dorsum of the foot. 'Foot-drop' follows, dorsal flexion of the toes and abduction of the foot becoming impossible. Later on talipes results, largely by the action of gravity and by the weight of the superincumbent bedclothes when the patient lies in bed.

The great sciatic nerve has been frequently cut down upon and stretched, or has been acupunctured, for the relief of sciatica. In order to define it on the surface, a point is taken at the junction of the middle and lower thirds of a line stretching from the posterior superior spine of the ilium to the outer part of the tuber ischii, and a line drawn from this to the middle of the upper part of the popliteal space. The line must be slightly curved with its convexity outwards, and as it passes downwards to the lower border of the Gluteus maximus is slightly nearer to the tuber ischii than to the great trochanter, as it crosses a line drawn between these two points. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve about the centre of the thigh. The skin, superficial structures, and deep fascia having been divided, the interval between the inner and outer hamstrings is to be defined, and these muscles pulled inwards and outwards respectively with retractors. The nerve will be found a little to the inner side of the Biceps. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the 'dry' plan. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position, the leg is forcibly extended to its full extent, and the foot as fully flexed on the leg.

The position of the external popliteal, close behind the tendon of the Biceps on the outer side of the ham, should be remembered in subcutaneous division of the tendon. After the tendon is divided, a cord often rises up close beside it, which might be mistaken for a small undivided portion of the tendon, and the surgeon might be tempted to reintroduce his knife and cut it. This must never be done, as the cord is the external popliteal nerve, which becomes prominent as soon as the tendon is divided. Where this nerve winds round the neck of the fibula, it is also liable to be severed accidentally if its exact situation is not kept in mind, and especial care must be used when dealing with sinuses leading down to carious bone in this situation. Section of the nerve results in complete 'foot-drop' from paralysis of the anterior tibial group of muscles and inversion of the foot from the unopposed action of the Tibialis posticus, the Peronei being paralysed, together with anæsthesia of the parts supplied by the nerve, and, owing to loss of nutrition, the limb frequently becomes blue and cold, and may develop 'trophic' sores.

THE SYMPATHETIC NERVES

The **sympathetic nerves** (fig. 816) are distributed to the viscera and blood-vessels * and are intimately connected with the spinal and certain of the cranial nerves. They are characterised by the presence of numerous ganglia which may be divided into three groups, central, collateral, and terminal.

The *central* ganglia are arranged in two vertical rows, one on either side of the middle line, situated partly in front and partly at the sides of the vertebral column. Each ganglion is joined by intervening nervous trunks to adjacent ganglia so that two chains or cords are formed, the *gangliated cords of the sympathetic*. The *collateral* ganglia are found in connection with three great *prevertebral plexuses*, placed within the thorax, abdomen, and pelvis respectively, while the *terminal* ganglia are located in the walls of the viscera.†

The **gangliated cords** (trunci sympathici) extend from the base of the skull to the coccyx. The cranial end of each is continued upwards through the carotid canal into the skull, and forms a plexus on the internal carotid artery; the lower ends of the two cords converge and end in a single ganglion, the *ganglion impar*, placed in front of the coccyx. The ganglia of each cord are distinguished as cervical, thoracic, lumbar, and sacral, and, except in the neck, they closely correspond in number to the vertebræ. They are arranged thus:

Cervical portion	3 ganglia
Thoracic ,, ...	12 ,,
Lumbar ,, ...	4 ,,
Sacral ,, ...	4 or 5 ,,

In the neck the ganglia lie in front of the transverse processes of the vertebræ; in the thoracic region in front of the heads of the ribs; in the lumbar region on the sides of the vertebral bodies; and in the sacral region in front of the sacrum.

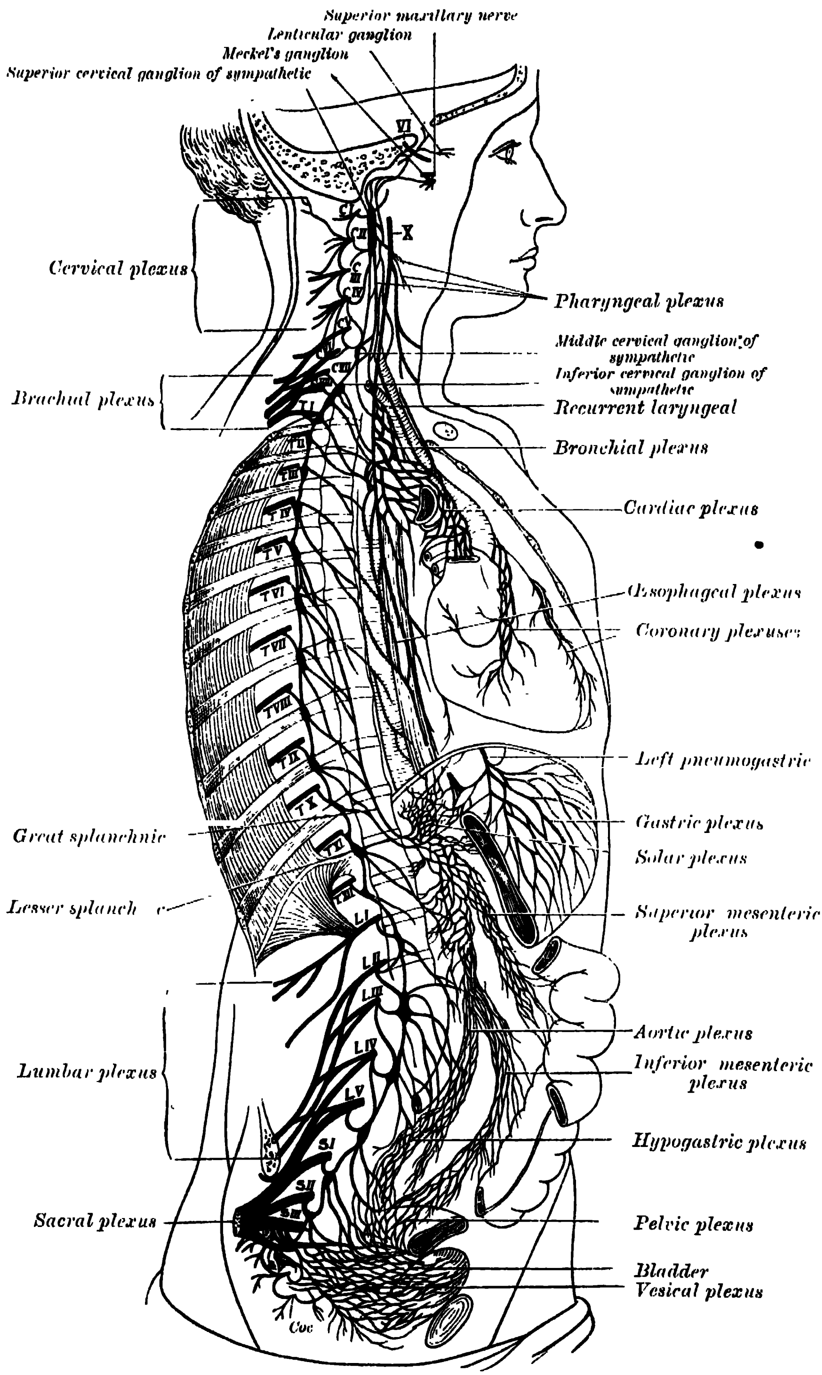
Connections with the spinal nerves.—Communications are established between the sympathetic and spinal nerves through what are known as the *grey* and *white rami communicantes* (fig. 790); the grey rami conveying sympathetic fibres into the spinal nerves and the white rami transmitting spinal fibres into the sympathetic. Each spinal nerve receives a grey ramus communicans from the gangliated cord of the sympathetic, but white rami are not supplied by all the spinal nerves. The white rami are derived from the first thoracic to the first lumbar nerves inclusive, while the visceral branches which run from the second, third, and fourth sacral nerves directly to the pelvic plexuses of the sympathetic belong to this category. The fibres which reach the sympathetic through the white rami communicantes are *medullated*; those which spring from the cells of the sympathetic ganglia are almost entirely non-medullated. The sympathetic nerves consist of efferent and afferent fibres, the origin and course of which are described on pages 944, 945.

* See footnote, p. 911.

† The ciliary, spheno-palatine, otic, and submaxillary ganglia, already described in connection with the fifth cranial nerve, may be regarded as belonging to the sympathetic.

The **three great gangliated plexuses** are situated in front of the spine in e thoracic, abdominal, and pelvic regions, and are named, respectively, the

FIG. 816.—The right sympathetic chain and its connections with the thoracic, abdominal, and pelvic plexuses. (After Schwalbe.)



cardiac, the *solar* or *epigastric*, and the *hypogastric plexuses*. They consist of collections of nerves and ganglia ; the nerves being derived from the gangliated cords and from the cerebro-spinal nerves. They distribute branches to the viscera.

Cervico-cephalic Portion of the Gangliated Cord (fig. 817)

The cervico-cephalic portion of each gangliated cord (pars cephalica et cervicalis s. sympathici) consists of three ganglia, distinguished, according to their position, as the superior, middle, and inferior cervical, connected by intervening cords. This portion of the sympathetic cord receives no white rami communicantes from the cervical spinal nerves, its spinal fibres being derived from the white rami of the upper thoracic nerves, which enter the corresponding thoracic ganglia of the sympathetic, and through these ascend into the neck.

The **superior cervical ganglion** (ganglion cervicale superius), the largest of the three, is placed opposite the second and third cervical vertebræ. It is of a reddish-grey colour, and usually fusiform in shape; sometimes broad and flattened, and occasionally constricted at intervals; it is believed to be formed by the coalescence of four ganglia, corresponding to the upper four cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery and internal jugular vein; behind, it lies on the Rectus capitis anticus major muscle.

Its branches may be divided into superior, inferior, external, internal, and anterior.

The **superior branch** (n. caroticus internus) appears to be a direct prolongation of the ganglion. It is soft in texture, and of a reddish colour. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, which lie one on the outer and the other on the inner side of that vessel.

The *outer branch*, the larger of the two, distributes filaments to the internal carotid artery, and forms the *carotid plexus.*

The *inner branch* also distributes filaments to the internal carotid artery, and, continuing onwards, forms the *cavernous plexus.*

The **carotid plexus** (plexus caroticus internus) is situated on the outer side of the internal carotid artery. Filaments from this plexus occasionally form a small gangliform swelling (the *carotid ganglion*) on the under surface of the artery. The carotid plexus communicates with the Gasserian ganglion, the sixth nerve, and the spheno-palatine ganglion; it distributes filaments to the wall of the carotid artery, and also communicates with Jacobson's nerve (the tympanic branch of the glosso-pharyngeal).

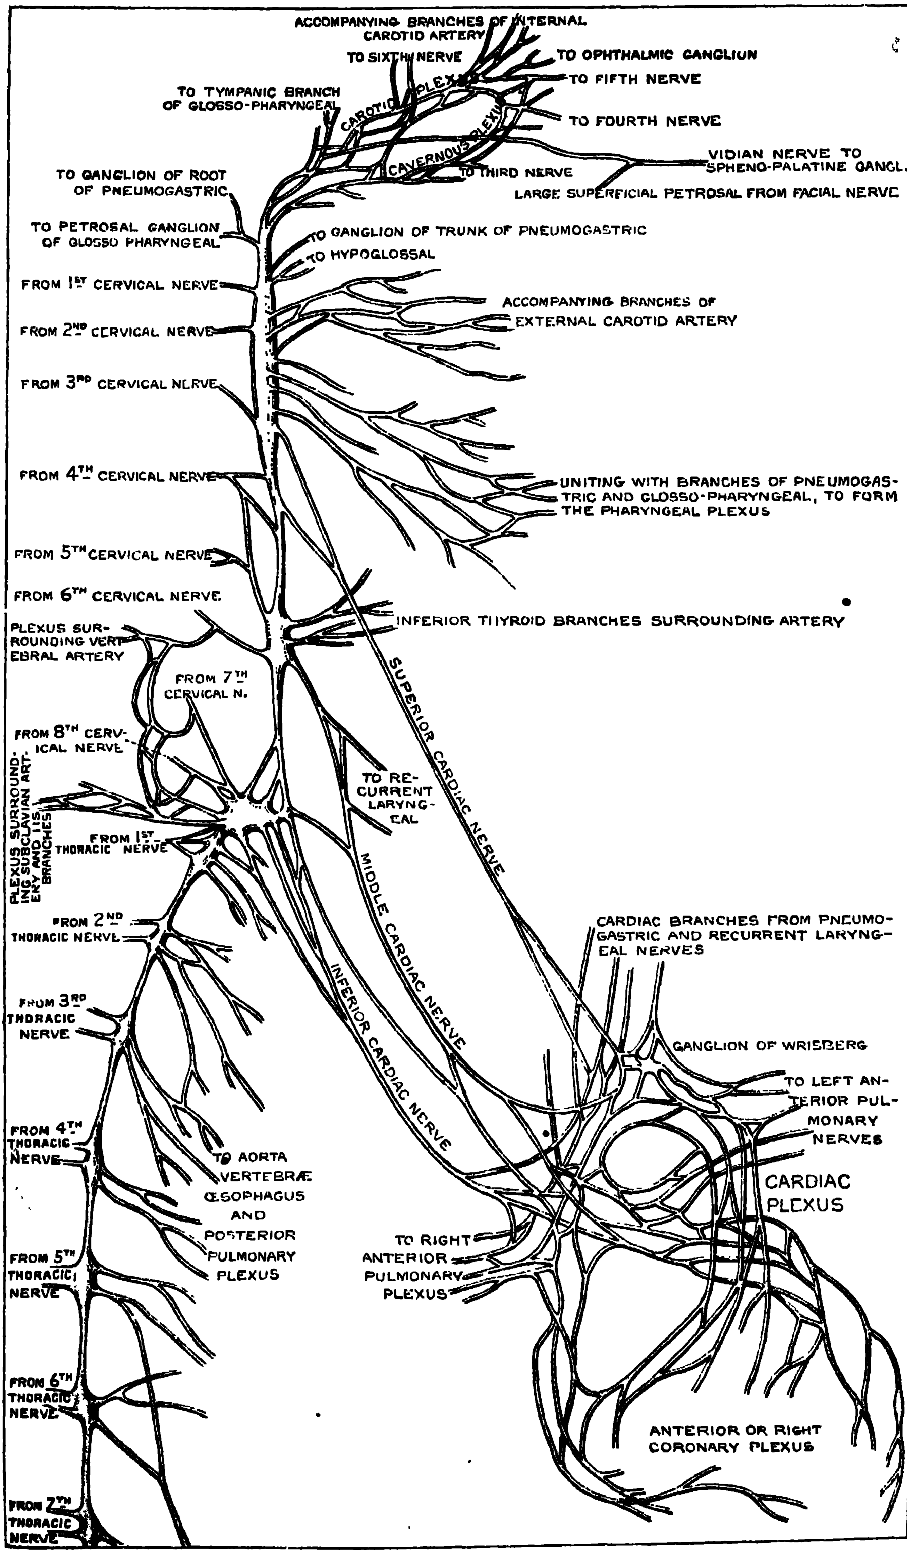
The communicating branches with the sixth nerve consist of one or two filaments which join that nerve as it lies upon the outer side of the internal carotid. The communication with the spheno-palatine ganglion is effected by a branch, the *large deep petrosal*, given off from the plexus on the outer side of the artery; this branch passes through the cartilage filling up the foramen lacerum medium, and joins the great superficial petrosal to form the Vidian nerve. The Vidian nerve then proceeds through the Vidian canal to the spheno-palatine ganglion. The communication with Jacobson's nerve is effected by two branches, one of which is called the *small deep petrosal nerve*, and the other the *carotico-tympanic*; the latter may consist of two or three delicate filaments.

The **cavernous plexus** (plexus cavernosus) is situated below and internal to that part of the internal carotid artery which is placed by the side of the sella turcica, in the cavernous sinus, and is formed chiefly by the internal division of the ascending branch from the superior cervical ganglion. It communicates with the third, the fourth, the ophthalmic division of the fifth, and the sixth nerves, and with the ciliary ganglion, and distributes filaments to the wall of the internal carotid. The branch of communication with the third nerve joins that nerve at its point of division; the branch to the fourth nerve joins it as it lies on the outer wall of the cavernous sinus; other filaments are connected with the under surface of the trunk of the ophthalmic nerve; and a second filament of communication joins the sixth nerve.

The filaments of connection with the ciliary ganglion (radices sympathicæ ganglii ciliaris) arise from the anterior part of the cavernous plexus and enter the orbit through the sphenoidal fissure; they may join the nasal branch of the ophthalmic nerve, or be continued forwards as a separate branch.

The terminal filaments from the carotid and cavernous plexuses are prolonged along the internal carotid, forming plexuses which entwine round

Fig. 817.—Plan of the cervico-cephalic portion of the sympathetic. (After Flower.)



the anterior and middle cerebral arteries and the ophthalmic artery: along the former vessels, they may be traced to the pia mater; along the latter, into the orbit, where they accompany each of the branches of the vessel. The filaments prolonged on to the anterior communicating artery connect the sympathetic nerves of the right and left sides.

The **inferior branch** communicates with the middle cervical ganglion.

The **external branches** are communicating, and consist of grey rami communicantes to the upper four cervical nerves and to certain of the cranial nerves. Sometimes the branch to the fourth cervical nerve may come from the cord connecting the upper and middle cervical ganglia. The branches to the cranial nerves consist of delicate filaments, which run to the ganglion of the trunk of the pneumogastric, and to the hypoglossal nerve. A separate filament (*nervus jugularis*) passes upwards to the base of the skull, and subdivides to join the petrous ganglion of the glosso-pharyngeal, and the ganglion of the root of the pneumogastric in the jugular foramen.

The **internal branches** are peripheral, and are the *pharyngeal branches*, and the *superior cardiac nerve*. The *pharyngeal branches* (rami laryngopharyngei) pass inwards to the side of the pharynx, where they join with branches from the glosso-pharyngeal, pneumogastric, and external laryngeal nerves to form the *pharyngeal plexus*.

The *superior cardiac nerve* (n. cardiacus superior) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the cord of communication between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, lying upon the Longus colli muscle; and crosses in front of the inferior thyroid artery, and recurrent laryngeal nerve. The course of the nerves on the two sides then differs.

The *right nerve*, at the root of the neck, passes either in front of or behind the subclavian artery, and along the innominate artery to the back part of the arch of the aorta, where it joins the deep cardiac plexus. It is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down, one or two twigs from the pneumogastric; and as it enters the thorax it is joined by a filament from the recurrent laryngeal. Filaments from the nerve communicate with the thyroid branches from the middle cervical ganglion.

The *left nerve*, in the chest, runs in front of the left common carotid artery and across the left side of the arch of the aorta, to the superficial cardiac plexus.

The **anterior branches** ramify upon the external carotid artery and its branches, forming round each a delicate plexus, on the nerves composing which small ganglia are occasionally found. The plexuses accompanying some of these arteries have important communications with other nerves. That surrounding the facial artery communicates with the submaxillary ganglion by a filament; and that accompanying the middle meningeal artery sends an offset to the otic ganglion, and a second, the *external superficial petrosal nerve*, to the geniculate ganglion of the facial nerve.

The **middle cervical ganglion** (ganglion cervicale medium) is the smallest of the three cervical ganglia, and is occasionally altogether wanting. It is placed opposite the sixth cervical vertebra, usually upon, or close to, the inferior thyroid artery. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.

It is joined by grey rami communicantes to the fifth and sixth cervical nerves.

It gives off the thyroid and the middle cardiac nerves.

The *thyroid branches* are small filaments, which accompany the inferior thyroid artery to the thyroid gland; they communicate, on the artery, with the superior cardiac nerve, and, in the gland, with branches from the recurrent and external laryngeal nerves.

The *middle cardiac nerve* (n. cardiacus medius), the largest of the three cardiac nerves, arises from the middle cervical ganglion, or from the cord between the middle and inferior ganglia. On the right side it descends behind the common carotid artery, and at the root of the neck runs either in front of or behind the subclavian artery; it then descends on the trachea, receives

a few filaments from the recurrent laryngeal nerve, and joins the right half of the deep cardiac plexus. In the neck, it communicates with the superior cardiac and recurrent laryngeal nerves. On the left side, the middle cardiac nerve enters the chest between the left carotid and subclavian arteries, and joins the left half of the deep cardiac plexus.

The **inferior cervical ganglion** (ganglion cervicale inferius) is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib, on the inner side of the superior intercostal artery. Its form is irregular; it is larger in size than the preceding, and is frequently joined with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the last two cervical nerves. It is connected to the middle cervical ganglion by two or more cords, one of which forms a loop around the subclavian artery and supplies offsets to it. This loop is named the *ansa Vieussenii.*

The ganglion is joined to the seventh and eighth cervical nerves by grey rami communicantes.

It gives off the inferior cardiac nerve, and offsets to blood-vessels.

The *inferior cardiac nerve* (n. cardiacus inferior) arises from the inferior cervical or first thoracic ganglion. It passes down behind the subclavian artery and along the front of the trachea, to join the deep cardiac plexus. It communicates freely behind the subclavian artery with the recurrent laryngeal and middle cardiac nerves.

The *offsets to blood-vessels* accompany the vertebral artery, and form a plexus around it; this plexus supplies filaments to the vessel, and is continued up the vertebral and basilar to the cerebral and cerebellar arteries.

Thoracic Portion of the Gangliated Cord (figs. 816, 818)

The thoracic portion of the gangliated cord (pars thoracalis s. sympathici) consists of a series of ganglia, which usually correspond in number to that of the vertebræ; but, from the occasional coalescence of two, their number is uncertain. The ganglia (ganglia thoracalia) are placed on either side of the vertebral column, resting against the heads of the ribs, and covered by the pleura costalis; the last two, however, are more anterior than the rest, being placed on the sides of the bodies of the eleventh and twelfth thoracic vertebræ. The ganglia are small in size, and of a greyish colour. The first, larger than the others, is of an elongated form, and frequently blended with the last cervical. They are connected together by the intervening portions of the cord.

Two rami communicantes, one white and the other grey, connect each ganglion with its corresponding spinal nerve.

The *branches from the upper five ganglia* are very small; they supply filaments to the thoracic aorta and its branches, and to the bodies of the vertebræ and their ligaments. Branches from the second, third, and fourth ganglia enter the posterior pulmonary plexus.

The *branches from the lower seven ganglia* are large, and white in colour; they distribute filaments to the aorta, and unite to form the three splanchnic nerves. These are named the *great*, the *lesser*, and the *least splanchnic.*

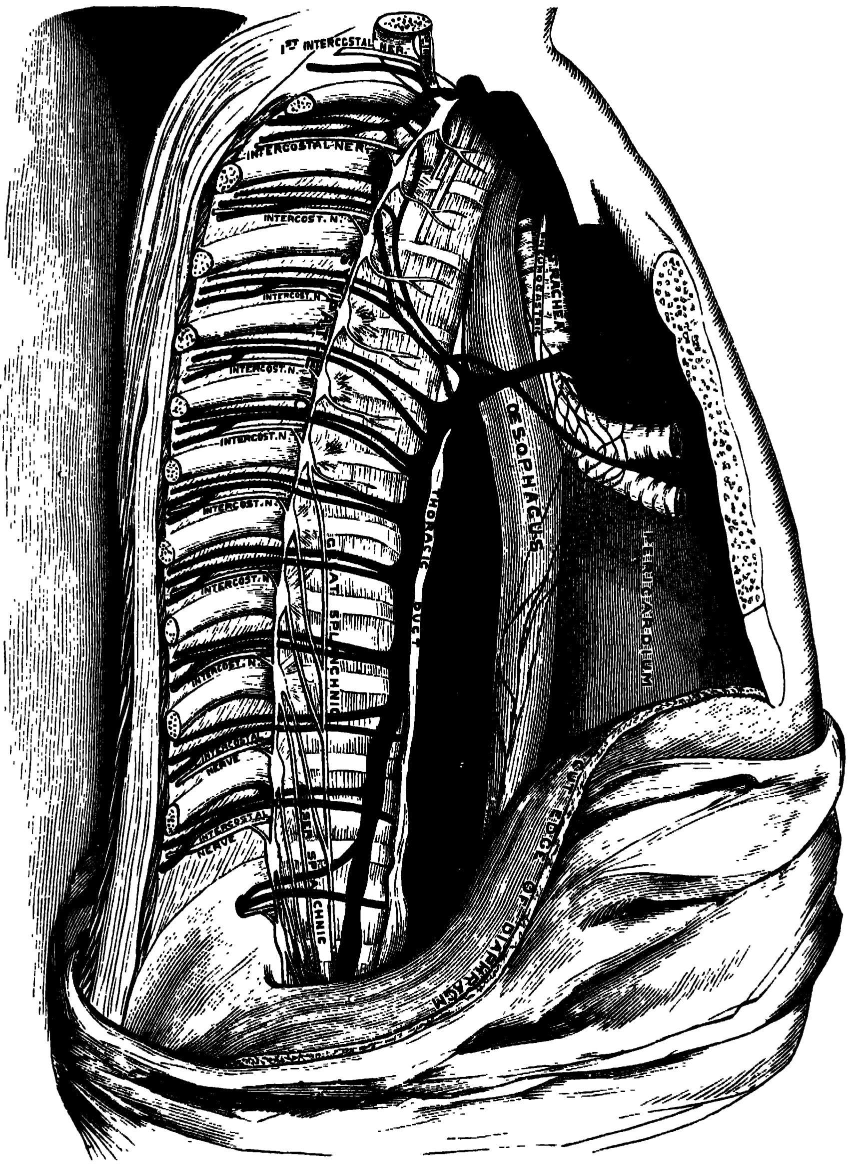
The *great splanchnic nerve* (n. splanchnicus major) is white in colour, firm in texture, and is formed by branches from the fifth to the ninth or tenth thoracic ganglia; but the fibres in the higher roots may be traced upwards in the sympathetic cord as far as the first or second thoracic ganglion. These roots unite to form a cord of considerable size. It descends obliquely inwards in front of the bodies of the vertebræ along the posterior mediastinum, perforates the crus of the Diaphragm, and terminates in the semilunar ganglion of the solar plexus, distributing filaments to the renal and suprarenal plexuses. A ganglion (the *ganglion splanchnicum*) exists on this nerve opposite the eleventh or twelfth thoracic vertebra.

The *lesser splanchnic nerve* (n. splanchnicus minor) is formed by filaments from the ninth and tenth, and sometimes the eleventh ganglia, and from the cord between them. It pierces the Diaphragm with the preceding nerve, and joins the aortico-renal ganglion of the solar plexus. It communicates in the chest with the great splanchnic nerve, and ends in the solar plexus.

The *least splanchnic nerve* (n. splanchnicus imus) arises from the last thoracic ganglion, and, piercing the Diaphragm, terminates in the renal plexus. It occasionally communicates with the preceding nerve.

A striking analogy exists between the splanchnic and the cardiac nerves. The cardiac nerves are three in number; they arise from all three cervical

Fig. 818.—Thoracic portion of the gangliated cord. Right side.



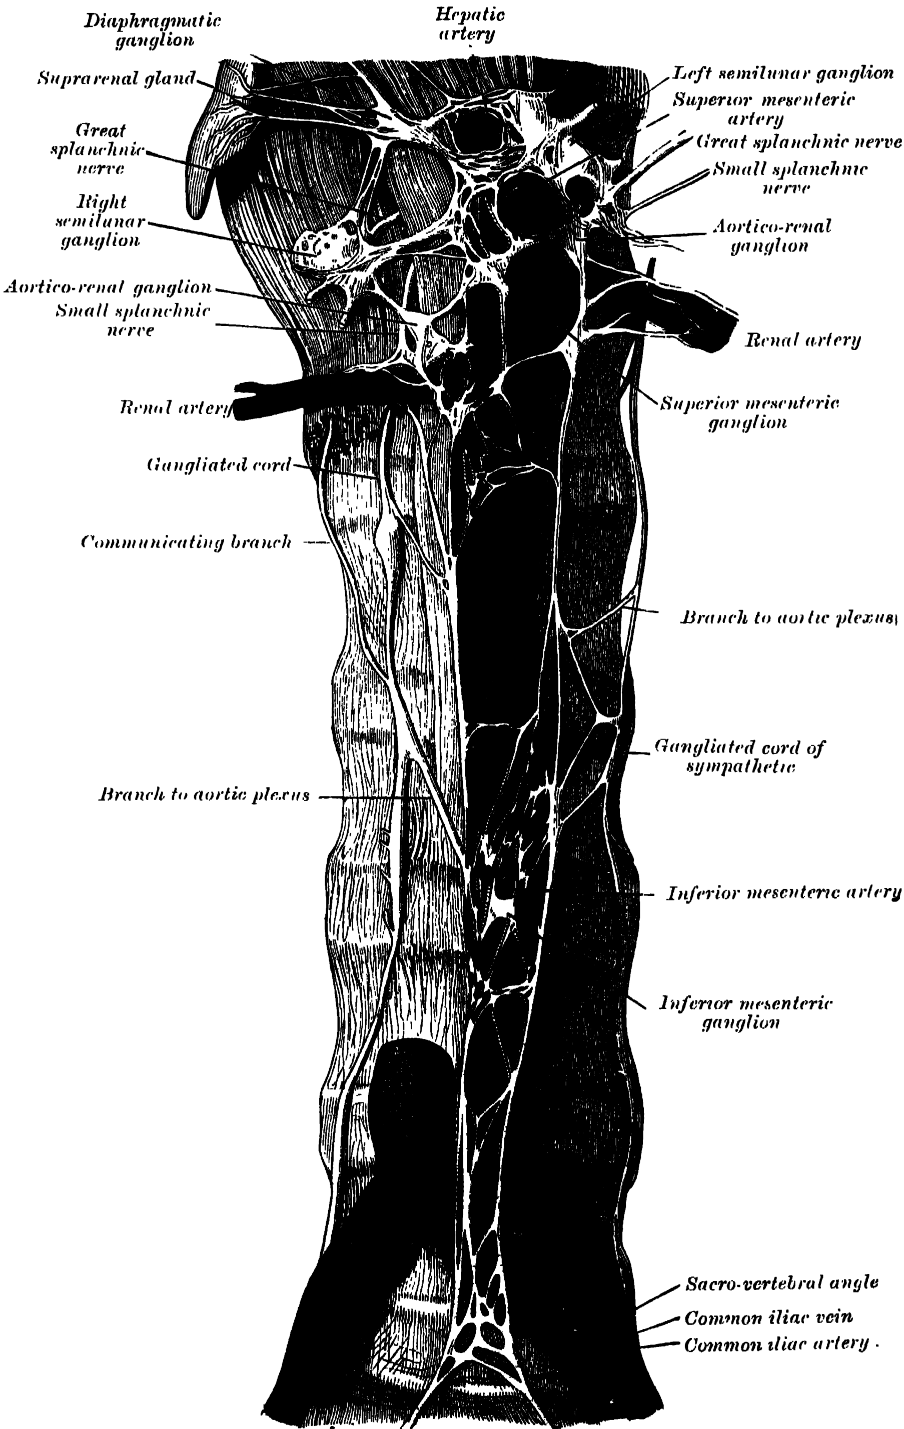
ganglia, and are distributed to a large and important organ in the thoracic cavity. The splanchnic nerves, also three in number, are connected probably with all the thoracic ganglia, and are distributed to important organs in the abdominal cavity.

Lumbar Portion of the Gangliated Cord (fig. 819)

The lumbar portion of the gangliated cord (pars abdominalis s. sympathici) is situated in front of the vertebral column, along the inner margin of the Psoas

magnus. It consists usually of four ganglia (ganglia lumbalia), connected together by interganglionic cords. It is continuous above with the thoracic portion beneath the internal arcuate ligament of the Diaphragm, and below

FIG. 819.—Lumbar portion of the gangliated cord, with the solar and hypogastric plexuses. (After Henle.)



with the sacral portion behind the common iliac artery. The ganglia are of small size, and placed much nearer the median line than are the thoracic ganglia.

Grey rami communicantes connect all the ganglia with the lumbar spinal nerves. There may be two from each ganglion, but the arrangement is not so uniform as in other regions. The first and second, and sometimes the third, lumbar nerves send white rami communicantes to the upper two or three ganglia. From the situation of the lumbar ganglia, these branches are longer than in the other regions. They accompany the lumbar arteries around the sides of the bodies of the vertebræ, passing beneath the fibrous arches from which some of the fibres of the Psoas arise.

Of the *branches of distribution*, some pass inwards, in front of the aorta, and help to form the aortic plexus. Other branches descend in front of the common iliac arteries, and, joining over the promontory of the sacrum, assist in forming the hypogastric plexus. Numerous delicate filaments are also distributed to the bodies of the vertebræ, and the ligaments connecting them.

Pelvic Portion of the Gangliated Cord

The pelvic portion of the gangliated cord (pars pelvina s. sympathici) is situated in front of the sacrum, along the inner side of the anterior sacral foramina. It consists of four or five small ganglia (ganglia sacralia) on either side, connected together by interganglionic cords, and continuous above with the lumbar portion. Below, these cords converge and unite on the front of the coccyx, by means of a small ganglion, the *ganglion impar*.

Grey rami communicantes pass from the ganglia to the sacral and coccygeal nerves. No white rami communicantes join this part of the gangliated cord, but the visceral branches which arise from the third and fourth, and sometimes from the second, sacral are regarded as homologous with white rami communicantes.

The *branches of distribution* communicate on the front of the sacrum with the corresponding branches from the opposite side; some, from the first two ganglia, pass to join the pelvic plexus, and others form a plexus, which accompanies the middle sacral artery and sends filaments to the coccygeal body.

THE GREAT PLEXUSES OF THE SYMPATHETIC

The great plexuses of the sympathetic are the large aggregations of nerves and ganglia, above alluded to, situated in the thoracic, abdominal, and pelvic cavities, and named the cardiac, solar, and hypogastric plexuses. They consist not only of sympathetic fibres derived from the ganglia, but of fibres from the central nervous system, which are conveyed through the white rami communicantes. From the plexuses branches are given to the thoracic, abdominal, and pelvic viscera.

Cardiac Plexus (figs. 816, 817)

The **cardiac plexus** (plexus cardiacus) is situated at the base of the heart, and is divided into a *superficial part*, which lies in the concavity of the arch of the aorta, and a *deep part*, which lies between the trachea and aorta. The two plexuses are, however, closely connected.

The **superficial cardiac plexus** lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the superior cardiac branch of the left sympathetic and the inferior cervical cardiac branch of the left vagus. A small ganglion, the *ganglion of Wrisberg* (g. cardiacum [Wrisbergi]), is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta, on the right side of the ductus arteriosus. The superficial cardiac plexus gives branches (*a*) to the deep cardiac plexus beneath the arch of the aorta; (*b*) to the right or anterior coronary plexus; and (*c*) to the left anterior pulmonary plexus.

The **deep cardiac plexus** is situated in front of the trachea at its bifurcation, above the point of division of the pulmonary artery, and behind the arch of the aorta. It is formed by the cardiac nerves derived from the cervical

ganglia of the sympathetic, and the cardiac branches of the recurrent laryngeal and vagus. The only cardiac nerves which do not enter into the formation of this plexus are the superior cardiac branch of the left sympathetic, and the inferior cervical cardiac branch from the left vagus, which pass to the superficial plexus.

The branches from the *right side* of this plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonary plexus, and are then continued onwards to form part of the right coronary plexus; those behind the pulmonary artery distribute a few filaments to the right auricle, and are then continued onwards to form part of the left coronary plexus.

The *left side* of the plexus is connected with the superficial cardiac plexus, and gives filaments to the left auricle of the heart, and to the anterior pulmonary plexus, and is then continued to form the greater part of the left coronary plexus.

The **left coronary plexus** (plexus coronarius posterior) is larger than the right, and accompanies the left coronary artery; it is chiefly formed by filaments prolonged from the left side of the deep cardiac plexus, and by a few from the right side. It gives branches to the left auricle and ventricle.

The **right coronary plexus** (plexus coronarius anterior) is formed partly from the superficial and partly from the deep cardiac plexus. It accompanies the right coronary artery, and gives branches to the right auricle and ventricle.

Epigastric or Solar Plexus (figs. 819, 820)

The **epigastric** or **solar plexus** supplies the viscera in the abdominal cavity. It consists of a great network of nerves and ganglia situated behind the stomach and lesser sac of the peritoneum, and in front of the aorta and crura of the Diaphragm. It surrounds the cœliac axis and root of the superior mesenteric artery, extending downwards as low as the pancreas, and outwards to the suprarenal glands. This plexus, and the ganglia connected with it, receive the great and small splanchnic nerves of both sides, and some filaments from the right vagus. It distributes filaments, which accompany, under the name of plexuses, all the branches from the front of the abdominal aorta.

Of the ganglia of which the solar plexus is partly composed the principal are the two **semilunar ganglia** (ganglia cœliaca), which are situated one on either side of the plexus, and are the largest peripheral ganglia in the body They are large irregular gangliform masses, formed by the aggregation of smaller ganglia, having interspaces between them. They are situated in front of the crura of the Diaphragm, close to the suprarenal glands, that on the right side lying behind the inferior vena cava. The upper part of each ganglion is joined by the great splanchnic nerve, and to the inner side of each the branches of the solar plexus are connected. The lower portion of each semilunar ganglion is segmented off, and is named the *aortico-renal ganglion*. This receives the lesser splanchnic nerve, and gives off the greater part of the renal plexus.

From the epigastric or solar plexus are derived the following:

Phrenic or Diaphragmatic plexus.	Cœliac plexus	Gastric plexus.
Suprarenal plexus.		Hepatic plexus.
Renal plexus.		Splenic plexus.
Spermatic plexus.	Superior mesenteric plexus.	
Aortic plexus.		

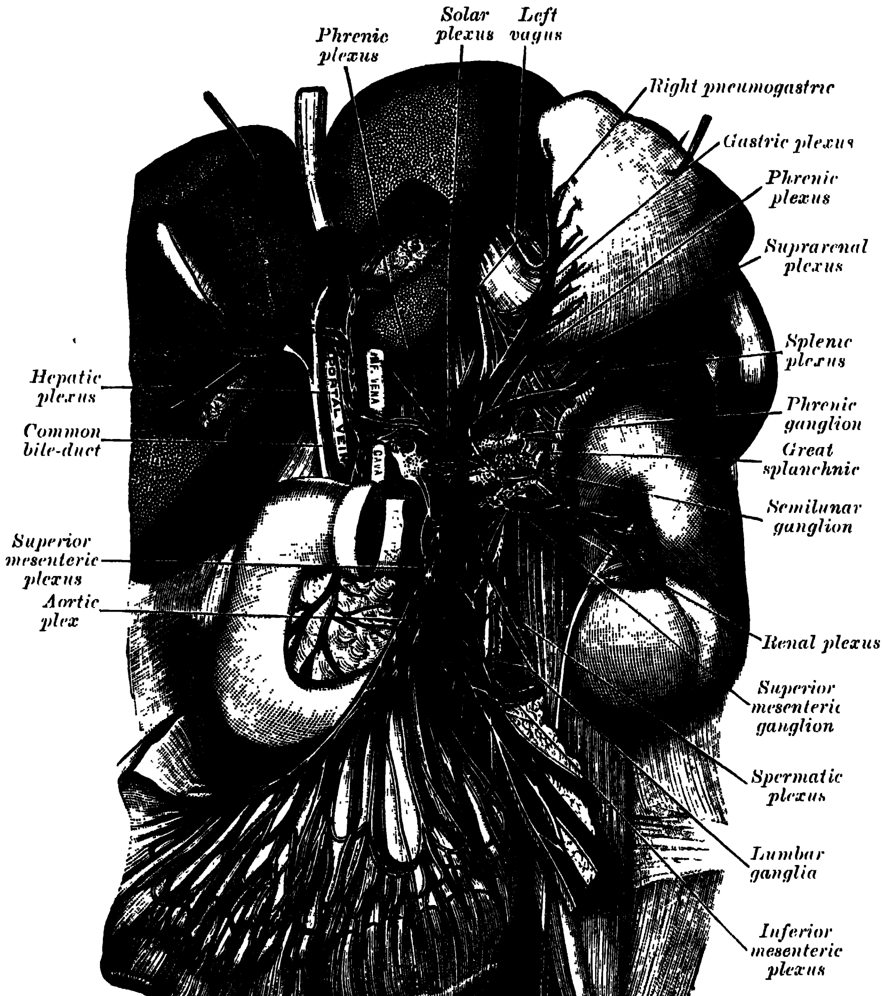
The **phrenic plexus** (plexus phrenicus) accompanies the inferior phrenic artery to the Diaphragm, some filaments passing to the suprarenal gland. It arises from the upper part of the semilunar ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. At the point of junction of the right phrenic plexus with the phrenic nerve is a small ganglion (*ganglion phrenicum*). This ganglion distributes branches to the inferior vena cava, the suprarenal gland, and the hepatic plexus. There is no ganglion on the left side.

The **suprarenal plexus** (plexus suprarenalis) is formed by branches from the solar plexus, from the semilunar ganglion, and from the phrenic and great

splanchnic nerves, a ganglion being formed at the point of junction with the latter nerve. The plexus supplies the suprarenal gland, being distributed chiefly to its medullary portion; its branches are remarkable for their large size in comparison with that of the organ they supply.

The **renal plexus** (plexus renalis) is formed by filaments from the solar plexus, the lower part of the semilunar ganglion (aortico-renal ganglion), and the aortic plexus. It is joined also by the smallest splanchnic nerve. The nerves from these sources, fifteen or twenty in number, have numerous ganglia developed upon them. They accompany the branches of the renal

Fig. 820.—The semilunar ganglia with the sympathetic plexuses of the abdominal viscera radiating from the ganglia. (From Toldt's 'Atlas,' published by Messrs. Rebman, Ltd., London.)



artery into the kidney; some filaments are distributed to the spermatic plexus and, on the right side, to the inferior vena cava.

The **spermatic plexus** (plexus spermaticus) is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the spermatic vessels to the testis.

Applied Anatomy.—The intimate connection which exists between the renal and spermatic plexuses serves to explain the very frequent symptom in renal calculus, of pain which is referred to the body of the testicle.

In the female, the **ovarian plexus** (plexus ovaricus) arises like the spermatic plexus, and is distributed to the ovary, and fundus of the uterus.

The **cœliac plexus** (plexus cœliacus), of large size, is a direct continuation from the solar plexus: it surrounds the cœliac axis, and subdivides into the gastric, hepatic, and splenic plexuses. It receives branches from the lesser splanchnic nerves, and, on the left side, a filament from the right vagus.

The *gastric* or *coronary plexus* (plexus gastricus superior) accompanies the gastric artery along the lesser curvature of the stomach, and joins with branches from the left vagus.

The *hepatic plexus* (plexus hepaticus), the largest offset from the cœliac plexus, receives filaments from the left vagus and right phrenic nerves. It accompanies the hepatic artery, ramifying upon its branches, and upon those of the portal vein in the substance of the liver.

Branches from this plexus accompany all the divisions of the hepatic artery. Thus there is a *pyloric plexus* on the pyloric branch of the hepatic, which joins with the gastric plexus and vagi nerves. There is also a *gastro-duodenal plexus*, subdividing into the *pancreatico-duodenal plexus*, which accompanies the superior pancreatico-duodenal artery, to supply the pancreas and duodenum, and joins with branches from the mesenteric plexus; and the *gastro-epiploic plexus*, which accompanies the right gastro-epiploic artery along the greater curvature of the stomach, and unites with branches from the splenic plexus. A *cystic plexus*, which supplies the gall-bladder, also arises from the hepatic plexus, near the liver.

The *splenic plexus* (plexus lienalis) is formed by branches from the cœliac plexus, the left semilunar ganglia, and from the right vagus nerve. It accompanies the splenic artery and its branches to the substance of the spleen, giving off, in its course, filaments to the pancreas (*pancreatic plexus*), and the *left gastro-epiploic plexus*, which accompanies the left gastro-epiploic artery along the greater curvature of the stomach.

The **superior mesenteric plexus** (plexus mesentericus superior) is a continuation of the lower part of the solar plexus, receiving a branch from the junction of the right vagus nerve with the cœliac plexus. It surrounds the superior mesenteric artery, accompanies it into the mesentery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery, viz. pancreatic branches to the pancreas; intestinal branches to the small intestine; and ileo-colic, right colic, and middle colic branches, which supply the corresponding parts of the great intestine. The nerves composing this plexus are white in colour and firm in texture; in the upper part of the plexus close to the origin of the superior mesenteric artery is a ganglion (*ganglion mesentericum superius*).

The **aortic plexus** (plexus aorticus abdominalis) is formed by branches derived, on either side, from the solar plexus and the semilunar ganglia, and receives filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; it also distributes filaments to the inferior vena cava.

The **inferior mesenteric plexus** (plexus mesentericus inferior) is derived chiefly from the left side of the aortic plexus. It surrounds the inferior mesenteric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery, viz. the *left colic* and *sigmoid plexuses*, which supply the descending and ilio-pelvic parts of the colon; and the *superior hæmorrhoidal plexus* (plexus hæmorrhoidalis superior) which supplies the rectum and joins in the pelvis with branches from the pelvic plexuses.

Hypogastric Plexus (fig. 816)

The **hypogastric plexus** (plexus hypogastricus) is situated in front of the promontory of the sacrum, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on either side from the aortic plexus, and from the lumbar ganglia. This plexus contains no evident ganglia; it bifurcates, below, into two lateral portions which form the *pelvic plexuses*.

Pelvic Plexuses (fig. 816)

The **pelvic plexuses** supply the viscera of the pelvic cavity, and are situated at the sides of the rectum in the male, and at the sides of the rectum and vagina in the female. They are formed on either side by a continuation of the hypogastric plexus, by the visceral branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the points of junction of these nerves small ganglia are found. From these plexuses numerous branches are distributed to the viscera of the pelvis. They accompany the branches of the internal iliac artery.

The **middle hæmorrhoidal plexus** (plexus hæmorrhoidalis medius) arises from the upper part of the pelvic plexus. It supplies the rectum, and joins with branches of the superior hæmorrhoidal plexus.

The **vesical plexus** (plexus vesicalis) arises from the fore-part of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve-fibres. They accompany the vesical arteries, and are distributed to the side and base of the bladder. Numerous filaments also pass to the vesicula seminalis and vas deferens; those accompanying the vas deferens join, on the spermatic cord, with branches from the spermatic plexus.

The **prostatic plexus** (plexus prostaticus) is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate gland, vesiculæ seminales, and erectile structure of the penis. The nerves supplying the erectile structure of the penis consist of two sets, the small and large cavernous nerves, which arise from the fore-part of the prostatic plexus, and, after joining with branches from the internal pudic nerve, pass forwards beneath the pubic arch.

The *small cavernous nerves* (nn. cavernosi penis minores) perforate the fibrous covering of the penis, near its root.

The *large cavernous nerve* (n. cavernosus penis major) passes forwards along the dorsum of the penis, joins with the dorsal nerve of the penis, and is distributed to the corpora cavernosa and corpus spongiosum.

The **vaginal plexus** (plexus vaginalis) arises from the lower part of the pelvic plexus. It is distributed to the walls of the vagina, to the erectile tissue of the vestibule, and to the clitoris. The nerves composing this plexus contain, like the vesical, a large proportion of spinal nerve-fibres.

The **uterine plexus** (plexus uterinus) accompanies the uterine artery to the side of the uterus, between the layers of the broad ligament; it communicates with the ovarian plexus.

Applied Anatomy.—Little is known as to the connection between the numerous microscopical alterations (pigmentation, atrophy, hæmorrhage, fibrosis) that have been described in the sympathetic nervous system, and the functional changes that ensue therefrom. Grosser lesions due to stabs, bullet-wounds, or the pressure of new growths, may cause either irritative or paralytic symptoms. In *paralysis* of the cervical sympathetic on one side, the pupil is small and does not dilate when shaded or on the instillation of cocaine, although it contracts still further when brightly illuminated; it also loses the cilio-spinal reflex, failing to dilate when the skin of the neck is pinched. The palpebral fissure narrows from paralysis of the involuntary muscle of the eyelid, and the eyeball sinks backwards into the orbit—enophthalmus—either from paralysis of Müller's orbital muscle which closes the spheno-maxillary fissure, or from wasting of the intra-orbital fat. The superficial vessels of the face and scalp are at first dilated, but later they contract. Anidrosis, or absence of sweating, is often noted on the affected side. *Irritation* of the cervical sympathetic produces signs mainly the converse of those described above. We have no definite knowledge of the signs and symptoms that follow lesions of the thoracic or abdominal sympathetic systems. It is likely, however, that a number of nervous disorders characterised by persistent vascular disturbances, such as dilatation of the vessels with throbbing, flushing, sweating, and localised œdema, or contraction of the vessels with pallor, chilliness, pain, and malnutrition of the affected parts, are due to implication of the sympathetic nervous system. It is possible, too, that the rare condition of *progressive facial hemiatrophy*, coming on between the ages of ten and twenty, and producing marked unilateral shrinkage of all the tissues of the face, is primarily an affection of the sympathetic.

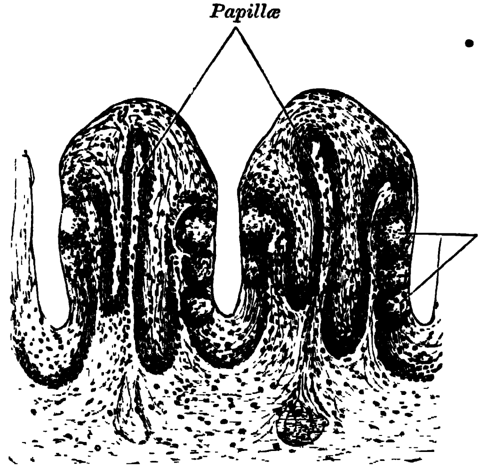
ORGANS OF SPECIAL SENSE

THE organs of the senses (organa sensuum) are five in number: viz. those of Touch, of Taste, of Smell, of Sight, and of Hearing. The skin, which is the principal seat of the sense of touch, has been described in the section on Histology. The remaining four are the organs of special sense.

ORGANS OF TASTE

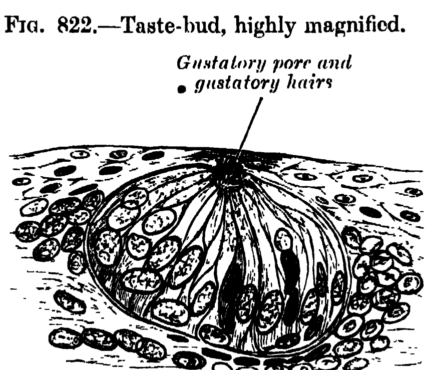
The peripheral organs of the sense of taste consist of certain flask-shaped groups of modified epithelial cells termed *taste-buds*, which are found on the tongue and adjacent parts. They occupy nests in the stratified epithelium, and are present in large numbers on the sides of the circumvallate papillæ (fig. 821), and to a less extent on their opposed walls. They are also found on the fungiform papillæ over the back part and sides of the tongue, and in the general epithelial covering of the same areas. They are very plentiful over the fimbriæ linguæ, and are also present on the under aspect of the soft palate, and on the posterior surface of the epiglottis.

FIG. 821.—Section of part of the papilla foliata of a rabbit. (Magnified.)



Structure.—Each taste-bud is flask-like in shape (fig. 822), its broad base resting on the corium, and its neck opening by an orifice, the *gustatory pore*, between the cells of the epithelium. The bud is formed by two kinds of cells: supporting cells and gustatory cells. The *supporting cells* are mostly arranged like the staves of a cask, and form an outer envelope for the bud. Some, however, are found in the interior of the bud between the gustatory cells. The *gustatory cells* occupy the central portion of the bud; they are spindle-shaped, and each possesses a large spherical nucleus near the middle of the cell. The peripheral end of the cell terminates at the gustatory pore in a fine hair-like filament, the *gustatory hair*. The central process passes towards the deep extremity of the bud, and there ends

FIG. 822.—Taste-bud, highly magnified.



in a single or bifurcated varicose filament, which was formerly supposed to be continuous with the terminal fibril of a nerve; the investigations of Lenhossék and others would seem to prove, however, that this is not so, but that the nerve-fibrils after losing their medullary sheaths enter the taste-bud, and terminate in fine extremities between the gustatory cells. Other nerve-fibrils may be seen ramifying between the supporting cells and terminating in fine extremities; these, however, are believed to be nerves of ordinary sensation and not gustatory.

Nerves of taste.—The chorda tympani nerve, derived from the sensory root of the facial, is generally regarded as the nerve of taste for the anterior two-thirds of the tongue; the nerve for the posterior third is the glosso-pharyngeal.

THE NOSE

The nose is the peripheral organ of the sense of smell: by means of the peculiar properties of its nerves, it protects the lungs from the inhalation of deleterious gases, and assists the organ of taste in discriminating the properties of food.

The organ of smell consists of two parts: an external, the *outer nose*, which projects from the centre of the face; and an internal, the *cavum nasi*, which is divided by a septum into *right* and *left nasal fossæ*.

The **outer nose** (nasus externus) is pyramidal in form, and its upper angle or *root* is connected directly with the forehead. Its *base* is perforated by two elliptical orifices, the *nares*, separated from each other by an antero-posterior

FIG. 823.—Cartilages of the nose. Side view.

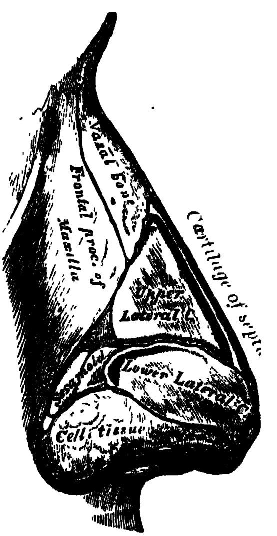


FIG. 824.—Cartilages of the nose, seen from below.

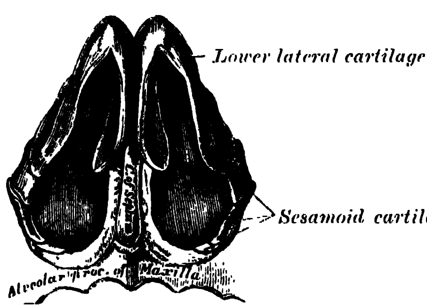


septum, the *columna*. The margins of the nares are provided with a number of stiff hairs, or *vibrissæ*, which arrest the passage of foreign substances carried with the current of air intended for respiration. The lateral surfaces of the nose form, by their union in the middle line, the *dorsum nasi*, the direction of which varies considerably in different individuals; the upper part of the dorsum is supported by the nasal bones, and is named the *bridge*. The lateral surface terminates below in a rounded eminence, the *ala nasi*.

The nose is composed of a framework of bones and cartilages, the latter being slightly acted upon by certain muscles. It is covered by the integument, lined by mucous membrane, and supplied with vessels and nerves.

The *bony framework* occupies the upper part of the organ; it consists of the nasal bones, and the frontal processes of the maxillæ.

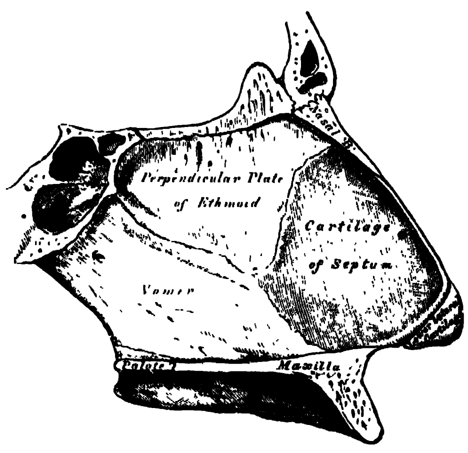
The *cartilaginous framework* consists of five pieces, the two upper and the two lower lateral cartilages, and the cartilage of the septum (figs. 823, 824, 825).

The *upper lateral cartilage* (cartilago nasi lateralis) is situated below the free margin of the nasal bone, and is flattened, and triangular in shape. Its anterior margin is thicker than the posterior, and is continuous above with the

cartilage of the septum, but separated from it below by a narrow fissure. Its posterior margin is attached to the nasal bone and the frontal process of the maxilla. Its inferior margin is connected by fibrous tissue with the lower lateral cartilage; one surface is turned outwards, the other inwards towards the nasal cavity.

The *lower lateral cartilage* (cartilago alaris major) is a thin, flexible plate, situated immediately below the preceding, bent upon itself in such a manner as to form the inner and outer walls of the naris of its own side. The portion which forms the inner wall (*crus mediale*) is thicker than the rest, and loosely connected with the corresponding portion of the opposite cartilage, to form a part of the columna; the opposed inferior borders form, with the thickened integument and subjacent tissue, the septum mobile nasi. The part which forms the outer wall (*crus laterale*) is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the frontal process of the maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates, the *cartilagines alares minores*. Above, it is connected by fibrous tissue to the upper lateral cartilage and front part of the cartilage of the septum; below, it falls short of the margin of the nostril, the ala being completed by fatty and fibrous tissue covered by skin. In front, the lower lateral cartilages are separated by a notch which corresponds with the point of the nose.

Fig. 825.—Bones and cartilages of septum of nose. Right side.



The *cartilage of the septum* (cartilago septi nasi) is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal fossæ in front. Its anterior margin, thickest above, is connected with the nasal bones, and is continuous with the anterior margins of the two upper lateral cartilages; below, it is connected to the inner portions of the lower lateral cartilages by fibrous tissue. Its posterior margin is connected with the perpendicular plate of the ethmoid; its inferior margin with the vomer and the palatal processes of the maxillæ.

It may be prolonged backwards (especially in children) for some distance between the vomer and perpendicular plate of the ethmoid, forming what is termed the *processus sphenoidalis*. The septal cartilage does not reach as far as the lowest part of the nasal septum. This is formed by the inner portions of the lower lateral cartilages and by the skin; it is freely movable, and hence is termed the *septum mobile nasi*.

The various cartilages are connected to each other, and to the bones, by a tough fibrous membrane, which allows the utmost facility of movement between them.

The *muscles of the nose* have been described on pages 463, 464.

The *integument* covering the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts; but where it forms the tip and the alæ of the nose it is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The *arteries of the outer nose* are the lateralis nasi from the facial, and the inferior artery of the septum from the superior coronary, which supply the alæ and septum; the sides and dorsum being supplied from the nasal branch of the ophthalmic and the infra-orbital branch of the internal maxillary. The *veins* terminate in the facial and ophthalmic.

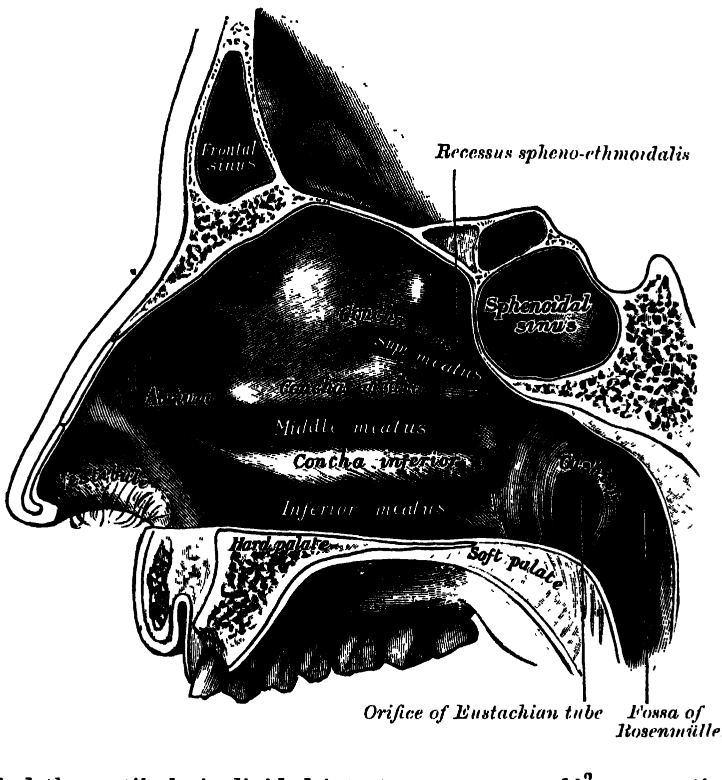
The *nerves* for the muscles of the nose are derived from the facial, while the skin receives branches from the infra-trochlear and nasal branches of the ophthalmic, and from the infra-orbital.

Nasal fossæ.—The nasal fossæ are two irregular cavities situated one on either side of the mesial plane. They open in front through the nares, and communicate behind through the choanæ with the naso-pharynx. The *nares* are somewhat pear-shaped apertures, each measuring about one inch antero-posteriorly and half an inch transversely at its widest part. The *choanæ* are two oval openings which are smaller in the living or recent subject than in the skeleton, because they are narrowed by the mucous membrane. Each measures an inch in the vertical, and half an inch in the transverse direction in a well-developed adult skull.

For the description of the bony boundaries of the nasal fossæ, see page 275.

Inside the aperture of the nostril is a slight dilatation, the *vestibule* (vestibulum nasi), bounded externally by the ala and outer plate of the lower lateral cartilage, and internally by the mesial plate of the same cartilage. It is lined by skin, and contains hairs and sebaceous glands, and extends as a small pouch, the *ventricle*, towards the point of the nose. The fossa, above

FIG. 826.—Outer wall of nasal fossa.



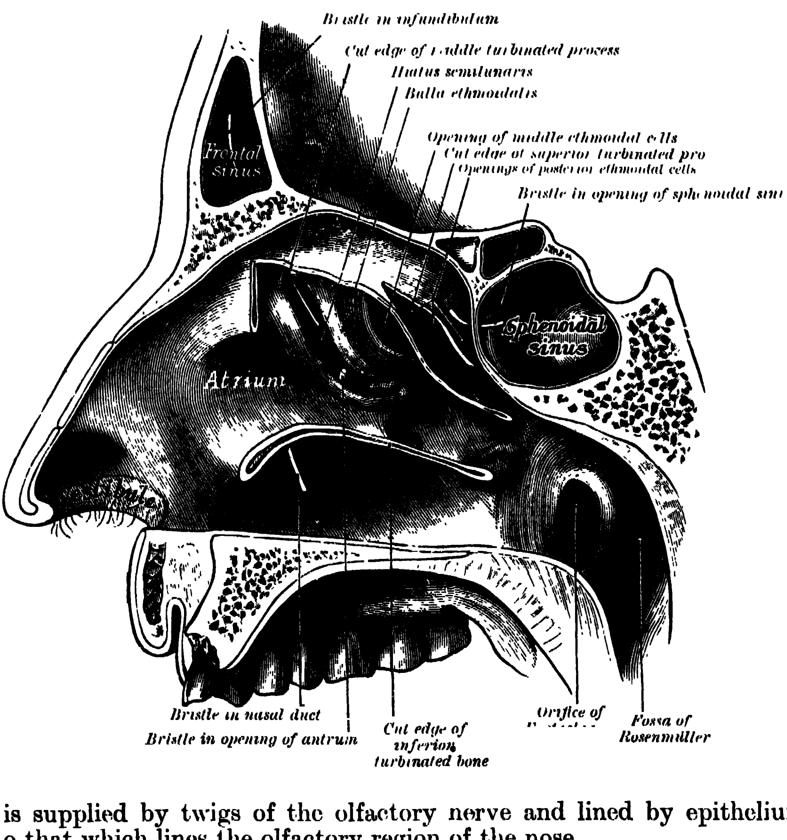
and behind the vestibule, is divided into two parts: an *olfactory* portion (regio olfactoria), consisting of the superior turbinated process and the opposed part of the septum, and a *respiratory* portion (regio respiratoria), which comprises the rest of the fossa.

Outer wall (figs. 826, 827).—The sphenoidal air-sinus opens into the recessus spheno-ethmoidalis, a narrow recess above the superior turbinated process. The posterior ethmoidal cells open into the front and upper part of the superior meatus. On raising or cutting away the middle turbinated bone the outer wall of the middle meatus is fully exposed, and presents (1) a rounded elevation, the *bulla ethmoidalis*, opening on or immediately above which are the orifices of the middle ethmoidal cells; (2) a deep, narrow, curved groove, in front of the bulla ethmoidalis, termed the *hiatus semilunaris*, into the lower part of which the antrum of Highmore opens, the orifice being placed near the roof of the antrum. The middle meatus is prolonged, above and in front, into the *infundibulum*; this leads into the frontal sinus, and into it the anterior

ethmoidal cells open. The anterior extremity of the meatus is continued into a depressed area, lying above the vestibule and named the *atrium meatus medii*. The *nasal duct* opens into the anterior part of the inferior meatus, the opening being overlapped sometimes by a fold of mucous membrane.

Inner wall (fig. 825).—The inner wall or septum is frequently more or less deflected from the mesial plane, thus lessening the size of one fossa and increasing that of the other. Ridges or spurs of bone growing outwards from the septum are also sometimes present. Immediately over the incisive foramen at the lower edge of the cartilage of the septum a depression, the *naso-palatine recess*, may be seen. In the septum close to this recess a minute orifice may be discerned: it leads backwards into a blind pouch, the rudimentary *organ of Jacobson* (organon vomeronasale), which is supported by a strip of cartilage, the *cartilage of Jacobson* (cartilago vomeronasalis). This organ is well-developed in many of the lower animals, where it apparently plays a part in the sense of smell,

FIG. 827.—Outer wall of nasal fossa; the turbinated processes of the ethmoid and the inferior turbinated bone have been removed.



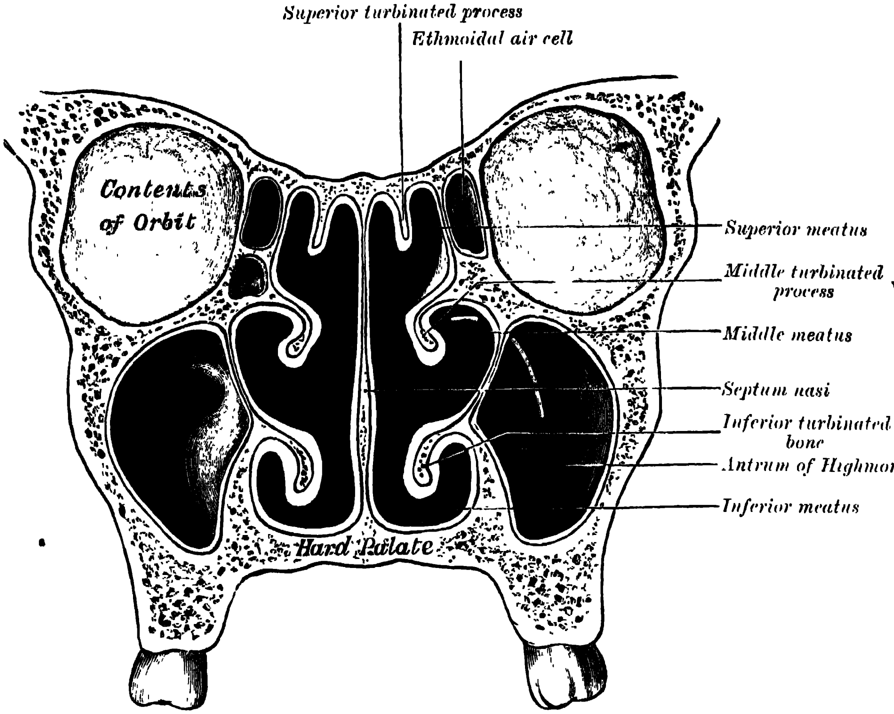
since it is supplied by twigs of the olfactory nerve and lined by epithelium similar to that which lines the olfactory region of the nose.

The *mucous membrane* lining the nasal fossæ is sometimes called the *Schneiderian membrane*, from Schneider,* who first showed that the nasal secretion proceeded from the mucous membrane, and not, as was formerly imagined, from the brain. It is intimately adherent to the periosteum or perichondrium over which it lies. It is continuous with the skin through the anterior nares, and with the mucous membrane of the naso-pharynx through the posterior nares. From the nasal fossæ its continuity with the conjunctiva may be traced, through the nasal duct and lachrymal canals; and with the frontal, ethmoidal, and sphenoidal sinuses, and the antrum of Highmore, through the several openings in the meatuses. The mucous membrane is thickest, and most vascular, over the turbinated bones and processes. It is

* Conrad Victor Schneider, 1614–1680, Professor of Anatomy at Wittemberg.

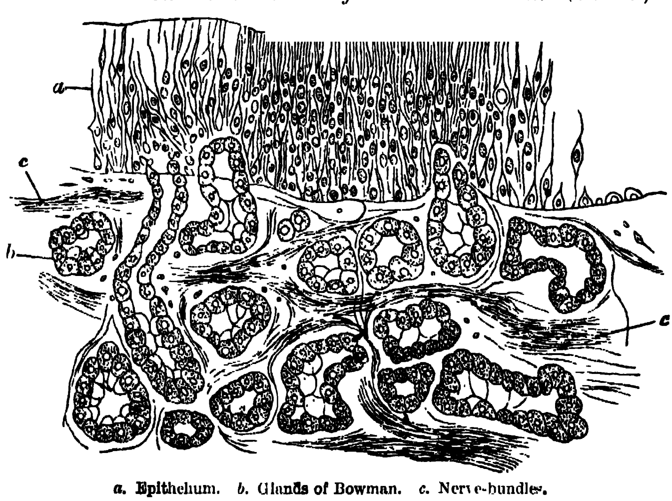
also thick over the septum ; but it is very thin in the meatuses and on the floor of the nasal fossæ. Where it lines the various sinuses it is thin and pale.

Fig. 828.—Coronal section of nasal fossæ.



Owing to the great thickness of this membrane, the nasal fossæ are much narrower, and the middle turbinated process and inferior turbinated bone appear larger and more prominent than in the skeleton. From the same circumstance, also, the various apertures communicating with the meatuses are considerably narrowed.

Fig. 829.—Section of the olfactory mucous membrane. (Cadiat.)

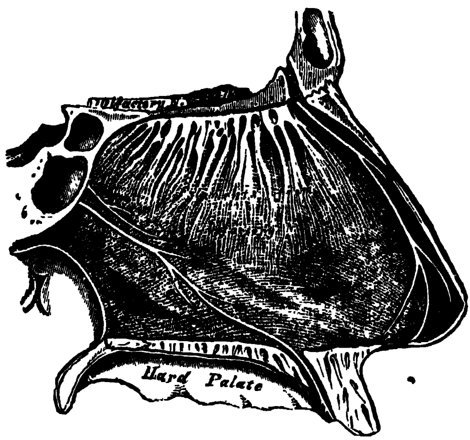


a. Epithelium. b. Glands of Bowman. c. Nerve-bundles.

Structure of the mucous membrane (fig. 829).—The epithelium covering the mucous membrane differs in its character according to the functions of the part

of the nose in which it is found. In the *respiratory region* it is columnar and ciliated. Interspersed among the columnar cells are goblet or mucin cells, while between their bases are found smaller pyramidal cells. Beneath the epithelium and its basement membrane is a fibrous layer infiltrated with lymph-corpuscles, so as to form in many parts a diffuse adenoid tissue, and under this a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the *olfactory region* the mucous membrane is yellowish in colour and the epithelial cells are columnar and non-ciliated; they are of two kinds, supporting cells and olfactory cells. The *supporting cells* contain oval nuclei, which are situated in the deeper parts of the cells and constitute the zone of oval nuclei; the outer part of the cell is columnar, and contains granules of yellow pigment, while its deeper portion is prolonged as a delicate process which ramifies and communicates with similar processes from neighbouring cells, so as to form a network in the mucous membrane. Lying between these central processes of the supporting cells are a number of spindle-shaped cells, the *olfactory cells*, each consisting of a large spherical nucleus surrounded by a small amount of granular protoplasm, and possessing two processes, one of which runs outwards between the columnar epithelial cells, and projects on the surface of the mucous membrane as a fine, hair-like process, the *olfactory hair*; the other or deep process runs inwards, is frequently beaded, and is continuous with one of the filaments of the olfactory nerve. Beneath the epithelium, and extending through the thickness of the mucous membrane, is a layer of tubular, often branched, glands, the *glands of Bowman*, identical in structure with serous glands.

Fig. 830.—Nerves of septum of nose. Right side.



Vessels and Nerves.—The *arteries* of the nasal fossæ are the anterior and posterior ethmoidal branches of the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; the spheno-palatine branch of the internal maxillary, which supplies the mucous membrane covering the turbinated processes and inferior turbinated bone, the meatuses and septum; the inferior artery of the septum, from the superior coronary of the facial; the infra-orbital and alveolar branches of the internal maxillary, which supply the lining membrane of the antrum; and the pterygo-palatine branch of the same artery, distributed to the sphenoidal sinus. The ramifications of these vessels form a close plexiform network, beneath and in the substance of the mucous membrane.

The *veins* of the nasal fossæ form a close cavernous network beneath the mucous membrane. This cavernous appearance is especially well marked over the lower part of the septum and over the middle turbinated process and inferior turbinated bone. Some of the veins open into the spheno-palatine vein; others join the facial vein; some accompany the ethmoidal arteries, and terminate in the ophthalmic vein; and, lastly, a few communicate with the veins in the interior of the skull, through the foramina in the cribriform plate of the ethmoid bone, and the foramen cæcum.

The *lymphatics* have already been described (page 770).

The *nerves* of ordinary sensation are, the nasal branch of the ophthalmic, filaments from the anterior dental branch of the superior maxillary, the Vidian, the naso-palatine, the large or anterior palatine, and nasal branches of Meckel's ganglion.

The nasal branch of the ophthalmic distributes filaments to the fore-part of the septum and outer wall of the nasal fossæ. Filaments from the anterior dental branch of the superior maxillary supply the inferior meatus and inferior turbinated bone. The Vidian nerve supplies the upper and back part of the septum, and superior spongy bone; and the upper nasal branches from the spheno-palatine ganglion have a similar distribution. The naso-palatine nerve supplies the middle of the septum. The large, or anterior palatine, nerve supplies the lower nasal branches to the middle turbinated process and inferior turbinated bone.

The *olfactory*, the special nerve of the sense of smell, is distributed to the olfactory region.

Accessory Sinuses of the Nose (figs. 826, 827, 828)

The **accessory sinuses or air-cells of the nose** are the frontal, ethmoidal, sphenoidal and maxillary; they vary in size and form in different individuals, and are lined by mucous membrane directly continuous with that of the nasal fossæ.

The **frontal sinuses**, situated behind the superciliary ridges, are rarely symmetrical, and the septum between them frequently deviates to one or other side of the middle line. Their average measurements are as follows: height, 1¼ in.; breadth, 1 in.; depth from before backwards, 1 in. Each opens into the anterior part of the corresponding middle meatus of the nose through the infundibulum which traverses the anterior part of the lateral mass of the ethmoid. Absent at birth, they are generally fairly well-developed between the ninth and twelfth years, but only reach their full size after puberty.

The **ethmoidal air-cells** consist of numerous thin-walled cavities situated in the lateral masses of the ethmoid and completed by the frontal, maxilla, lachrymal, sphenoid, and palate. They lie between the upper parts of the nasal fossæ and the orbits, and are separated from these cavities by thin bony laminæ. They are arranged in three groups, anterior, middle, and posterior. The anterior and middle groups open into the middle meatus of the nose, the former by way of the infundibulum, the latter directly on or above the bulla ethmoidalis. The posterior cells open into the superior meatus under cover of the superior turbinated process; sometimes one or more of them opens into the sphenoidal sinus.

The **sphenoidal sinuses** contained within the body of the sphenoid vary in size and shape; owing to the lateral displacement of the intervening septum they are rarely symmetrical. The following are their average measurements: vertical height ⅞ in.; transverse breadth ¾ in.; antero-posterior depth ⅞ in. When exceptionally large they may extend into the roots of the pterygoid processes or greater wings, and may invade the basilar process of the occipital. Each sinus communicates with the recessus spheno-ethmoidalis by means of an aperture in the upper part of its anterior wall. Their development does not begin until about the eighth year.

The **maxillary sinus** or **antrum of Highmore**, the largest of the accessory sinuses of the nose, is a pyramidal cavity in the body of the maxilla. Its base is formed by the outer wall of the nasal fossa, and its apex extends into the zygomatic process. Its roof or orbital wall is frequently ridged by the infra-orbital canal, while its floor is formed by the alveolar process and is usually on a level with the floor of the nose; projecting into the latter are several conical elevations corresponding with the roots of the first and second molar teeth, and in some cases the floor is perforated by one or more of these roots. The size of the sinus varies in different skulls, and even on the two sides of the same skull. The following measurements are those of an average-sized antrum: vertical height opposite the first molar tooth 1½ in.; transverse breadth 1 in.; antero-posterior depth 1¼ in. In the antero-superior part of its base is an opening through which it communicates with the lower part of the hiatus semilunaris; a second orifice is frequently seen in, or immediately behind, the hiatus. The maxillary antrum appears as a shallow groove on the inner surface of the bone about the fourth month of fœtal life, but does not reach its full size until after the second dentition.*

Applied Anatomy.—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the outer nose, an aperture only being present; or perfect development on one side, and suppression or malformation on the other. Deformities which have been acquired are much more common, such as flattening of the nose, the result of syphilitic necrosis; or imperfect development of the nasal bones in cases of congenital syphilis; or a lateral deviation of the nose may result from fracture.

The skin over the alæ and tip of the nose is thick and closely adherent to subjacent parts; inflammation of this part is therefore very painful, on account of the tension. It is largely supplied with blood, and, the circulation here being terminal, vascular engorgement is liable to occur, especially in women at the menopause, and in both sexes from disorders of digestion, exposure to cold, &c. The skin of the nose also contains a large number of sebaceous follicles, and these, as the result of intemperance, are apt to become affected and the nose reddened, congested, and irregularly swollen. To this the term 'grog-blossom' is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues. Epithelioma and rodent ulcer may attack

* The various measurements of the accessory sinuses of the nose given above are quoted from Aldren Turner's *Accessory Sinuses of the Nose.*

the nose, the latter being the more common of the two. Lupus and syphilitic ulceration frequently affect the nose, and may destroy the whole of the cartilaginous portion. In fact, lupus vulgaris begins more frequently on the ala of the nose than in any other situation.

To examine the nasal cavities, the head should be thrown back and the nose drawn upwards, the parts being dilated by some form of speculum. The posterior nares can be explored by reflected light from the mouth, through which they can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the presence of foreign bodies or tumours in the naso-pharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The septum of the nose may be displaced or may deviate from the middle line ; this may be the result of an injury or of some congenital defect. Sometimes the deviation may be so great that the septum may come into contact with the outer wall of the nasal fossa, and may even become adherent to it, thus producing complete obstruction. Perforation of the septum is not an uncommon affection, and may arise from several causes : syphilitic or tuberculous ulceration, blood-tumour or abscess of the septum. When small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside without treatment ; but in the more violent hæmorrhages of later life it may be necessary to plug the posterior nares. In performing this operation it is desirable to remember the size of the posterior nares. A ready method of regulating the bulk of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

Foreign bodies, such as boot-buttons, are frequently inserted into the nostrils by children, and require some care in removal, as unskilled attempts only result in pushing the foreign body further into the nasal fossa. Bodies which remain in the nose for any length of time set up ulceration of the mucous membrane, sometimes spreading to the bone, and a profuse purulent discharge results. A condition of unilateral nasal discharge in a child is always suggestive of the presence of a foreign body. The removal of such objects is best effected by giving the child an anæsthetic, opening the mouth with a gag, and placing the left forefinger in the naso-pharynx, so as to prevent the escape of the body into the air-passages ; the foreign body is then removed through the anterior naris by a suitable scoop or forceps manipulated by the right hand.

Enlargement of the mucous membrane covering the inferior turbinated bone or middle turbinated process is a very frequent accompaniment of chronic nasal catarrh. In old-standing cases the bones themselves may become enlarged, constituting the 'hypertrophied turbinals' which are so often the cause of nasal obstruction. In the case of the inferior turbinated the anterior or posterior extremity is usually more especially affected, giving rise to a reddened mass of tissue often confused with a nasal polypus : the appearances, however, are totally different, as the true nasal polypi appear as glistening greyish-white bodies between the turbinates. Turbinal hypertrophy can be temporarily reduced to a great extent by the local application of cocaine, and if the reduction by this means is to practically the normal condition, then treatment by application of the galvano-cautery will be sufficient ; otherwise the enlarged portion of the bone or bones will require removal by a wire snare after the attachment to the lateral wall of the nasal fossa has been freed, by special nasal scissors, in the case of enlargement of the anterior end, and by the spoke-shave when the posterior end is enlarged. It is highly inadvisable to remove more than is necessary, as too free removal results in a dry condition of the air-passages, which conduces to a chronic dry pharyngitis and laryngitis.

Nasal polypi are of frequent occurrence ; in the common gelatinous form they spring from the outer wall of the nasal fossa and project down between the turbinateds, giving rise to obstructed nasal respiration. They are always accompanied by purulent discharge, and are due, in all instances to small areas of carious bone in the region of the *bulla ethmoidalis*, or about the ethmoidal or sphenoidal air-cells. They appear as glistening greyish-white bodies swinging on a pedicle, and the larger ones can be encircled with a cold wire snare and thus removed ; usually, however, after the extirpation of the larger ones has been carried out, numerous small polypi can be seen springing from the region of their bases, and cauterisation of such affected areas must be thoroughly carried out if a recurrence of the trouble is to be avoided. In bad cases a free curetting of the ethmoidal air-cells may be called for after removal of the middle turbinated process. Fibrous polypi are also more rarely met with, and these are of the nature of new growths ; they most frequently spring from the base of the skull behind the posterior nares and form pedunculated tumours occupying the naso-pharynx. Malignant polypi also occur, most commonly originating in the antrum and projecting through its inner wall into the nasal fossa ; for such cases removal of the maxilla offers the only hope of cure.

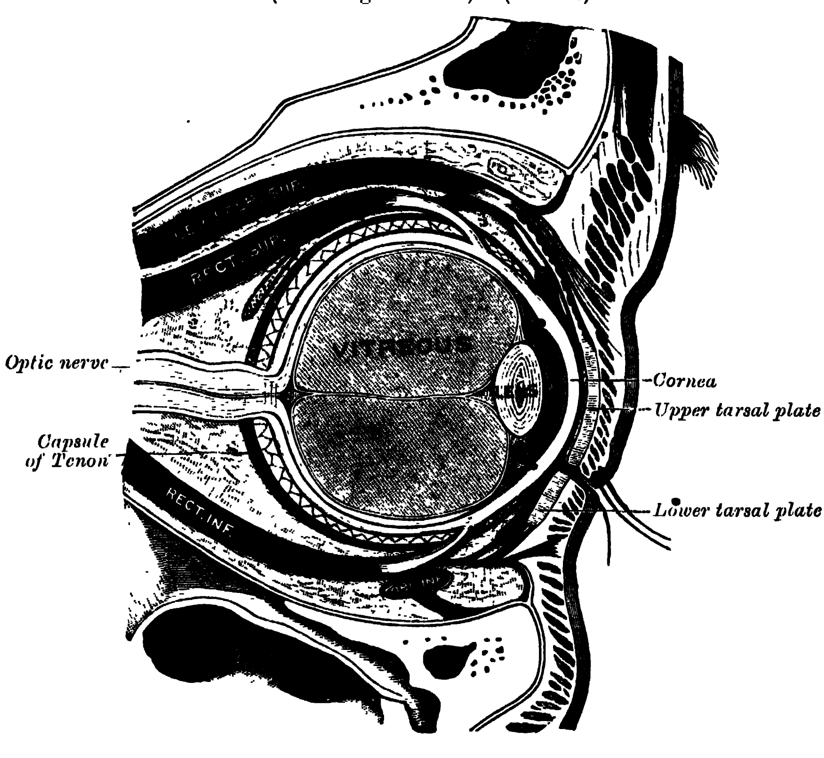
Suppuration in the accessory nasal sinuses is of frequent occurrence, and in connection with this it is advisable that the student should recollect the situations at which the various sinuses normally communicate with the nasal fossæ : thus one finds they fall into two main groups : the anterior, opening into the middle meatus and draining the maxillary

antrum, the frontal sinus and the anterior ethmoidal air-cells, the two latter *via* the infundibulum; and the posterior group, opening into the superior meatus and spheno-ethmoidal recess and draining the posterior ethmoidal and sphenoidal air-cells. Suppuration in the anterior group is the more common, and the pus can be seen running down over the anterior end of the inferior turbinated, whereas in the case of the posterior group, the pus does not come forwards, but runs back into the naso-pharynx over the posterior end of the middle turbinated process. Again, it is of importance to notice that the middle meatus is of such a form that pus running down the infundibulum from the frontal sinus is directed by the groove beneath the bulla ethmoidalis straight into the ostium of the maxillary antrum. So that the latter sinus may, in some cases, act as a secondary reservoir for pus discharged from the frontal sinus. All the accessory sinuses can be and are infected from the nasal fossa, but it should be noted that in the case of one sinus, viz. the maxillary antrum, the infection is frequently conveyed in another way, and that is from the teeth. This sinus is the one most frequently the seat of chronic suppuration and it often requires drainage. This drainage can be carried out by drilling a hole through the alveolus after removal of a tooth, preferably the first molar, or by gouging away the facial aspect of the maxilla, after having reflected the gum by incision of the mucous membrane, or by removing bone from the outer wall of the inferior meatus of the nose. Simple drainage, however, is not usually sufficient, and more extensive operations have often to be performed.

THE EYE

The eyeball (bulbus oculi) is contained in the cavity of the orbit. In this situation it is protected from injury, while its position is such as to ensure an extensive range of sight; it is additionally protected in front by several appendages, such as the eyebrow, eyelids, &c.

FIG. 831.—The right eye in sagittal section, showing the capsule of Tenon (semi-diagrammatic). (Testut.)



The eyeball is imbedded in the fat of the orbit, but is surrounded by a thin membranous sac, the *capsule of Tenon*, which isolates it, so as to allow of free movement.

The **capsule of Tenon** (fascia bulbi) (fig. 831) is a thin membrane which envelops the eyeball from the optic nerve to the ciliary region, separating it

from the orbital fat and forming a socket in which it plays. Its inner surface is smooth, and is separated from the outer surface of the sclera by the *periscleral lymph-space*. This lymph-space is continuous with the subdural and subarachnoid spaces, and is traversed by delicate bands of connective tissue which extend between the capsule and the sclera. The capsule is perforated behind by the ciliary vessels and nerves and by the optic nerve, being continuous with the sheath of the latter. In front it blends with the ocular conjunctiva, and with it is attached to the ciliary region of the eyeball. It is perforated by the tendons of the ocular muscles, and is reflected backwards on each as a tubular sheath. The sheath of the Superior oblique is carried as far as the fibrous pulley of that muscle; that on the Inferior oblique reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the Recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the Superior rectus blends with the tendon of the Levator palpebræ; that of the Inferior rectus is attached to the inferior tarsal plate. These two Recti, therefore, will exercise some influence on the movements of the eyelids. The expansions from the sheaths of the Internal and External recti are strong, especially that from the latter muscle, and are attached to the lachrymal and malar bones respectively. As they probably check the action of these two Recti they have been named the *internal* and *external check ligaments*.

Lockwood has described a thickening of the lower part of the capsule of Tenon, which he has named the *suspensory ligament of the eye*. It is slung like a hammock below the eyeball, being expanded in the centre, and narrow at its extremities which are attached to the malar and lachrymal bones respectively.*

The eyeball is composed of segments of two spheres of different sizes. The anterior segment is one of a small sphere; it is transparent, and forms about one-sixth of the eyeball. It is more prominent than the posterior segment, which is one of a larger sphere, and is opaque, and forms about five-sixths of the globe. The term *anterior pole* is applied to the central point of the anterior curvature of the eyeball, and that of *posterior pole* to the central point of its posterior curvature; a line joining the two poles forms the *axis optica*. The axes of the eyeballs are nearly parallel, and therefore do not correspond to the axes of the orbits, which are directed forwards and outwards. The optic nerves follow the direction of the axes of the orbits, and are therefore not parallel; each enters its eyeball about 1 mm. below and 3 mm. to the inner or nasal side of the posterior pole. The eyeball measures rather more in its transverse and antero-posterior diameters than in its vertical diameter, the former amounting to about 24 mm. the latter to about 23·5 mm.; in the female all three diameters are rather less than in the male. At birth the eyeball has a diameter of about 17·5 mm., while at puberty it measures from 20 to 21 mm.

The eyeball is composed of three tunics, and of three refracting media.

Tunics of the Eye (fig. 832)

From without inwards the three tunics are: (1) A fibrous tunic (tunica fibrosa oculi), consisting of the *sclera* behind and the *cornea* in front; (2) a vascular pigmented tunic (tunica vasculosa oculi), comprising, from behind forwards, the *choroid*, *ciliary body*, and *iris*; and (3) a nervous tunic, the *retina*.

I. The Sclera and Cornea

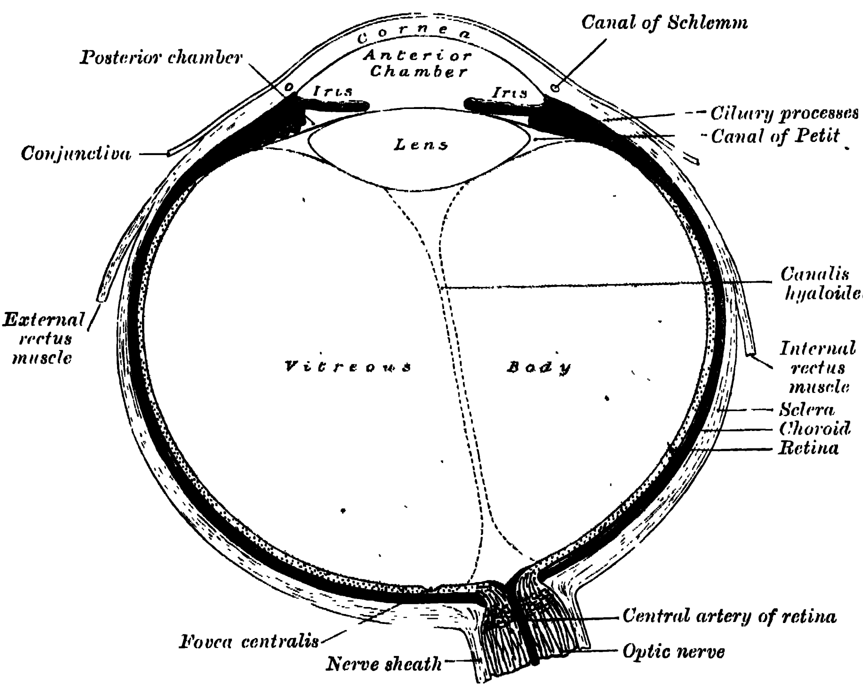
The sclera and cornea (fig. 832) form the external tunic of the eyeball; they are essentially fibrous in structure, the sclera being opaque, and forming the posterior five-sixths of the surface of the globe; the cornea forms the remaining sixth, and is transparent.

The **sclera** has received its name from its extreme density and hardness; it is a firm, unyielding, fibrous membrane, serving to maintain the form of the globe. It is much thicker behind than in front. Its *external surface* is of a white colour, and is in contact with the inner surface of the capsule of Tenon; it is quite smooth, except at the points where the Recti and Obliqui

* See a paper by C. B. Lockwood, *Journal of Anatomy and Physiology*, vol. xx. part i. p. 1.

are inserted into it, and its anterior part is covered by the conjunctival membrane: hence the whiteness and brilliancy of the front of the eyeball. Its *inner surface* is stained of a brown colour and marked by grooves, in which are lodged the ciliary nerves and vessels; it is separated from the outer surface of the choroid by an extensive lymph-space (*spatium perichorioideale*) which is traversed by an exceedingly fine cellular tissue, the *lamina suprachorioidea*. Behind, it is pierced by the optic nerve, and is continuous through the fibrous sheath of this nerve with the dura mater. At the point where the optic nerve passes through the sclera, the tunic forms a thin cribriform lamina, the *lamina cribrosa scleræ*; the minute orifices in this lamina serve for the transmission of the nervous filaments, and the fibrous septa dividing them from one another are continuous with the membranous processes which separate the bundles of nerve-fibres. One of these openings, larger than the rest, occupies the centre of the lamella; it transmits the central artery and vein of the retina. Around the cribriform lamella are numerous small apertures for the transmission of the ciliary vessels and nerves, and about midway between

FIG. 832.—Horizontal section of the eyeball.



the margin of the cornea and the entrance of the optic nerve are four or five large apertures, for the transmission of veins (*venæ vorticosæ*). In front, the fibrous tissue of the sclera is directly continuous with that of the cornea, but the opaque sclera slightly overlaps the outer surface of the transparent cornea.

Structure.—The sclera is formed of white fibrous tissue intermixed with fine elastic fibres, and of flattened connective-tissue corpuscles, some of which are pigmented, contained in cell-spaces between the fibres. The fibres are aggregated into bundles, which are arranged chiefly in a longitudinal direction. Its *vessels* are not numerous, the capillaries being of small size, uniting at long and wide intervals. Its *nerves* are derived from the ciliary nerves, but their exact mode of ending is not known.

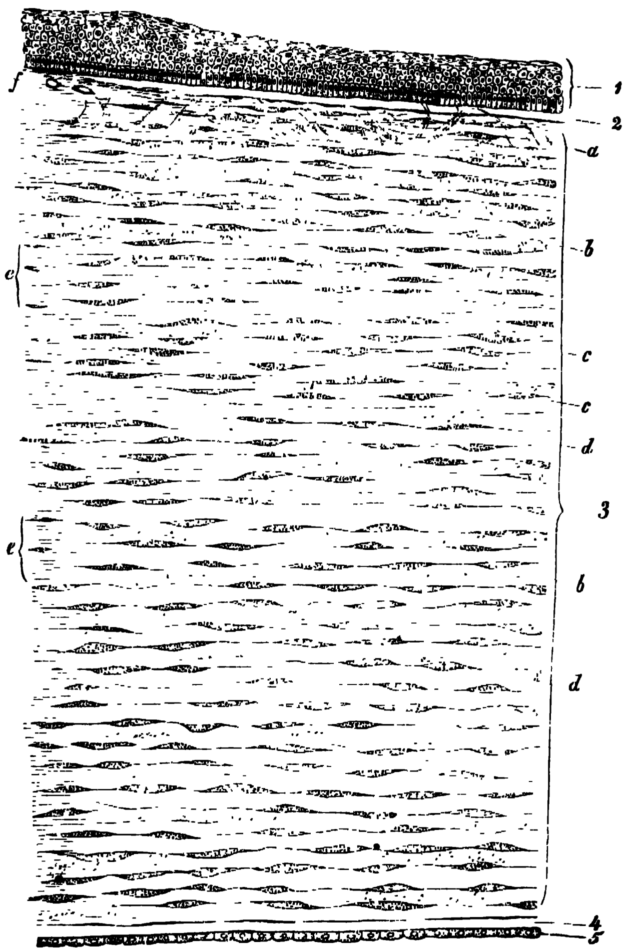
The **cornea** is the projecting transparent part of the external tunic of the eyeball, and forms the anterior sixth of the surface of the globe. It is almost circular in outline, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects forwards from the sclera in the same manner that a watch-glass does from its case. Its degree of curvature varies in different individuals, and in the same individual at different

periods of life, being more pronounced in youth than in advanced life. The cornea is dense and of uniform thickness throughout; its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in extent, from the latter being overlapped by the tissue of the sclera.

Structure (fig. 833).—The cornea consists from before backwards of the four following layers, viz.: (1) a layer of stratified epithelium, continuous with that of the conjunctiva; (2) the *substantia propria*; (3) a homogeneous elastic lamina; and (4) a layer of endothelium.

The *stratified epithelium* (epithelium corneæ) covering the front of the cornea consists of several layers of cells. The cells of the deepest layer are columnar;

FIG. 833.—Vertical section of human cornea from near the margin. (Waldeyer.) Magnified.



1. Epithelium. 2. Anterior homogeneous lamina. 3. Substantia propria. 4. Posterior homogeneous (elastic) lamina. 5. Endothelium of the anterior chamber. *a.* Oblique fibres in the anterior layer of the substantia propria. *b.* Lamellæ the fibres of which are cut across, producing a dotted appearance. *c.* Corneal corpuscles appearing fusiform in section. *d.* Lamellæ the fibres of which are cut longitudinally. *e.* Transition to the sclera, with more distinct fibrillation, and surmounted by a thicker epithelium. *f.* Small blood-vessels cut across near the margin of the cornea.

then follow two or three layers of polyhedral cells, the majority of which present finger-like processes (i.e. prickle-cells) similar to those found in the cuticle. Lastly, there are three or four layers of scaly epithelium, with flattened nuclei.

The *substantia propria* is fibrous, tough, unyielding, perfectly transparent, and continuous with the sclera. It is composed of about sixty flattened lamellæ, superimposed one on another. These lamellæ are made up of bundles

of modified connective tissue, the fibres of which are directly continuous with the fibres of the sclera. The fibres of each lamella are for the most part parallel with one another, but at right angles to those of adjacent lamellæ. Fibres, however, frequently pass from one lamella to the next.

The lamellæ are connected with each other by an interstitial cement-substance, in which are spaces, the *corneal spaces*. These are stellate in shape and have numerous offsets, by which they communicate with each other. Each contains a cell, the *corneal corpuscle*, resembling in form the space in which it is lodged, but not entirely filling it.

Immediately beneath the conjunctival epithelium, the cornea proper presents certain characteristics which have led some anatomists to regard it as a distinct membrane, and it has been named the *lamina elastica anterior of Bowman*. It differs, however, from the lamina elastica posterior, in presenting evidence of fibrillar structure, and in not having the same tendency to curl inwards, or to undergo fracture, when detached from the other layers of the cornea. It consists of extremely closely interwoven fibrils, similar to those found in the substantia propria, but contains no corneal corpuscles. It may be regarded as a part of the proper tissue of the cornea.

The *lamina elastica posterior* (*membrane of Descemet or Demours*) covers the posterior surface of the substantia propria, and consists of an elastic, transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. It is very brittle, but its most remarkable properties are its extreme elasticity, and the tendency which it presents to curl up, or roll upon itself, with the attached surface innermost, when separated from the proper substance of the cornea. Its use appears to be 'to preserve the requisite permanent correct curvature of the flaccid cornea proper' (Jacob).

At the margin of the cornea the lamina elastica posterior breaks up into fibres which form a reticular structure at the outer angle of the anterior chamber, the intervals between the fibres forming small cavernous spaces, the *spaces of Fontana* (spatia anguli iridis). These spaces communicate with a circular canal in the substance of the sclera close to its junction with the cornea. This is the *canal of Schlemm* (sinus venosus scleræ); it communicates internally with the anterior chamber through the spaces of Fontana, and externally with the scleral veins. Some of the fibres of this reticulated structure are continued into the substance of the iris, forming the *ligamentum pectinatum iridis*; while others are connected with the fore-part of the sclera and choroid.

The *layer of endothelium* (endothelium cameræ anterioris) covers the posterior surface of the elastic lamina, is reflected on to the front of the iris, and also lines the spaces of Fontana. It consists of a single stratum of polygonal, flattened, nucleated cells, similar to those lining other serous cavities.

Vessels and Nerves.—The cornea is a non-vascular structure, the capillary vessels terminating in loops at its circumference. Lymphatic vessels have not as yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these are lined by an endothelium. The nerves are numerous and are derived from the ciliary nerves. They form an *annular plexus* around the periphery of the cornea, from which fibres enter the substantia propria. They lose their medullary sheaths and ramify throughout its substance in a delicate network, and their terminal filaments form a firm and closer plexus on the surface of the cornea proper, beneath the epithelium. This is termed the *sub-epithelial plexus*, and from it fibrils are given off which ramify between the epithelial cells, forming an *intra-epithelial plexus*.

II. The Vascular and Pigmented Tunic (figs. 832, 834, 835.)

The middle tunic of the eye is formed from behind forwards by the choroid, the ciliary body, and the iris.

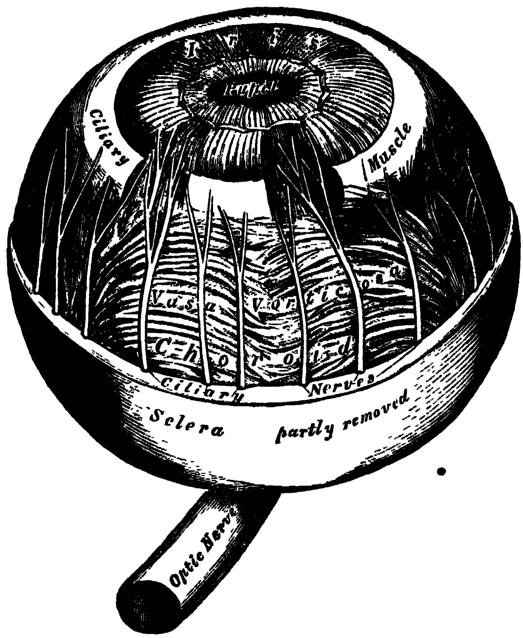
The choroid invests the posterior five-sixths of the globe, and extends as far forwards as the ora serrata of the retina. The ciliary body connects the choroid to the circumference of the iris. The iris is a circular diaphragm behind the cornea, and presents in its centre a rounded aperture, the *pupil*.

The **choroid** (chorioidea) is a thin, highly vascular membrane, of a dark brown or chocolate colour, which invests the posterior five-sixths of the globe; it is pierced behind by the optic nerve, and in this situation is firmly adherent

to the sclera. It is thicker behind than in front. Externally, it is loosely connected by the lamina fusca with the inner surface of the sclera. Its inner surface is attached to the pigmented layer of the retina.

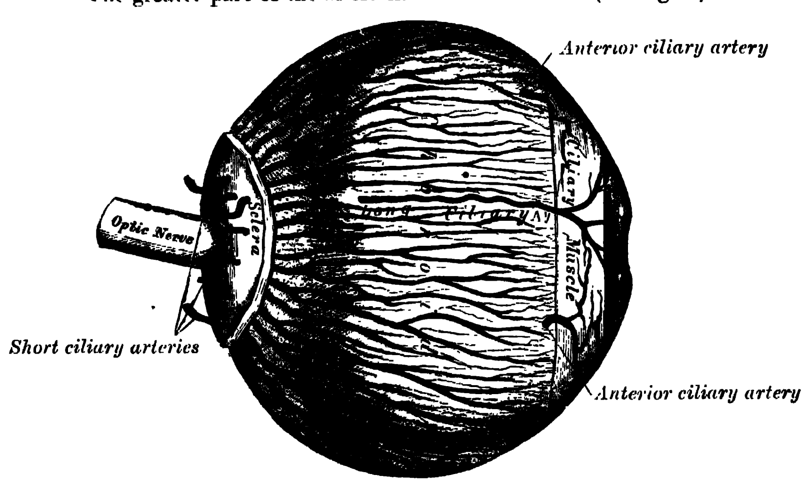
Structure.—The choroid consists mainly of a dense capillary plexus, and of small arteries and veins carrying blood to and returning it from this plexus. On its external surface, i.e. the surface next the sclera, is a thin membrane, the *lamina suprachorioidea*, composed of delicate non-vascular lamellæ—each lamella consisting of a network of fine elastic fibres among which are branched pigment-cells. The spaces between the lamellæ are lined by endothelium, and open freely into the perichoroidal lymph-space, which, in its turn, communicates with the periscleral space by the perforations in the sclera through which the vessels and nerves are transmitted.

FIG. 834.—The choroid and iris. (Enlarged.)



Internal to this lamina is the *choroid proper*, and in consequence of the small arteries and veins being arranged on the outer surface of the capillary network, it is customary to describe this as consisting of two layers: an outer, composed of small arteries and veins, with pigment-cells interspersed between them; and an inner, consisting of a capillary plexus. The *outer layer* or *lamina vasculosa* consists, in part, of the larger branches of the short ciliary arteries which run forwards between the veins, before they bend inwards to terminate in the capillaries, but is formed principally of veins,

FIG. 835.—The arteries of the choroid and iris.
The greater part of the sclera has been removed. (Enlarged.)



named, from their arrangement, the *venæ vorticosæ*. They converge to four or five equidistant trunks, which pierce the sclera midway between the margin of the cornea and the entrance of the optic nerve. Interspersed between the vessels are dark star-shaped pigment-cells, the processes of which, communicating

with those of neighbouring cells, form a delicate network or stroma, which, towards the inner surface of the choroid, loses its pigmentary character. The *inner layer* or *lamina choriocapillaris* consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels; the network is closer, and finer in the posterior than in the anterior part of the choroid. About half an inch behind the cornea its meshes become larger, and are continuous with those of the ciliary processes. These two laminæ are connected by a *stratum intermedium* consisting of fine elastic fibres. On the inner surface of the lamina choriocapillaris is a very thin, structureless, or faintly fibrous membrane, called the *lamina basalis* (*membrane of Bruch*); it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina.

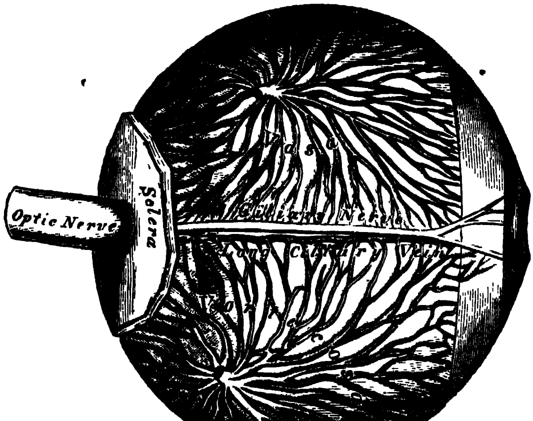
Tapetum.—This name is applied to the outer and posterior part of the choroid, which in many animals presents an iridescent appearance.

The **ciliary body** (corpus ciliare) comprises the orbiculus ciliaris, the ciliary processes, and the Ciliary muscle.

The *orbiculus ciliaris* is a zone of about one-sixth of an inch (4 mm.) in width, directly continuous with the anterior part of the choroid; it presents numerous ridges arranged in a radial manner.

The *ciliary processes* (processus ciliares) are formed by the inward folding of the various layers of the choroid (i.e. the choroid proper and the lamina basalis), and are received between corresponding foldings of the suspensory ligament of the lens, thus establishing a connection between the choroid and inner tunic of the eye. They are arranged in a circle, and form a sort of frill behind the iris, round the margin of the lens. They vary from sixty to eighty in number, lie side by side, and may be divided into large and small; the former are about one-tenth of an inch (2·5 mm.) in length, and the latter, consisting of about one-third of the entire number, are situated in the spaces between them, but without regular arrangement. They are attached by their periphery to three or four of the ridges of the orbiculus ciliaris, and are continuous with the layers of the choroid: their opposite extremities are free and rounded, and are directed towards the posterior chamber of the eyeball and circumference of the lens. In front, they are continuous with the periphery of the iris. Their posterior surfaces are connected with the suspensory ligament of the lens.

FIG. 836.—The veins of the choroid. (Enlarged.)



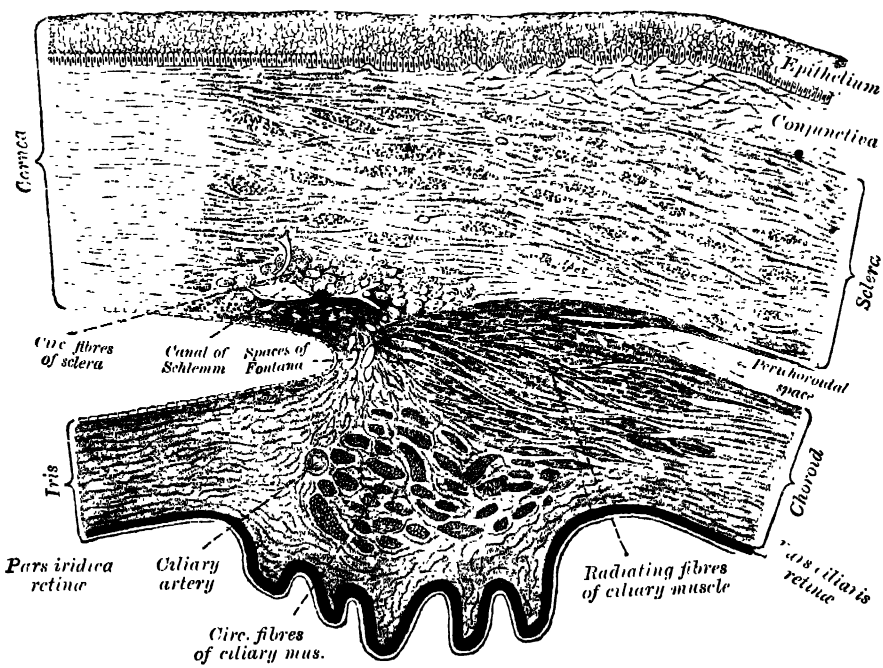
Structure (fig. 837).—The ciliary processes are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. Their posterior surfaces are covered by a bilaminar layer of black pigment-cells, which is continued forwards from the retina, and is named the *pars ciliaris retinæ*. In the stroma of the ciliary processes there are also stellate pigment-cells, but these are not so numerous as in the choroid itself.

The *Ciliary muscle* (m. ciliaris) consists of unstriped fibres: it forms a greyish, semitransparent, circular band, about one-eighth of an inch (3 mm.) broad, on the outer surface of the fore-part of the choroid. It is thickest in front, and consists of two sets of fibres, *radial* and *circular*. The radial fibres (fibræ meridionales), much the more numerous, arise from the junction of the cornea and sclera, and from the ligamentum pectinatum iridis; they run backwards, and are attached to the ciliary processes and orbiculus ciliaris. One bundle, according to Waldeyer, is continued backwards to be inserted into the sclera. The circular fibres (fibræ circulares) are internal to the radiating

ones and to some extent unconnected with them, and have a circular course around the attachment of the iris. They are sometimes called the *ring muscle* of Müller, and were formerly described as the ciliary ligament. They are well developed in hypermetropic, but are rudimentary or absent in myopic eyes. The Ciliary muscle is the chief agent in accommodation, i.e. in adjusting the eye to the vision of near objects. When it contracts, it draws forwards the ciliary processes, relaxes the suspensory ligament of the lens, and thus allows the anterior surface of the lens to become more convex; the pupil is at the same time slightly contracted.

The **iris** has received its name from its various colours in different individuals. It is a thin, circular, contractile disc, suspended in the aqueous humour between the cornea and lens, and perforated a little to the nasal side of its centre by a circular aperture, the *pupil* (pupilla), for the transmission of light. By its periphery it is continuous with the ciliary body, and is also connected with the posterior elastic lamina of the cornea by means of the pectinate ligament;

Fig. 837.—Section of the eye, showing the relations of the cornea, sclera, and iris, together with the Ciliary muscle and the spaces of Fontana near the angle of the anterior chamber. (Waldeyer.)



its surfaces are flattened, and look forwards and backwards, the anterior towards the cornea, the posterior towards the ciliary processes and lens. The iris divides the space between the front of the lens and the back of the cornea into two chambers—anterior and posterior. The *anterior chamber* (camera oculi anterior) is bounded in front by the posterior surface of the cornea; behind by the front of the iris and the central part of the lens. The *posterior chamber* (camera oculi posterior) is a narrow chink between the peripheral part of the iris, the suspensory ligament of the lens and the ciliary processes. In the adult the two chambers communicate through the pupil, but in the fœtus of the seventh month, when the pupil is closed by the *membrana pupillaris*, the two chambers are quite separate.

Structure.—The iris is composed of the following structures:

1. In front is a layer of flattened endothelial cells placed on a delicate hyaline basement-membrane. This layer is continuous with the epithelial layer covering the membrane of Descemet, and in men with dark-coloured irides the cells contain pigment-granules.

2. *Stroma.*—The stroma iridis consists of fibres and cells. The former are made up of delicate bundles of fibrous tissue, of which some few fibres have a circular direction at the circumference of the iris; but the chief mass consists of fibres radiating towards the pupil. They form, by their interlacement, delicate meshes, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine processes. In dark eyes many of them contain pigment-granules, but in blue eyes and the pink eyes of albinos they are unpigmented.

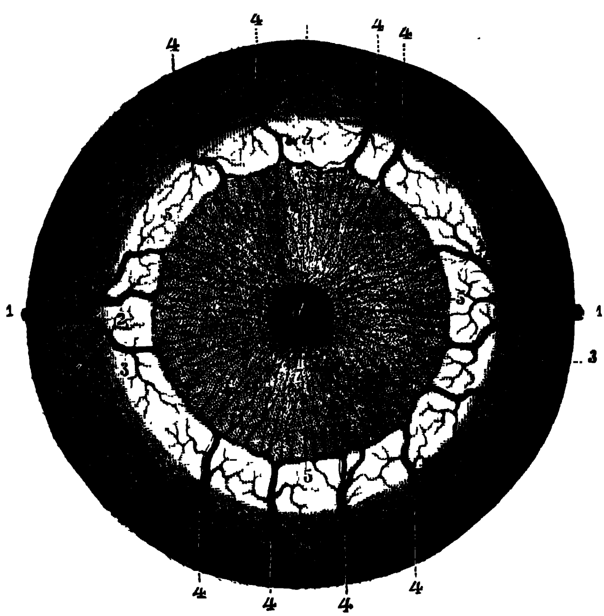
3. The *muscular fibres* are involuntary, and consist of circular and radiating fibres. The *circular fibres* (m. sphincter pupillæ) surround the margin of the pupil on the posterior surface of the iris, like a sphincter, forming a narrow band about one-thirtieth of an inch (1 mm.) in width; those near the free margin are closely aggregated; those more external, somewhat separated, form incomplete circles. The *radiating fibres* (m. dilatator pupillæ) converge from the circumference towards the centre, and blend with the circular fibres near the margin of the pupil. These fibres are regarded by some as elastic, not muscular.

4. The posterior surface (facies posterior) of the iris is of a deep purple tint, being covered by two layers of pigmented columnar epithelium, continuous at the periphery of the iris with the pars ciliaris retinæ. This pigmented epithelium is named the *pars iridica retinæ* or, from the resemblance of its colour to that of a ripe grape, the *uvea*.

The colour of the iris is produced by the reflection of light from dark pigment-cells underlying a translucent tissue, and is therefore determined by the amount of the pigment and its distribution throughout the texture of the iris. The number and the situation of the pigment-cells differ in different irides. In the albino pigment is absent. In the various shades of blue eyes the pigment-cells are confined to the posterior surface of the iris, whereas in grey, brown, and black eyes pigment is found also in the cells of the stroma and in those of the epithelial layer on the front of the iris.

Vessels and Nerves.—The *arteries of the iris* are derived from the long and anterior ciliary arteries, and from the vessels of the ciliary processes (see page 648). The long ciliary arteries, two in number, having reached the attached margin of the iris, divide each into an upper and lower branch; these anastomose with corresponding branches from the opposite side and thus encircle the iris; into this vascular zone (*circulus arteriosus major*) the anterior ciliary arteries pour their blood. From this zone vessels converge to the free margin of the iris, and there communicate by branches from one to another to form a second zone (*circulus arteriosus minor*) (figs. 838 and 840).

FIG. 840.—The iris, viewed from in front, with its great and small arterial circles. (Testut.)



a. Choroid. *b.* Ciliary muscle. *c.* Iris. *d.* Pupil. 1 and 1′. The two long ciliary arteries, with 2, their ascending branch of bifurcation; 3, their descending branch of bifurcation. 4. The anterior ciliary arteries. 5. Circulus major; 6, its branches radiating through the iris. 7. Circulus minor around the pupil.

The *nerves of the choroid and iris* are derived from the ciliary branches of the lenticular ganglion, and the long ciliary from the nasal branch of the ophthalmic division of the fifth. They pierce the sclera around the entrance of the optic nerve, run forwards in the perichoroidal space, and supply the blood-vessels of the choroid. After reaching the iris they form a plexus around its attached margin; from this are derived non-medullated fibres which terminate in the circular and radiating muscular fibres. Their exact mode of termination has not been ascertained. Other fibres from the plexus terminate in a network on the anterior surface of the iris. The fibres derived from the motor root of the lenticular ganglion (third nerve) supply the circular fibres, while those derived from the sympathetic supply the radiating fibres.

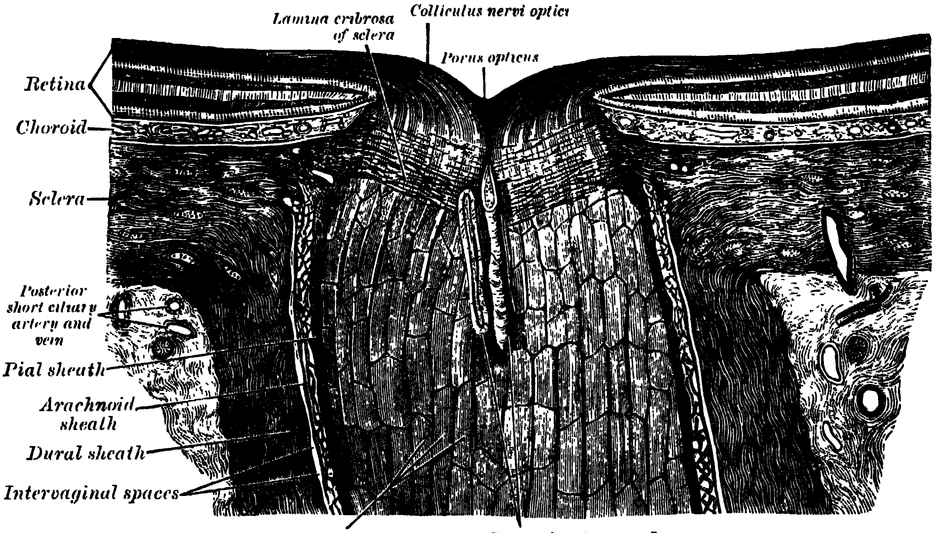
Membrana pupillaris.—In the fœtus, the pupil is closed by a delicate vascular membrane, the *membrana pupillaris*, which divides the space in which the iris is suspended into two distinct chambers. This membrane contains numerous minute vessels, continued from the margin of the iris to those on the front part of the capsule of the lens. These vessels have a looped arrangement,

and converge towards each other without anastomosing. Between the seventh and eighth month the membrane begins to disappear by absorption from the centre towards the circumference, and at birth only a few fragments are present; in exceptional cases it may persist.

III. The Retina

The **retina** is a delicate nervous membrane, upon the surface of which the images of external objects are received. Its outer surface is in contact with the choroid; its inner with the vitreous body. Behind, it is continuous with the optic nerve; it gradually diminishes in thickness from behind forwards, and extends nearly as far as the ciliary body, where it appears to terminate in a jagged margin, the *ora serrata*. Here the nervous tissues of the retina end, but a thin prolongation of the membrane extends forwards over the back of the ciliary processes and iris, forming the *pars ciliaris retinæ* and *pars iridica retinæ* already referred to. This forward prolongation consists of the pigmentary layer of the retina together with a stratum of columnar epithelium. The retina is soft, semitransparent, and of a purple tint in the fresh state, owing to the presence of a colouring material named *rhodopsin* or *visual purple*; but it soon becomes clouded, opaque, and bleached when exposed to sunlight.

Fig. 841.—The terminal portion of the optic nerve and its entrance into the eyeball, in horizontal section. (From Toldt's 'Atlas,' published by Messrs. Rebman, Ltd., London.)



Exactly in the centre of the posterior part of the retina, corresponding to the axis of the eye, and at a point in which the sense of vision is most perfect, is an oval yellowish area, the *yellow spot* (macula lutea); in the spot is a central depression, the *fovea centralis*. At the fovea centralis the retina is exceedingly thin, and the dark colour of the choroid is distinctly seen through it. It exists only in man, the quadrumana, and some saurian reptiles. About one eighth of an inch (3 mm.) to the inner side, and about 1 mm. below the level of the yellow spot, is the point of entrance of the optic nerve (*porus opticus* or *optic disc*), the circumference of which is slightly raised so as to form an eminence (*colliculus nervi optici*) (fig. 841); the arteria centralis retinæ pierces its centre. This is the only part of the surface of the retina from which the power of vision is absent, and is termed the 'blind spot.'

Structure (figs. 842, 843).—The retina is exceedingly complex, and, when examined microscopically by means of sections made perpendicularly to its

surface, is found to consist of ten layers, named from within outwards as follows:

1. Membrana limitans interna.
2. Layer of nerve-fibres (stratum opticum).
3. Ganglionic layer, consisting of nerve-cells.
4. Inner plexiform layer.
5. Inner nuclear layer, or layer of inner granules.
6. Outer plexiform layer.
7. Outer nuclear layer, or layer of outer granules.
8. Membrana limitans externa.
9. Jacob's membrane (layer of rods and cones).
10. Pigmented layer (tapetum nigrum).

1. The *membrana limitans interna* is the innermost layer, and is in contact with the hyaloid membrane of the vitreous body. It is derived from the supporting framework of the retina, with which it will be described.

2. The *layer of nerve-fibres* is formed by the expansion of the optic nerve, the fibres of which pass through all the layers of the retina, except the membrana limitans interna. As the nerve passes through the lamina cribrosa scleræ, its fibres lose their medullary sheaths and are continued onwards through the choroid and retina as simple axis cylinders. When these non-medullated fibres reach the internal surface of the retina they radiate from their point of entrance over the surface of the retina, grouped in bundles, and in many places arranged in plexuses. Most of the fibres in this layer are centripetal, and are the direct continuations of the axis-cylinder processes of the cells of the next layer, but a few of them are centrifugal and run through this and the next succeeding layer to ramify in the inner molecular and inner nuclear layers, where they terminate in enlarged extremities (fig. 843). The layer of nerve-fibres is thickest near the optic nerve disc, gradually diminishing towards the ora serrata.

FIG. 842.—Section of retina. (Magnified.)

3. The *ganglionic layer* consists of a single layer of large ganglion-cells, except in the macula lutea, where there are several strata. The cells are somewhat flask-shaped; the rounded internal surface of each resting on the preceding layer, and sending off an axon which is prolonged as a nerve-fibre into the fibrous layer. From the opposite extremity numerous dendrites extend into the inner plexiform layer, where they branch and form flattened arborisations at different levels (fig. 843). The ganglion-cells vary much in size, and the dendrites of the smaller ones as a rule arborise in the inner plexiform layer as soon as they enter it; while those of the larger cells ramify close to the inner nuclear layer.

4. The *inner plexiform layer* is made up of a dense reticulum of minute fibrils, formed by the interlacement of the dendrites of the ganglion-cells with those of the cells of the inner nuclear layer, immediately to be described. Within the reticulum formed by these fibrils a few branched spongioblasts are sometimes imbedded.

5. The *inner nuclear layer* or *layer of inner granules* is made up of a number of closely packed cells, of which there are three varieties, viz. bipolar cells, horizontal cells and amacrine cells.

The *bipolar cells* are by far the most numerous, and are round or oval in shape, each cell being prolonged into an inner and an outer process. They are divisible into rod-bipolars and cone-bipolars. The inner processes of the *rod-bipolars* run through the inner plexiform layer and arborise around the bodies of the cells of the ganglionic layer; their outer processes end in tufts of fibrils around the button-like ends of a number of rod-fibres. The inner processes of

the *cone-bipolars* ramify in the inner plexiform layer in contact with the dendrites of the ganglionic cells.

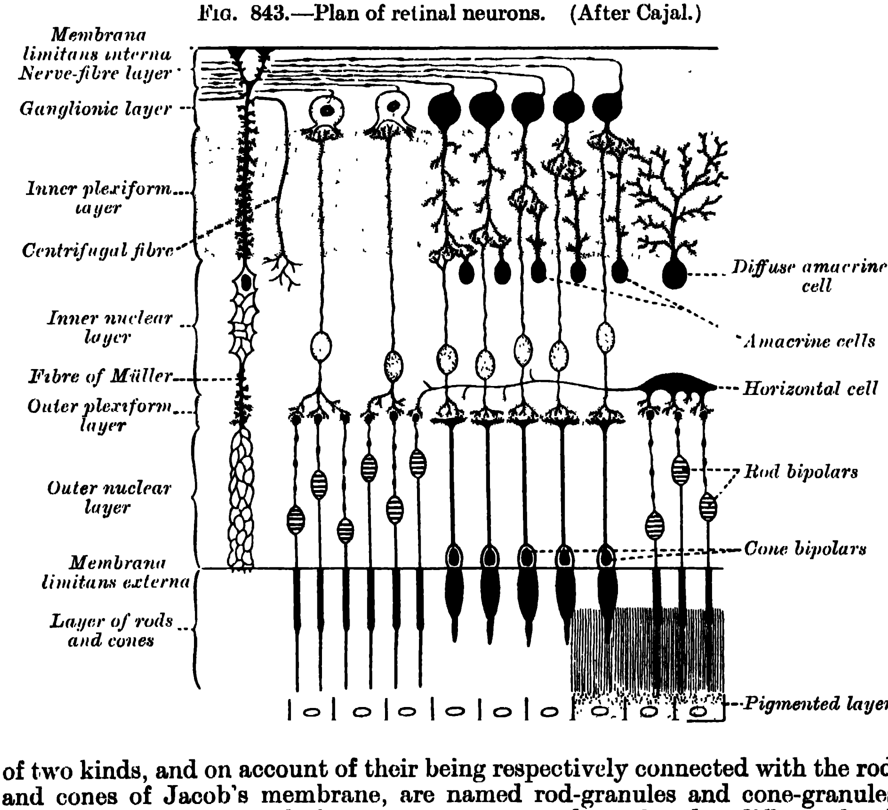
The *horizontal cells* lie in the outer part of the inner nuclear layer and possess somewhat flattened cell bodies. Their dendrites divide into numerous branches in the outer plexiform layer while their axons run horizontally for some distance and finally ramify in the same layer.

The *amacrine cells* are placed in the inner part of the inner nuclear layer, and are so named because they have not yet been shown to possess axis-cylinder processes. Their dendrites undergo extensive ramification in the inner plexiform layer.

6. The *outer plexiform layer* is much thinner than the inner plexiform layer; but, like it, consists of a dense network of minute fibrils derived from the processes of the horizontal cells of the preceding layer, and the outer processes of the bipolar cells, which ramify in it, forming arborisations around the ends of the rod-fibres and with the branched foot-plates of the cone-fibres.

7. *The outer nuclear layer* or *layer of outer granules.*—Like the inner nuclear layer, this layer contains several strata of clear oval nuclear bodies; they are

FIG. 843.—Plan of retinal neurons. (After Cajal.)



of two kinds, and on account of their being respectively connected with the rods and cones of Jacob's membrane, are named rod-granules and cone-granules. The *rod-granules* are much the more numerous, and are placed at different levels throughout the layer. Their nuclei present a peculiar cross-striped appearance, and prolonged from either extremity of the cell is a fine process: the outer process is continuous with a single rod of Jacob's membrane; the inner passes inwards towards the outer plexiform layer and terminates in an enlarged extremity, and is imbedded in the tuft into which the outer processes of the rod-bipolars break up. In its course it presents numerous varicosities. The *cone-granules*, fewer in number than the rod-granules, are placed close to the membrana limitans externa, through which they are continuous with the cones of Jacob's membrane. They do not present any cross striping, but contain a pyriform nucleus, which almost completely fills the cell. From the inner extremity of the granule a thick process passes inwards to the outer plexiform layer, where it expands into a pyramidal enlargement or foot-plate, from which are given

off numerous fine fibrils, which come in contact with the outer processes of the cone-bipolars.

8. *The membrana limitans externa.*—This layer, like the membrana limitans interna, is derived from the supporting framework of the retina, with which it will be described.

9. *Jacob's membrane* (*layer of rods and cones*).—The elements which compose this layer are of two kinds, *rods* and *cones*, the former being much more numerous than the latter. The *rods* are of nearly uniform size, and are arranged perpendicularly to the surface. Each rod consists of two segments, an outer and inner, of about equal lengths. The segments differ from each other as regards refraction and in their behaviour with colouring reagents, the inner segment becoming stained by carmine, iodine, &c., the outer segment remaining unstained with these reagents, but staining yellowish-brown with osmic acid. The outer segment is marked by transverse striæ, and tends to break up into a number of thin discs superimposed on one another. It also exhibits faint longitudinal markings. The inner segment at its deeper part where it is joined to the outer process of the rod-granule, is indistinctly granular; its more superficial part presents a longitudinal striation, being composed of fine, bright, highly refracting fibrils. The visual purple or rhodopsin is found only in the outer segments.

The *cones* are conical or flask-shaped, their broad ends resting upon the membrana limitans externa, the narrow pointed extremity being turned to the choroid. Like the rods, each is made up of two segments, outer and inner; the outer segment is a short conical process, which, like the outer segment of the rod, exhibits transverse striæ. The inner segment resembles the inner segment of the rods in structure, presenting a superficial striated and deep granular part, but differs from it in size and shape, being bulged out laterally and flask-shaped. The chemical and optical characters of the two portions are identical with those of the rods.

10. *The pigmented layer.*—The most external layer of the retina, formerly regarded as a part of the choroid, consists of a single layer of hexagonal epithelial cells, loaded with pigment-granules. They are smooth externally, where they are in contact with the choroid, but internally they are prolonged into fine, straight processes, which extend between the rods, this being especially the case when the eye is exposed to light. In the eyes of albinos, the cells of the pigmented layer are present, but they contain no colouring matter.

Supporting framework of the retina.—Almost all these layers of the retina are connected together by a supporting framework, formed by the *fibres of Müller*, or *radiating fibres*, from which the membranæ limitans interna et externa are derived. These fibres stretch between the two limiting layers, 'as columns between a floor and a ceiling,' and pass through all the nervous layers, except Jacob's membrane. Each commences on the inner surface of the retina by an expanded, often forked, base, which sometimes contains a spheroidal body, staining deeply with hæmatoxylin, the edges of the bases of adjoining fibres being united to form the membrana limitans interna. As they pass through the nerve-fibre and ganglionic layers they give off few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the inner granules, while in the outer nuclear layer they form a network around the rod- and cone-fibrils, and unite to form the external limiting membrane at the bases of the rods and cones. In the inner nuclear layer each fibre of Müller presents a clear oval nucleus, which is sometimes situated at the side of, sometimes altogether within, the fibre.

Macula lutea and fovea centralis.—The structure of the retina at the yellow spot presents some modifications. In the macula lutea: (1) the nerve-fibres are wanting as a continuous layer; (2) the ganglionic layer consists of several strata of cells, instead of a single layer; (3) in Jacob's membrane there are no rods, but only cones, and these are longer and narrower than in other parts; and (4) in the outer nuclear layer there are only cone-fibres, which are very long and arranged in curved lines. At the fovea centralis the only parts which exist are (1) the cones of Jacob's membrane; (2) the outer nuclear layer, the cone-fibres of which are almost horizontal in direction; (3) an exceedingly thin inner plexiform layer; (4) the pigmented layer, which is thicker and its pigment more pronounced than elsewhere. The colour of the macula seems to

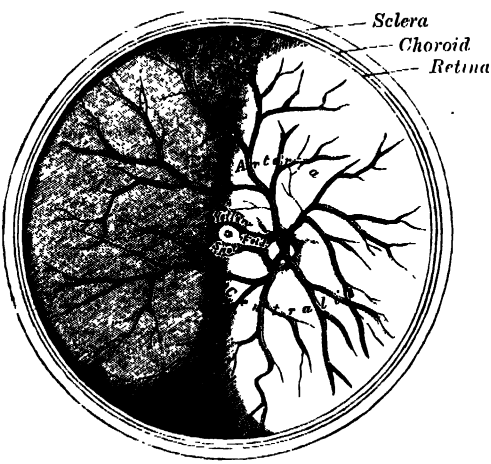
imbue all the layers except Jacob's membrane ; it is of a rich yellow, deepest towards the centre, and does not appear to be due to pigment-cells, but is simply a staining of the constituent parts.

At the ora serrata the nervous layers of the retina terminate abruptly, and the retina is continued onwards as a single layer of columnar cells covered by the pigmented layer. This prolongation is known as the *pars ciliaris retinæ*, and can be traced forwards from the ciliary processes on to the back of the iris, where it is termed the *pars iridica retinæ* or *uvea*.

From the description given of the nervous elements of the retina it will be seen that there is no direct continuity between the structures which form its different layers except between the ganglionic and nerve-fibre layers, the majority of the nerve-fibres being formed of the axons of the ganglionic cells. In the inner plexiform layer the dendrites of the ganglionic layer interlace with those of the cells of the inner nuclear layer, while in the outer plexiform layer a like synapsis occurs between the processes of the inner granules and the rod and cone elements.

The *arteria centralis retinæ* (fig. 844) and its accompanying vein pierce the optic nerve, and enter the globe of the eye through the porus opticus. The artery immediately bifurcates into an upper and a lower branch, and each of these again divides into an inner or nasal and an outer or temporal branch, which at first run between the hyaloid membrane and the nervous layer ; but they soon enter the latter, and pass forwards, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond

Fig. 844.—The arteria centralis retinæ, yellow spot, &c. ; the anterior half of the eyeball has been removed. (Enlarged.)



the inner nuclear layer. The macula receives small twigs from the temporal branches and others directly from the central artery ; these do not, however, reach as far as the fovea centralis, which has no blood-vessels. The branches of the arteria centralis retinæ do not anastomose with each other—in other words they are terminal arteries. In the fœtus, a small vessel passes forwards as a continuation of the arteria centralis retinæ through the vitreous humour, to the posterior surface of the capsule of the lens.

Refracting Media

The refracting media are three, viz. :

Aqueous humour. Vitreous body. Crystalline lens.

I. Aqueous Humour

The **aqueous humour** fills the anterior and posterior chambers of the eyeball. It is small in quantity (scarcely exceeding, according to Petit, four or five grains in weight) and has an alkaline reaction ; it consists mainly of water, less than one-fiftieth of its weight being solid matter, chiefly chloride of sodium.

II. Vitreous Body

The **vitreous body** (corpus vitreum) forms about four-fifths of the globe of the eye. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, the *fossa hyaloidea*, for the reception of the lens. It is perfectly transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the *membrana hyaloidea*. It has been supposed, by Hannover, that from its inner surface numerous thin lamellæ are prolonged inwards in a radiating manner, forming spaces in which the fluid is contained. In the adult, these lamellæ cannot be detected even after careful microscopic examination in the fresh state, but in preparations hardened in weak chromic acid it is possible to make out a distinct lamellation at the periphery of the body; and in the fœtus a peculiar fibrous texture pervades the mass, the fibres joining at numerous points, and presenting minute nuclear granules at their point of junction. In the centre of the vitreous humour, running from the entrance of the optic nerve to the posterior surface of the lens, is a canal, the *canalis hyaloideus*, filled with fluid and lined by a prolongation of the hyaloid membrane. This canal, in the embryonic vitreous body, conveyed the minute vessel from the central artery of the retina to the back of the lens. The fluid from the vitreous body is nearly pure water; it contains, however, some salts, and a little albumen.

The *membrana hyaloidea* encloses the whole of the vitreous body. In front of the ora serrata it is thickened by the accession of radial fibres and is termed the *zonule of Zinn* or *zonula ciliaris*. Here it presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they adhere, as is shown by the fact that when they are removed some of their pigment remains attached to the zonule. The zonule of Zinn splits into two layers, one of which is thin and lines the fossa hyaloidea, the other is named the *suspensory ligament of the lens*; it is thicker, and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator. Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the radial fibres of the Ciliary muscle, so that the lens is allowed to become more convex. Behind the suspensory ligament there is a sacculated canal, the *canal of Petit*, which encircles the equator of the lens and which can be easily inflated through a fine blowpipe inserted under the suspensory ligament.

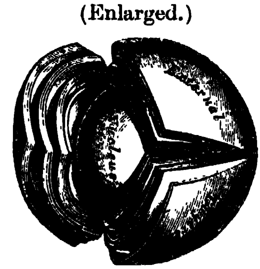
No vessels penetrate the vitreous body; so that its nutrition must be carried on by the vessels of the retina and ciliary processes, situated upon its exterior.

III. Crystalline Lens

The **crystalline lens** (lens crystallina), enclosed in its capsule, is situated immediately behind the iris, in front of the vitreous body, and encircled by the ciliary processes, which slightly overlap its margin.

The *capsule of the lens* (capsula lentis) is a transparent structureless membrane which closely surrounds the lens, and is thicker in front than behind. It is brittle but highly elastic, and when ruptured the edges roll up with the outer surface innermost. It rests, behind, in the fossa hyaloidea in the fore-part of the vitreous body; in front, it is in contact with the free border of the iris, but recedes from it at the circumference, thus forming the posterior chamber of the eye; it is retained in its position chiefly by the suspensory ligament of the lens, already described.

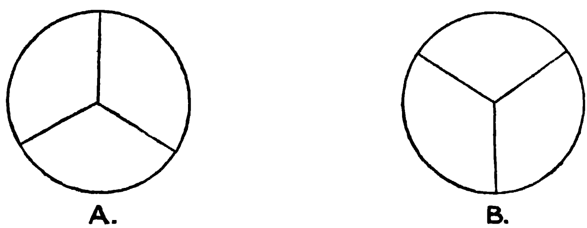
Fig. 845.—The crystalline lens, hardened and divided. (Enlarged.)



The *lens* is a transparent biconvex body, the convexity of its anterior being less than that of its posterior surface. The central points of these surfaces are termed respectively the *anterior* and *posterior poles*. A line connecting the poles constitutes the *axis* of the lens (axis lentis), while the marginal circumference is termed the *equator* (æquator lentis).

Structure.—The lens is made up of an outer, soft part (substantia corticalis) and a central, firm part (nucleus lentis) (fig. 845). Faint lines (radii lentis) radiate from the poles to the equator. In the adult there may be six or more of these lines, but in the fœtus they are only three in number and diverge from each other at angles of 120 degrees (fig. 846). On the anterior surface one line ascends vertically and the other two diverge downwards and outwards. On the posterior surface one ray descends vertically and the other two diverge upwards. They correspond with the free edges of an equal number of septa composed of an amorphous substance, which dip into the substance of the lens. When the lens has been hardened it is seen to consist of a series of concentrically arranged laminæ, each of which is interrupted at the septa referred to. Each lamina is built up of a number of hexagonal, ribbon-like fibres (fibræ lentis) the edges of which are more or less serrated—the serrations fitting between those of neighbouring fibres, while the ends of the fibres come into apposition at the septa. The fibres run in a curved manner from the septa on the anterior surface to those on the posterior surface. No fibres pass from pole to pole; they are arranged in such a way that those which commence near the pole on one aspect of the lens terminate near the peripheral extremity of the plane on the

FIG. 846.—Diagram to show the direction and arrangement of the radiating lines on the front and back of the fœtal lens. A. From the front. B. From the back.



other, and *vice versa*. The fibres of the outer layers of the lens are nucleated, and together form a layer (nuclear layer) on the surface of the lens, most distinct towards its circumference. The anterior surface of the lens is covered by a layer of transparent, columnar, nucleated cells (epithelium lentis). At the equator the cells become elongated, and their gradual transition into lens fibres can be traced (fig. 847).

In the fœtus, the lens is nearly spherical, and has a slightly reddish tint; it is not perfectly transparent, and is so soft as to break down readily on the slightest pressure. A small branch from the arteria centralis retinæ runs forwards, as already mentioned, through the vitreous body to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network, which covers its surface, and they are continuous round the margin of the capsule with the vessels of the pupillary membrane, and with those of the iris.

In the adult, the posterior surface is more convex than the anterior; it is colourless, transparent, firm in texture, and devoid of vessels.

In old age it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increased in density.

Vessels and Nerves.—The *arteries of the globe of the eye* are the short, long, and anterior ciliary arteries, and the arteria centralis retinæ. They have been already described (see page 648).

The *ciliary veins* are seen on the outer surface of the choroid, and are named, from their arrangement, the *venæ vorticosæ*. They converge to four or five equidistant trunks which pierce the sclera midway between the margin of the cornea and the entrance of the optic nerve. Another set of veins accompanies the anterior ciliary arteries and opens into the ophthalmic vein.

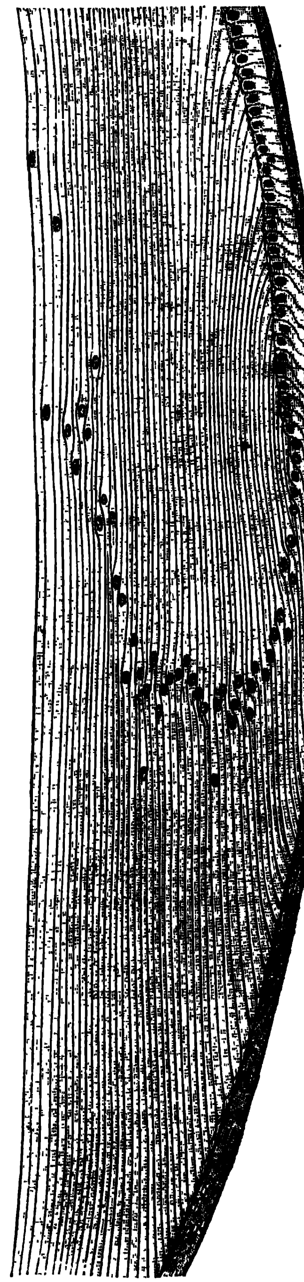
The *ciliary nerves* are derived from the nasal branch of the ophthalmic nerve and from the ciliary or ophthalmic ganglion.

Applied Anatomy.—From a surgical point of view the cornea may be regarded as consisting of three layers: (1) an external epithelial layer, developed from the ectoderm, and continuous with the epithelial covering of the rest of the body, so that its lesions resemble those of the epidermis; (2) the cornea proper, derived from the

mesoderm, and associated in its diseases with the fibro-vascular structures of the body; and (3) the posterior elastic layer with its endothelium, also derived from the mesoderm and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the other serous and synovial membranes of the body.

The cornea contains no blood-vessels except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on its anterior surface. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of Fontana. This lack of a direct blood-supply renders the cornea very apt to inflame in the cachectic and ill-nourished. In cases of *granular lids*, there is a peculiar affection of the cornea, called *pannus*, in which the anterior layers of the cornea become vascularised, and a rich network of blood-vessels may be seen upon it; and in interstitial keratitis new vessels extend into the cornea, giving it a pinkish hue to which the term 'salmon patch' is applied. The cornea is richly supplied with nerves, derived from the ciliary, which enter the cornea through the fore-part of the sclera and form plexuses in the stroma, terminating between the epithelial cells by free ends or in corpuscles. In cases of glaucoma the ciliary nerves may be pressed upon as they course between the choroid and sclera, and the cornea becomes anæsthetic.

Fig. 847. — Section through the margin of the lens, showing the transition of the epithelium into the lens-fibres. (Babuchin.)



The sclera has very few blood-vessels and nerves. The blood-vessels are derived from the anterior ciliary, and form an open plexus in its substance. As they approach the corneal margin the arrangement is peculiar. Some branches pass through the sclera to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forwards to the cornea, forming its marginal plexus. In inflammation of the sclera and episcleral tissue these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the *zone of ciliary injection*. In inflammation of the iris and ciliary body this zone is present, since the sclera speedily becomes involved when these structures are inflamed. But in inflammation of the cornea the sclera is seldom much affected, though the two are structurally continuous. This would appear to be due to the fact, that the nutrition of the cornea is derived from a different source than that of the sclera. The sclera may be ruptured subcutaneously without any laceration of the conjunctiva and the rupture usually occurs near the corneal margin, where the tunic is thinnest. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hæmorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclera and has been found under the conjunctiva. Wounds of the sclera are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia.

One of the functions of the choroid is to provide nutrition for the retina, and to convey vessels and nerves to the ciliary body and iris. Inflammation of the choroid is therefore followed by grave disturbances in the nutrition of the retina, and is attended with early interference with vision. Its diseases bear a considerable analogy to those which affect

the skin, and it is one of the places from which melanotic sarcomata may grow. These tumours contain a large amount of pigment in their cells, and originate only in those parts where pigment is naturally present.

The iris may be absent, either in part or altogether as a congenital condition, and in some instances the pupillary membrane may remain persistent, though it is rarely complete. Again, the iris may be the seat of a malformation, termed *coloboma*, which consists in a deficiency or cleft, clearly due in a great number of cases to an arrest in development. In these cases it is found at the lower aspect, extending directly downwards from the pupil, and the gap frequently extends through the choroid to the entrance of the optic nerve. In some rarer cases the gap is found in other parts of the iris, and is not then associated with any deficiency of the choroid. Wounds of the iris, especially if complicated with injury to the ciliary body, may be followed by serious consequences. If septic matter is introduced, and a suppurative inflammation is set up, complete loss of vision may result; and, what is perhaps of greater consequence, similar inflammatory changes may be set up in the sound eye, from spreading of the infective process through the connective tissue surrounding the optic nerve to the commissure, and thence down the opposite nerve to the sound eye. The iris is abundantly supplied with blood-vessels and nerves, and is very prone to become inflamed, and when inflamed, in consequence of the intimate relationship which exists between the vessels of the iris and choroid, this latter tunic is very liable to participate in the inflammation. The iris is covered with epithelium, and partakes of the character of a serous membrane, and, like these structures, is apt to pour out a plastic exudation, when inflamed, and contract adhesions, either to the cornea in front (*synechia anterior*), or to the capsule of the lens behind (*synechia posterior*). In iritis the lens may become involved, and the condition known as secondary cataract may be set up. Tumours occasionally commence in the iris; of these, cysts, which are usually congenital, and sarcomatous tumours, are the most common. Gummata are not infrequently found in this situation. In some forms of injury of the eyeball, as from the impact of a spent shot, the rebound of a twig, or a blow with a whip, the iris may be detached from the Ciliary muscle, the amount of detachment varying from the slightest degree to separation of the whole iris from its ciliary connection.

The retina, with the exception of its pigment layer and its vessels, is perfectly transparent when examined by the ophthalmoscope, so that its diseased conditions are recognised by its loss of transparency. In retinitis, for instance, there is more or less dense and extensive opacity of its structure, and not infrequently extravasations of blood into its substance. Hæmorrhages may also take place into the retina, from rupture of a blood-vessel without inflammation. The retina may become displaced from effusion of serum between it and the choroid, or by blows on the eyeball, or may occur without apparent cause in progressive myopia, and in this case the ophthalmoscope shows an opaque, tremulous cloud. Glioma, a form of sarcoma, and essentially a disease of early life, is occasionally met with in connection with the retina.

The lens has no blood-vessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does, however, present certain morbid or abnormal conditions of various kinds. Thus, variations in shape, and displacements, are among its congenital defects. Opacities may occur from injury, senile changes, or malnutrition. These opacities give rise to *cataract*, of which the senile variety is the most common. They vary as to the part of the lens in which the opacity commences, and are classified accordingly, as nuclear, cortical, lamellar, anterior and posterior polar. Senile changes may take place in the lens, impairing its elasticity and rendering it harder than in youth, so that it loses its power of altering its curvature to suit the requirements of near vision. This condition is known as *presbyopia*. And, finally, the lens may be dislocated or displaced by blows upon the eyeball; and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the 'filtration area,' and the other as the 'dangerous area.' The *filtration area* is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm through which the chief transudation of fluid from the eye is believed to take place. If any obstruction to this transudation occur, increased intra-ocular tension is set up, and the disease known as *glaucoma* results. The *dangerous area of the eye* is the region in the neighbourhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is apt to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected with it by nervous and vascular supplies.

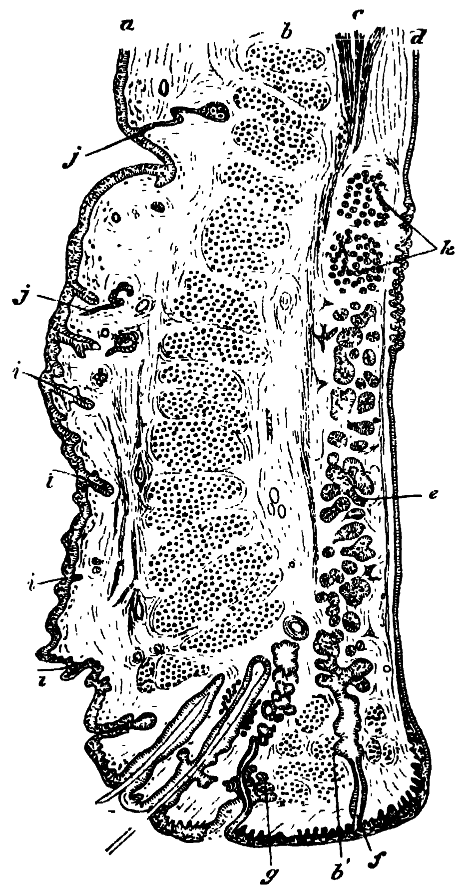
Appendages of the Eye

The appendages of the eye (organa oculi accessoria) include the eyebrows, the eyelids, the conjunctiva, and the lachrymal apparatus, viz. the lachrymal gland, the lachrymal sac, and the nasal duct.

The **eyebrows** (supercilia) are two arched eminences of integument, which surmount the upper circumference of the orbit on either side, and support numerous short, thick hairs, directed obliquely on the surface. In structure, the eyebrows consist of thickened integument, connected beneath with the Orbicularis palpebrarum, Corrugator supercilii, and Occipito-frontalis muscles. These muscles serve, by their action on this part, to control to a certain extent the amount of light admitted into the eye.

The **eyelids** (palpebræ) are two thin, movable folds, placed in front of the eye, protecting it from injury by their closure. The upper lid is the larger, and the more movable of the two, and is furnished with an elevator muscle, the Levator palpebræ superioris. When the eyelids are open, an elliptical space (*rima palpebrarum*) is left between their margins, the angles of which correspond to the junctions of the upper and lower lids, and are called *canthi*.

Fig. 848.—Vertical section through the upper eyelid. (After Waldeyer.)



a. Skin. *b.* Orbicularis palpebrarum. *b′* Marginal fasciculus of Orbicularis (ciliary bundle). *c.* Levator palpebræ. *d.* Conjunctiva. *e.* Tarsal plate. *f.* Meibomian gland. *g.* Sebaceous gland. *h.* Eye *i.* Small hairs of skin. *j.* Sweat-glands. *k.* Posterior tarsal lands.

The *outer canthus* (commissura palpebrarum lateralis) is more acute than the inner, and the lids here lie in close contact with the globe: but the *inner canthus* (commissura palpebrarum medialis) is prolonged for a short distance inwards towards the nose, and the two lids are separated by a triangular space, the *lacus lacrimalis*. At the basal angles of the lacus lacrimalis, on the margin of each eyelid, is a small conical elevation, the *lachrymal papilla*, the apex of which is pierced by a small orifice, the *punctum lacrimale*, the commencement of the lachrymal canal.

The *eyelashes* (*cilia*) are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row at the margin of the lids: those of the upper lid, more numerous and longer than those of the lower, curve upwards; those of the lower lid curve downwards, so that they do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of a number of glands, *glands of Moll*, arranged in several rows close to the free margin of the lid. They are regarded as enlarged and modified sweat-glands.

Structure of the eyelids.—The eyelids are composed of the following structures taken in their order from without inwards: integument, areolar tissue, fibres of the Orbicularis muscle, tarsal plate and its ligament, Meibomian glands and conjunctiva. The upper lid has, in addition, the aponeurosis of the Levator palpebræ (fig. 848).

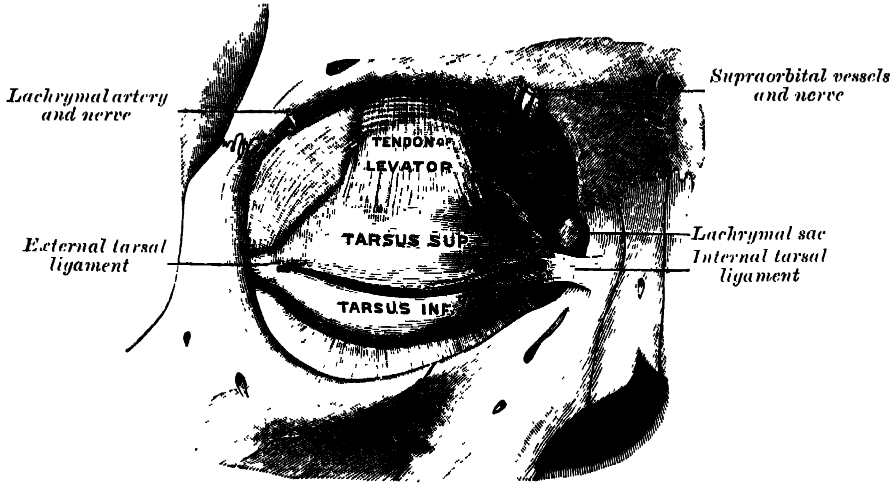
The *integument* is extremely thin, and continuous at the margins of the lids with the conjunctiva.

The *subcutaneous areolar tissue* is very lax and delicate, seldom contains any fat, and is extremely liable to serous infiltration.

The *palpebral fibres of the Orbicularis muscle* are thin, pale in colour, and possess an involuntary action.

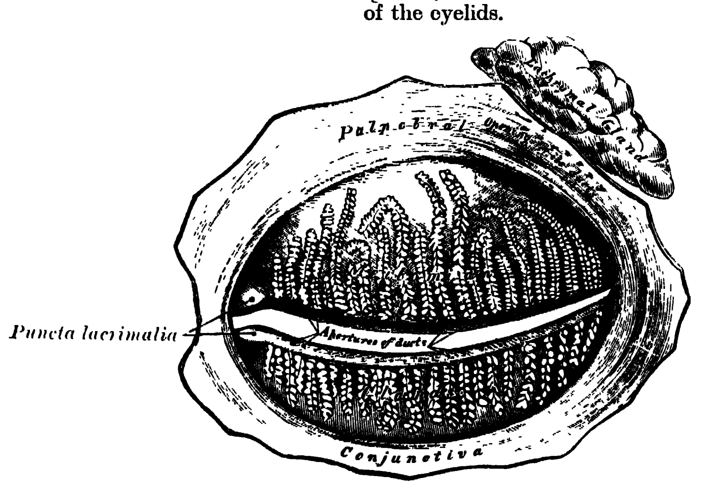
The *tarsal plates* (fig. 849) are two thin elongated plates of dense connective tissue, about an inch in length. They are placed one in each lid, and contribute to its form and support. The *superior tarsal plate* (tarsus superior), the larger, is of a semilunar form, about one-third of an inch in breadth at the centre,

FIG. 849.—The tarsal plates and their ligaments. Right eye; front view. (Testut.)



and gradually narrowing towards each of its extremities. To the anterior surface of this plate the aponeurosis of the Levator palpebræ is attached. The *inferior tarsal plate* (tarsus inferior), the smaller, is thinner, and of an elliptical form. The *free* or *ciliary margins* of these plates are thick, and present perfectly straight edges. The *attached* or *orbital margins* are connected to the circumference of the orbit by the superior and inferior palpebral ligaments. The *outer*

FIG. 850.—The Meibomian glands, &c., seen from the inner surface of the eyelids.



angles are attached to the malar bone by the external tarsal ligament. The *inner angles* of the two plates end at the lacus lacrimalis, and are attached to the frontal process of the maxilla by the internal tarsal ligament or tendo oculi.

The *palpebral* ligaments are membranous expansions situated one in each lid, and attached marginally to the edge of the orbit, where they are continuous with the periosteum. The superior ligament blends with the tendon of the Levator palpebræ and the superior tarsal plate, the inferior with the inferior

tarsal plate. Externally the two ligaments fuse to form the external tarsal ligament, just referred to; internally they are much thinner and, becoming separated from the internal tarsal ligament, are fixed to the lachrymal bone immediately behind the lachrymal sac. Together, the ligaments form an incomplete septum, the *septum orbitale*, which is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp.

The *Meibomian glands* (glandulæ tarsales) (fig. 850) are situated upon the inner surfaces of the eyelids, between the tarsal plates and conjunctiva, and may be distinctly seen through the mucous membrane on everting the eyelids, presenting an appearance like parallel strings of pearls. They are about thirty in number in the upper eyelid, and somewhat fewer in the lower. They are imbedded in grooves in the inner surfaces of the tarsal plates, and correspond in length with the breadth of each plate; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margins of the lids by minute foramina which correspond in number to the follicles. The use of their secretion is to prevent adhesion of the lids.

Structure.—These glands are a variety of the cutaneous sebaceous glands, each consisting of a single straight tube or follicle, having a cæcal termination, and with numerous small lateral diverticula opening into it. The tubes are supported by a basement membrane, and are lined at their mouths by stratified epithelium; the deeper parts of the tubes and the lateral offshoots are lined by a layer of polyhedral cells. They are thus identical in structure with the sebaceous glands.

The **conjunctiva** is the mucous membrane of the eye. It lines the inner surfaces of the eyelids, and is reflected over the fore-part of the sclera and cornea. In each of these situations its structure presents some peculiarities.

The *palpebral portion* is thick, opaque, highly vascular, and covered with numerous papillæ, its deeper parts presenting a considerable amount of lymphoid tissue. At the margins of the lids it becomes continuous with the lining membrane of the ducts of the Meibomian glands, and, through the lachrymal canals, with the lining membrane of the lachrymal sac and nasal duct. At the outer angle of the upper lid the lachrymal ducts open on its free surface; and at the inner angle of the eye it forms a semilunar fold, the *plica semilunaris*. The line of reflection of the conjunctiva from the upper lid on to the eyeball is named the *fornix conjunctivæ superior* and that from the lower lid the *fornix conjunctivæ inferior*. Upon the *sclera* the conjunctiva is loosely connected to the globe; it becomes thinner, loses its papillary structure, is transparent, and only slightly vascular in health. Upon the *cornea*, the conjunctiva consists only of epithelium, constituting the stratified epithelium of the cornea, already described (see page 1013). *Lymphatics* arise in the conjunctiva in a delicate zone around the cornea, from which the vessels run to the ocular conjunctiva.

In and near the fornices, but more plentiful in the upper than in the lower lid, a number of convoluted tubular glands open on the surface of the conjunctiva. Other glands, analogous to lymphoid follicles, and called by Henle *trachoma glands*, are found in the conjunctiva, and, according to Strohmeyer, are chiefly situated near the inner canthus of the eye. They were first described by Brush, in his description of Peyer's patches of the small intestine, as 'identical structures existing in the under eyelid of the ox.'

The *caruncula lacrimalis* is a small, reddish, conical-shaped body, situated at the inner canthus of the eye, and filling up the *lacus lacrimalis*. It consists of a small island of skin containing sebaceous and sweat glands, and is the source of the whitish secretion which constantly collects at the inner angle of the eye. A few slender hairs are attached to its surface. On the outer side of the caruncula is a slight semilunar fold of mucous membrane, the concavity of which is directed towards the cornea; it is called the *plica semilunaris*. Müller found smooth muscular fibres in this fold, and in some of the domesticated animals a thin plate of cartilage has been discovered. This structure is considered to be the rudiment of the third eyelid in birds, the *membrana nictitans*.

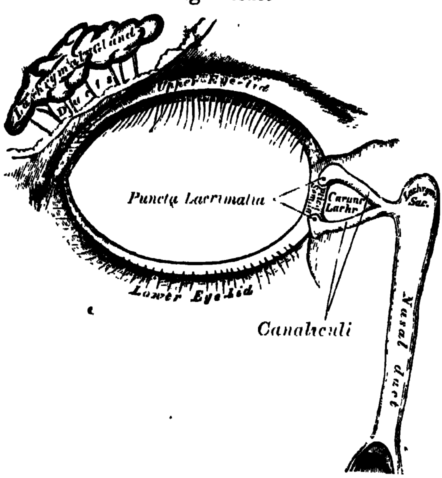
The nerves in the conjunctiva are numerous and form rich plexuses. According to Krause they terminate in a peculiar form of tactile corpuscle, which he terms 'terminal bulb.'

Lachrymal Apparatus (fig. 851)

The lachrymal apparatus (apparatus lacrimalis) consists of the lachrymal gland which secretes the tears, and its excretory ducts which convey the fluid to the surface of the eye; the fluid is carried away by the lachrymal canals into the lachrymal sac, and along the nasal duct into the cavity of the nose.

The lachrymal gland is lodged in the lachrymal fossa, on the inner side of the external angular process of the frontal bone. It is of an oval form, about the size and shape of an almond, and consists of an upper and a lower portion. The upper portion (*glandula lacrimalis superior*) is connected to the periosteum of the orbit by a few fibrous bands, and rests upon the Superior and External recti, which separate it from the globe of the eye. The lower part (*glandula lacrimalis inferior*) is separated from the upper by a fibrous septum, and projects into the back part of the upper eyelid, where its deep surface is related to the conjunctiva. The ducts of the gland, from six to twelve in number, run obliquely beneath the mucous membrane for a short distance, and, separating from each other, open by a series of minute orifices on the upper and outer half of the conjunctiva, near the superior fornix. These orifices are arranged in a row, so as to disperse the secretion over the surface of the membrane.

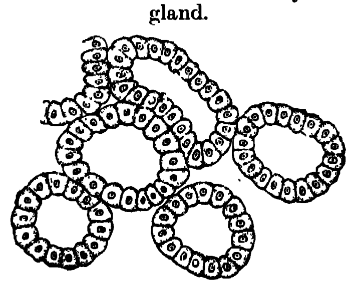
Fig. 851.—The lachrymal apparatus. Right side.



Structure of the lachrymal gland (fig. 852).—In structure and general appearance the lachrymal resembles the serous salivary glands (page 1112). In the recent state the cells are so crowded with granules that their limits can hardly be defined. They contain oval nuclei, and the cell protoplasm is finely fibrillated.

The **lachrymal canals** (ductus lacrimales) commence at the minute orifices, *puncta lacrimalia*, on the summit of small conical elevations, the *papillæ lacrimales*, seen on the margins of the lids, at the outer extremity of the lacus lacrimalis. The *superior canal*, the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes inwards and downwards to the lachrymal sac. The *inferior canal* at first descends, and then passes almost horizontally inwards to the lachrymal sac. They are dense and elastic in structure and are dilated into *ampullæ* at their angles. The mucous membrane is covered with stratified scaly epithelium, placed on a basement membrane. Outside the latter is a layer of striped muscle, continuous with the Tensor tarsi; at the bases of the lachrymal papillæ the fibres of this layer are circularly arranged and form a kind of sphincter.

Fig. 852.—Alveoli of lachrymal gland.



The **lachrymal sac** (saccus lacrimalis) is the upper dilated extremity of the nasal duct, and is lodged in a deep groove formed by the lachrymal bone and frontal process of the maxilla. It is oval in form, its upper extremity being closed in and rounded, while below, it is continued into the nasal duct. It is covered by a fibrous expansion derived from the tendo oculi, and on its deep surface it is crossed by the Tensor tarsi muscle (Horner's muscle, page 460), which is attached to the ridge on the lachrymal bone.

Structure.—The lachrymal sac consists of a fibrous elastic coat, lined internally by mucous membrane: the latter being continuous, through the lachrymal canals, with the mucous lining of the conjunctiva, and through the nasal duct with the mucous membrane of the nose.

The **nasal duct** (ductus nasolacrimalis) is a membranous canal, about three-quarters of an inch in length, which extends from the lower part of the lachrymal sac to the inferior meatus of the nose, where it terminates by a somewhat expanded orifice, provided with an imperfect valve, the *plica lacrimalis* (*Hasneri*), formed by a fold of the mucous membrane. It is contained in an osseous canal, formed by the maxilla, the lachrymal, and the inferior turbinated, is narrower in the middle than at either extremity, and takes a direction downwards, backwards, and a little outwards. It is lined by mucous membrane which is continuous below with that of the nose. This membrane in the lachrymal sac and nasal duct is covered with columnar epithelium as in the nose; this epithelium is in places ciliated.

Surface Form.—The palpebral fissure, or opening between the eyelids, is elliptical in shape, and differs in size in different individuals and in different races of mankind. In the Mongolian races, for instance, the opening is very small, merely a narrow fissure, and this makes the eye appear small in these races, whereas the size of the eyeball is relatively very constant. The normal form of the fissure is oblique, in a direction upwards and outwards, so that the outer angle is on a slightly higher level than the inner. This is exaggerated in the Mongolian races, in whom, owing to the upward projection of the malar bone and the shortness of the external angular process of the frontal bone, the tarsal plate of the upper lid is raised at its outer part, and gives a very oblique direction to the palpebral fissure. When the eyes are directed forwards, as in ordinary vision, the upper part of the cornea is covered by the upper lid, and the lower margin of the cornea corresponds to the level of the lower lid, so that about the lower three-fourths of the cornea are exposed under ordinary circumstances.

On the margins of the lids, about a quarter of an inch from the inner canthus, are two small openings, the *puncta lacrimalia*, the commencement of the lachrymal canals. They are best seen by everting the eyelids. In the natural condition they are in contact with the conjunctiva of the eyeball, and are maintained in this position by the Tensor tarsi muscle, so that the tears running over the surface of the globe easily find their way into the lachrymal canals. The position of the lachrymal sac into which the canals open is indicated by a little tubercle (page 282), which is plainly to be felt on the lower margin of the orbit. The lachrymal sac lies immediately above and to the inner side of this tubercle, and a knife passed through the skin in this situation would open the cavity. The position of the lachrymal sac may also be indicated by the tendo oculi, or internal tarsal ligament. If both lids be drawn outwards so as to tighten the skin at the inner angle, a prominent cord will be seen beneath the tightened skin. This is the *tendo oculi*, which lies directly over the lachrymal sac, bisecting it, and thus forming a useful guide to its situation. A knife entered immediately beneath the tense cord would open the lower part of the sac. A probe introduced through this opening can be readily passed downwards, through the duct into the inferior meatus of the nose. The direction of the duct is downwards, outwards, and backwards, and this course should be borne in mind in passing the probe, otherwise the point may be driven through the thin bony walls of the canal. A convenient plan is to direct the probe in such a manner, that if it were pushed onwards it would strike the first molar tooth of the mandible on the same side of the head. In other words, the surgeon standing in front of his patient should carry in his mind the position of the first molar tooth, and should push his probe onwards as if he desired to reach this structure.

Beneath the internal angular process of the frontal bone, the pulley of the Superior oblique can be plainly felt by pushing the finger backwards between the upper and inner angle of the eye and the roof of the orbit; passing backwards and outwards from this pulley the tendon can be felt for a short distance.

Applied Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin which covers them is exceedingly thin and delicate, and is supported on a quantity of loose areolar subcutaneous tissue, which contains no fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighbouring cicatrices, and thus produce an eversion of the lid, known as *ectropion*. Inversion of the lids (*entropion*) from spasm of the Orbicularis palpebrarum or from chronic inflammation of the palpebral conjunctiva may also occur. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as nævi. Rodent ulcer frequently commences about the inner canthus. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue, the extravasation of blood may be so great as to produce considerable swelling of the lids and complete closure of the eye, and the same is the case

when inflammatory products are poured out. The follicles of the eyelashes, or the sebaceous glands associated with these follicles may, be the seat of inflammation, constituting the ordinary 'sty.' The Meibomian glands are affected in the so-called 'tarsal tumour': the tumour, according to some, being caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The ciliary follicles are liable to become inflamed, constituting the disease known as *blepharitis ciliaris* or 'blear eye.' Irregular or disorderly growth of the eyelashes not infrequently occurs; some of them being turned towards the eyeball and producing inflammation and ulceration of the cornea, and possibly eventually complete destruction of the eye. The Orbicularis palpebrarum may be the seat of spasm, either in the form of slight quivering of the lids; or repeated twitchings, most commonly due to errors of refraction in children; or more continuous spasm, due to some irritation of the fifth or seventh cranial nerve. The Orbicularis may be paralysed, generally associated with paralysis of the other facial muscles. Under these circumstances the patient is unable to close the lids, and, if he attempts to do so, rolls the eyeball upwards under the upper lid. The tears overflow from displacement of the lower lid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. Ptosis, or dropping of the upper eyelid, may be congenital, or may be due to paralysis of the Levator palpebræ superioris, in which case there will probably be other symptoms of implication of the third nerve. The eyelids may be the seat of bruises, wounds, or burns. Following burns, adhesion of the margins of the lids to each other, or adhesion of the lids to the globe, may take place. The eyelids are sometimes the seat of emphysema, after fracture of some of the thin bones forming the inner wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostril through the lacerated structures into the connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling characteristic of this affection.

Foreign bodies frequently get into the conjunctival sac and cause great pain, especially if they come in contact with the corneal surface, during the movements of the lid and the eye on each other. The conjunctiva is often involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a burn, either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of inflammation arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclera, which is present in inflammation of the deeper structures of the globe. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off towards the corneal margin; they anastomose freely and form a dense network, and they can be emptied or displaced by gentle pressure. Inflammation of the underlying sclera, ciliary body, or iris, is a far more serious condition; the injection is in the deeper vessels of the eye, and as seen through the sclera presents a diffuse and dull purplish or violet zone of circumcorneal discoloration.

The lachrymal gland is occasionally, though rarely, the seat of inflammation, either acute or chronic; it is also sometimes the seat of tumours, benign or malignant, and for these may require removal. This may be done by an incision through the skin, just below the eyebrow; and the gland, being invested with a special capsule of its own, may be isolated and removed, without opening the general cavity of the orbit. The canaliculi may be obstructed, either as a congenital defect, or by some foreign body, as an eyelash or a dacryolith, causing the tears to run over the cheek. The canaliculi may also become occluded as a result of burns or injury; overflow of the tears may in addition result from deviation of the puncta, or from chronic inflammation of the lachrymal sac. This latter condition is set up by some obstruction to the nasal duct, frequently occurring in tuberculous subjects. In consequence of this the tears and mucus accumulate in the lachrymal sac, distending it. Suppuration in the lachrymal sac is sometimes met with; this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers, in cases where the lachrymal passages were previously quite healthy. It may lead to lachrymal fistula from an abscess forming in the sac, which bursts or is opened on the surface; and this condition is often seen in badly nourished, tuberculous children.

THE EAR

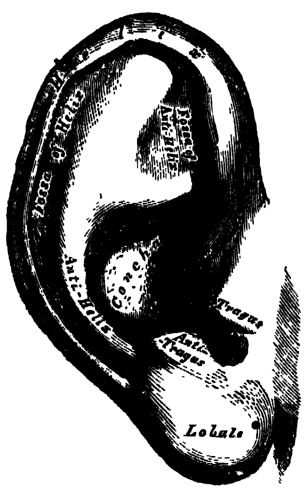
The organ of hearing (organon auditus) is divisible into three parts: the external ear, the middle ear or tympanum, and the internal ear or labyrinth.

The External Ear

The **external ear** consists of the expanded portion named the *pinna* or *auricula*, and the *auditory canal* or *meatus*. The former serves to collect the vibrations of the air by which sound is produced; the latter conducts those vibrations to the tympanum.

The **pinna** or **auricula** (fig. 853) is of an ovoid form, with its larger end directed upwards. Its outer surface is irregularly concave, directed slightly forwards, and presents numerous eminences and depressions to which names have been assigned. Thus the external prominent rim of the auricle is called the *helix*. Where the helix turns downwards behind, a small tubercle, the *tubercle of Darwin* (tuberculum auriculæ) is frequently seen. This tubercle is very evident about the sixth month of fœtal life; at this stage the human pinna has a close resemblance to that of some of the adult monkeys. Another curved prominence, parallel with and in front of the helix, is called the *antihelix*; this divides above into two crura, which enclose a triangular depression, the *fossa of the antihelix* (*fossa triangularis*). The narrow curved depression between the helix and the antihelix is called the *fossa of the helix* (*scapha*); the antihelix describes a curve round a deep, capacious cavity, the *concha auriculæ*, which is partially divided into two parts by the *crus helicis* or the commencement of the helix; the upper part is termed the *cymba conchæ*, the lower part the *cavum conchæ*. In front of the concha, and projecting backwards over the meatus, is a small pointed eminence, the *tragus*: so called from its being generally covered on its under surface with a tuft of hair, resembling a goat's beard. Opposite the tragus, and separated from it by a deep notch (*incisura intertragica*), is a small tubercle, the *antitragus*. Below this is the *lobule* (lobulus auriculæ), composed of tough areolar and adipose tissues, and wanting the firmness and elasticity of the rest of the pinna.

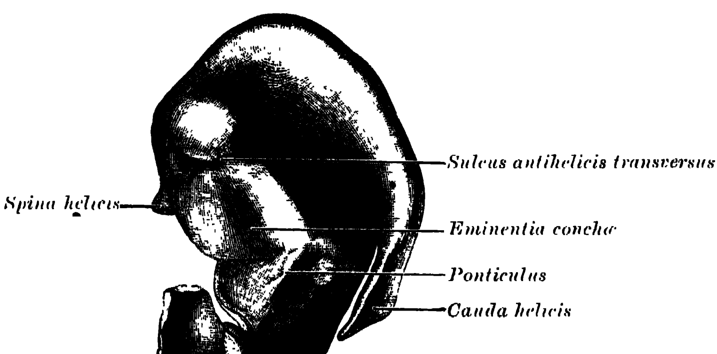
FIG. 853.—The pinna, or auricle. Outer surface.



The cranial surface of the pinna presents elevations which correspond to the depressions on its outer surface and after which they are named, e.g. eminentia conchæ, eminentia triangularis, &c.

Structure of the pinna.—The pinna is composed of a thin plate of yellow fibro-cartilage, covered with integument, and connected to the surrounding parts by the extrinsic ligaments and muscles; and to the commencement of the external auditory canal by fibrous tissue.

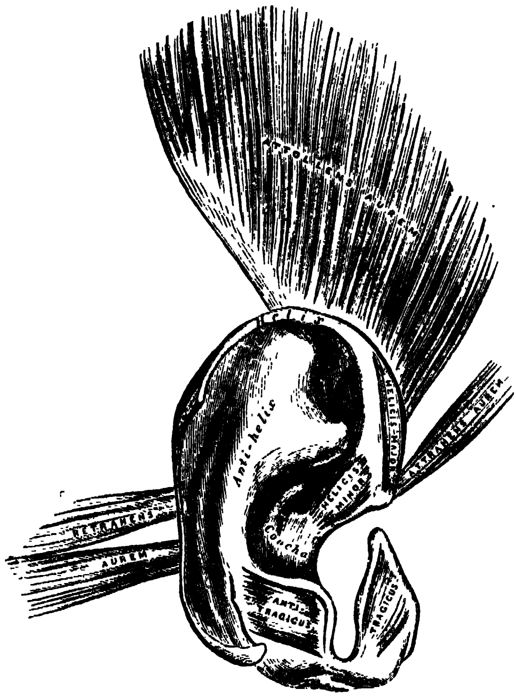
FIG. 854.—Cranial surface of cartilage of right pinna.



The *integument* is thin, closely adherent to the cartilage, and covered with hairs furnished with sebaceous glands which are most numerous in the concha and scaphoid fossæ. The hairs are most numerous and largest on the tragus and antitragus.

The *cartilage of the pinna* (cartilago auriculæ) (figs. 854, 855) consists of one single piece; it gives form to this part of the ear, and upon its surface are found all the eminences and depressions above described. It does not enter into the construction of all parts of the auricle; thus it does not form a constituent part of the lobule; it is deficient, also, between the tragus and beginning of the helix, the gap being filled up by dense fibrous tissue. At the front part of the pinna, where the helix bends upwards, is a small projection of cartilage, called the *spina helicis*, while the lower part of the helix is prolonged downwards as a tail-like process, the *cauda helicis*; this is separated from the antihelix by a fissure, the *fissura antitragohelicina*. The cranial aspect of the cartilage exhibits a transverse furrow, the *sulcus antihelicis transversus*, which corresponds with the inferior crus of the antihelix and separates the prominence produced by the concha from that caused by the fossa triangularis. The eminentia conchæ is crossed by a vertical ridge (*ponticulus*) which gives attachment to the Retrahens auriculam muscle. The cartilage of the pinna presents several intervals or fissures in its substance, which partially separate the different parts. The fissure of the helix is a short vertical slit, situated at the forepart of the pinna. Another fissure, the fissure of the tragus, is seen upon the anterior surface of the tragus. The cartilage of the pinna is of that form which is known as yellow fibro-cartilage.

FIG. 855.—The muscles of the pinna.



The *ligaments of the pinna* consist of two sets: (1) extrinsic, connecting it to the side of the head; (2) intrinsic, connecting various parts of its cartilage together.

The *extrinsic ligaments* are two in number, anterior and posterior. The *anterior ligament* extends from the spina helicis and tragus to the root of the zygoma. The *posterior ligament* passes from the posterior surface of the concha to the outer surface of the mastoid process of the temporal bone.

The chief *intrinsic ligaments* are: (*a*) a strong fibrous band, stretching across from the tragus to the commencement of the helix, completing the meatus in front, and partly encircling the boundary of the concha; and (*b*) a band which extends between the antihelix and the cauda helicis. Other less important bands are found on the cranial surface of the pinna.

The *muscles of the pinna* (fig. 855) consist of two sets: (1) the *extrinsic*, which connect it with the side of the head, moving the pinna as a whole, viz. the Attollens, Attrahens, and Retrahens auriculam (page 459); and (2) the *intrinsic*, which extend from one part of the auricle to another, viz.:

Helicis major.	Antitragicus.
Helicis minor.	Transversus auriculæ.
Tragicus.	Obliquus auriculæ.

The *Helicis major* is a narrow vertical band of muscular fibres, situated upon the anterior margin of the helix. It arises below, from the crus helicis, and is inserted into the anterior border of the helix, just where it is about to curve backwards.

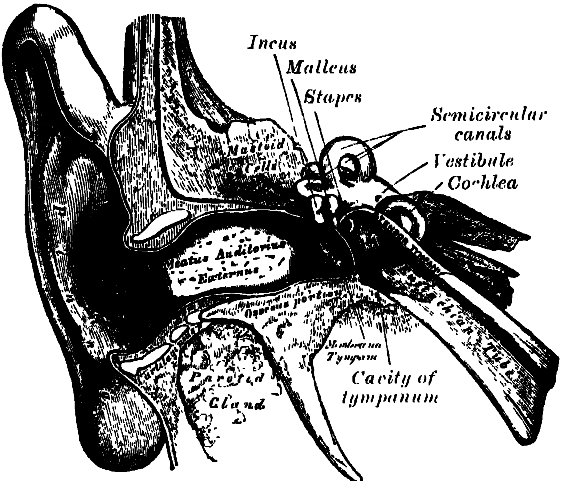
The *Helicis minor* is an oblique fasciculus, which covers the crus helicis.

The *Tragicus* is a short, flattened vertical band of muscular fibres situated upon the outer surface of the tragus.

The *Antitragicus* arises from the outer part of the antitragus: its fibres are inserted into the cauda helicis and antihelix. This muscle is usually very distinct.

The *Transversus auriculæ* is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the convexity of the concha to the prominence corresponding with the groove of the helix.

FIG. 856.—A front view of the organ of hearing. Right side.

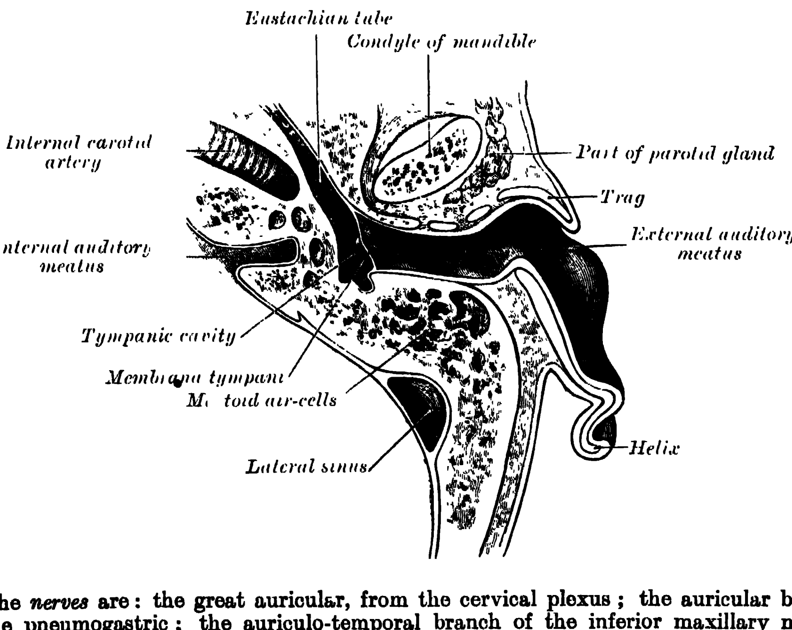


The *Obliquus auriculæ* consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

The *arteries of the pinna* are the posterior auricular from the external carotid, the anterior auricular from the temporal, and an auricular branch from the occipital artery.

The *veins* accompany the corresponding arteries.

FIG. 857.—Horizontal section through left ear; upper half of section.



The *nerves* are: the great auricular, from the cervical plexus; the auricular branch of the pneumogastric; the auriculo-temporal branch of the inferior maxillary nerve; the small occipital from the cervical plexus, and the great occipital or internal branch of the posterior primary division of the second cervical nerve. The muscles of the pinna are supplied by the facial nerve.

The auditory canal (meatus acusticus externus) extends from the bottom of the concha to the membrana tympani (figs. 856, 857). It is about an inch and

a half in length if measured from the tragus; from the bottom of the concha its length is about an inch. It forms a sort of S-shaped curve, and is directed at first inwards, forwards, and slightly upwards (*pars externa*); it then passes inwards and backwards (*pars media*), and lastly is carried inwards, forwards, and slightly downwards (*pars interna*). It forms an oval cylindrical canal, the greatest diameter being in the vertical direction at the external orifice, but nearly in the horizontal direction at the tympanic end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the *isthmus*, in the osseous portion, about three-quarters of an inch from the bottom of the concha. The membrana tympani, which closes the inner end of the meatus, is obliquely directed; in consequence of this the floor of the canal is longer than the roof, and the anterior wall longer than the posterior. The auditory canal is formed partly by cartilage and membrane, and partly by bone, and is lined by skin.

The *cartilaginous portion* is about one-third of an inch (8 mm.) in length; it is continuous with the cartilage of the pinna, and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at its upper and back part, its place being supplied by fibrous membrane. This part of the canal is rendered freely movable by two or three deep fissures (*incisuræ Santorini*) which extend through the cartilage in a vertical direction.

The *osseous portion* is about two-thirds of an inch (16 mm.) in length, and narrower than the cartilaginous portion. It is directed inwards and a little forwards, forming in its course a slight curve the convexity of which is upwards and backwards. Its inner end, which communicates, in the dry bone, with the cavity of the tympanum, is smaller than the outer, and sloped, the anterior wall projecting beyond the posterior for about one-sixth of an inch; it is marked, except at its upper part, by a narrow groove, the *sulcus tympanicus*, in which the circumference of the membrana tympani is attached. Its outer end is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the pinna. Its transverse section is oval, the greatest diameter being from above downwards and backwards. The front and lower parts of this canal are formed by a curved plate of bone, the tympanic plate, which, in the fœtus, exists as a separate ring (*annulus tympanicus*), incomplete at its upper part. See section on Osteology (page 231).

The *skin* lining the meatus is very thin, adheres closely to the cartilaginous and osseous portions of the tube, and covers the surface of the membrana tympani, forming its outer layer. After maceration, the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands, which secrete the ear-wax. They resemble in structure sweat-glands, and their ducts open on the surface of the skin.

Relations of the meatus.—In front of the osseous part is the condyle of the mandible, which, however, is separated from the cartilaginous part by the retro-mandibular part of the parotid gland. The movements of the jaw influence to some extent the lumen of this latter portion. Behind the osseous part are the mastoid air-cells, separated from the meatus by a thin layer of bone.

The *arteries* supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal.

The *nerves* are chiefly derived from the auriculo-temporal branch of the inferior maxillary nerve and the auricular branch of the pneumogastric.

Applied Anatomy.—Malformations, such as imperfect development of the external parts, absence of the meatus, or supernumerary auricles, are occasionally met with. The skin of the auricle is thin and richly supplied with blood, but in spite of this it is often the seat of frost-bite, due to the fact that it is much exposed to cold, and lacks the usual underlying subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (*hæmatoma auris*), usually the result of traumatism, but not necessarily due to this cause. It is said to occur most frequently in the ears of the insane. Keloid sometimes grows in the auricle around the puncture made for earrings, and epithelioma occasionally affects this part. Deposits of urate of soda are often met with in the pinna in gouty subjects.

The external auditory meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions the whole of the canal and membrana tympani can be brought into view. In using this instrument, it is advisable that the pinna should be drawn upwards, backwards, and a

little outwards, so as to render the canal as straight as possible. The points to be noted are, the presence of wax or foreign bodies ; the size of the canal ; and the condition of the membrana tympani. Accumulation of wax is often a cause of deafness, and may give rise to very serious consequences, such as ulceration of the membrane, and it is best removed by syringing. Foreign bodies are not infrequently introduced into the ear by children, and, when situated in the first portion of the canal, may be removed with tolerable facility by means of a minute hook or loop of fine wire, aided by reflected light ; but when they have slipped beyond the narrow middle part of the meatus, their removal is in no wise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the membrana tympani and possibly the contents of the tympanum. The calibre of the external auditory canal may be narrowed by inflammation of its lining membrane, running on to suppuration ; by periostitis ; by polypi ; or by exostoses.

At the point of junction of the osseous and cartilaginous portions an obtuse angle, which projects into the tube at its antero-inferior wall, is formed. This produces a sort of constriction in this situation, and renders it a narrow portion of the canal—an important point to be borne in mind in connection with the presence of foreign bodies in the ears. The cartilaginous is connected to the bony part by fibrous tissue which renders the outer part of the tube very movable, and therefore by drawing the pinna upwards and backwards the canal is rendered almost straight. At the external orifice are a few short, crisp hairs, which serve to prevent the entrance of small particles of dust, or flies and other insects. In the external auditory meatus the secretion of the ceruminous glands serves to catch any small particles which may find their way into the canal, and prevent their reaching the membrana tympani, where their presence might excite irritation. The shortness of the canal in children should be borne in mind in introducing the aural speculum, so that it be not pushed in too far, at the risk of injuring the membrana tympani ; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions, and thus assist the operator in obtaining, by the aid of reflected light, a good view of the membrana tympani. Just in front of the membrane is a well-marked depression, situated on the floor of the canal, and bounded by a somewhat prominent ridge ; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upwards and backwards, the greater part of the membrana tympani is rendered visible. It is a pearly-grey membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle (about fifty-five degrees), while with the roof it forms an obtuse angle. At birth it is more horizontal, situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upwards, is a reddish-yellow streak ; this is the handle of the malleus, which is inserted into the membrane. At the upper part of this streak, close to the roof of the meatus, a little white, rounded prominence is plainly to be seen ; this is the processus brevis of the malleus, projecting against the membrane. The membrana tympani does not present a plane surface ; on the contrary, its centre is drawn inwards, on account of its connection with the handle of the malleus, and thus the external surface is rendered concave.

The connections of the nerves of the meatus explain the fact of the occurrence, in cases of irritation of the meatus, of constant coughing and sneezing, from implication of the pneumogastric, and the vomiting which may follow syringing the ears of children, and the occasional heart failure similarly induced in elderly people. No doubt also the association of earache with toothache or with cancer of the tongue is due to implication of the inferior maxillary, a branch of the fifth, which supplies also the teeth and the tongue. The upper half of the membrana tympani is much more richly supplied with blood than the lower half. For this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

THE MIDDLE EAR, OR TYMPANUM

The **middle ear, or tympanic cavity** (cavum tympani) is an irregular laterally compressed cavity, situated within the temporal bone. It is filled with air, and communicates with the naso-pharynx by the Eustáchian tube. It contains a chain of movable bones, which connect its outer to its inner wall, and serve to convey the vibrations communicated to the membrana tympani across the cavity to the internal ear.

The tympanic cavity consists of two parts : the *atrium* or *tympanic cavity proper*, opposite the tympanic membrane, and the *attic* or *recessus epitympanicus,* above the level of the upper part of the membrane ; the latter contains the upper half of the malleus and the greater part of the incus. Including the attic the vertical and antero-posterior diameters of the tympanic cavity each measures about fifteen millimetres. From without inwards it measures about six millimetres above and four millimetres below ; opposite the centre of the tympanic membrane it is only about two millimetres. It is bounded

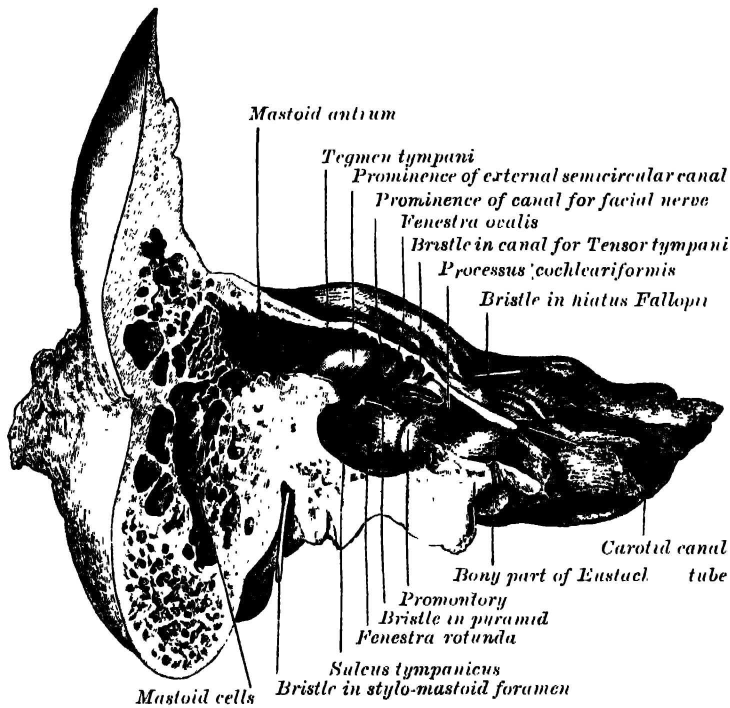
externally by the membrana tympani and meatus; internally, by the outer wall of the internal ear; it communicates, behind, with the mastoid antrum and through it with the mastoid cells, and in front with the Eustachian tube.

The **roof** (paries tegmentalis) is broad, flattened, and formed of a thin plate of bone (*tegmen tympani*), which separates the cranial and tympanic cavities. It is situated on the anterior surface of the petrous portion of the temporal bone close to its angle of junction with the squamous portion of the same bone, and is prolonged backwards so as to roof in the mastoid antrum; it is also carried forwards to cover in the canal for the Tensor tympani muscle. Its outer edge corresponds with the remains of the petro-squamous suture.

The **floor** (paries jugularis) is narrow, and is separated by a thin plate of bone (*fundus tympani*) from the jugular fossa. It presents, near the inner wall, a small aperture for the passage of Jacobson's nerve.

The **outer wall** (paries membranacea) is formed mainly by the membrana tympani, partly by the ring of bone into which this membrane is inserted.

FIG. 858.—Coronal section of right temporal bone.



This ring of bone is incomplete at its upper part, forming a notch (*incisura Rivini*), close to which are three small apertures: the iter chordæ posterius, the Glaserian fissure, and the iter chordæ anterius.

The *iter chordæ posterius* (apertura tympanica canaliculi chordæ) is situated in the angle of junction between the posterior and outer walls of the tympanum, immediately behind the membrana tympani and on a level with the upper end of the handle of the malleus; it leads into a minute canal, which descends in front of the aquæductus Fallopii, and terminates in that canal near the stylo-mastoid foramen. Through it the chorda tympani nerve enters the tympanum.

The *Glaserian fissure* (fissura petrotympanica) opens just above and in front of the ring of bone into which the membrana tympani is inserted; in this situation it is a mere slit about a line in length. It lodges the long process and anterior ligament of the malleus, and gives passage to the tympanic branch of the internal maxillary artery.

The *iter chordæ anterius* (*canal of Huguier*) is placed at the inner end of the Glaserian fissure; through it the chorda tympani nerve leaves the tympanum.

The **inner wall** (paries labyrinthica) (fig. 858) is vertical in direction, and looks directly outwards. It presents for examination the following parts:

Fenestra ovalis.	Promontorium.
Fenestra rotunda.	Prominentia canalis facialis.

The *fenestra ovalis* (fenestra vestibuli) is a reniform opening leading from the tympanum into the vestibule of the internal ear; its long diameter is directed horizontally, and its convex border is upwards. In the recent state it is occupied by the base of the stapes, the circumference of which is fixed by the annular ligament to the margin of the foramen.

The *fenestra rotunda* (fenestra cochleæ) is situated below and a little behind the fenestra ovalis, from which it is separated by a rounded elevation, the *promontorium*. It is placed at the bottom of a funnel-shaped depression and, in the macerated bone, leads into the cochlea of the internal ear; it is closed in the recent state by a membrane (*membrana tympani secundaria*) which is concave towards the tympanum, convex towards the cochlea. This membrane consists of three layers: an external, or mucous, derived from the mucous lining of the tympanum; an internal from the lining membrane of the cochlea; and an intermediate, or fibrous layer.

The *promontorium* is a rounded hollow prominence, formed by the projection outwards of the first turn of the cochlea; it is placed between the fenestræ, and is furrowed on its surface by three small grooves, which lodge branches of the tympanic plexus. A minute spicule of bone frequently connects the promontorium to the pyramid.

The *prominentia canalis facialis* indicates the position of the bony canal (aquæductus Fallopii), in which the facial nerve is contained; this canal traverses the inner wall of the tympanum above the fenestra ovalis, and behind that opening curves nearly vertically downwards along the posterior wall.

The **posterior wall** (paries mastoidea) is wider above than below, and presents for examination the

Opening of the antrum.	Pyramid.	Fossa incudis.

The *opening of the antrum* is a large irregular aperture, which extends backwards from the epitympanic recess and leads into a considerable air space, the *mastoid antrum* (antrum tympanicum) (see page 226). The antrum communicates with large irregular cavities contained in the interior of the mastoid process, the *mastoid air-cells* (cellulæ mastoideæ). These cavities vary considerably in number, size, and form; they are lined by mucous membrane, continuous with that lining the cavity of the tympanum. On the inner wall of the opening into the antrum is a rounded eminence, situated above and behind the eminence of the aquæductus Fallopii; it corresponds with the position of the ampullated extremities of the superior and external semicircular canals.

The *pyramid* (eminentia pyramidalis) is a conical eminence, situated immediately behind the fenestra ovalis, and in front of the vertical portion of the Fallopian aqueduct; it is hollow in the interior, and contains the Stapedius muscle; its summit projects forwards towards the fenestra ovalis, and presents a small aperture which transmits the tendon of the muscle. The cavity in the pyramid is prolonged downwards and backwards in front of the aquæductus Fallopii, and communicates with it by a minute canal which transmits a twig from the facial nerve to the Stapedius muscle.

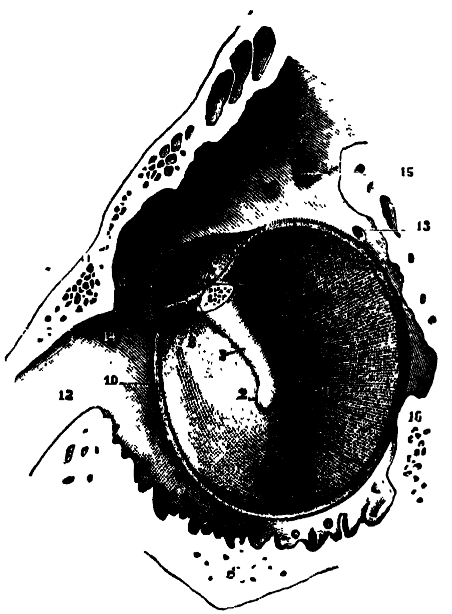
The *fossa incudis* is a small depression which is situated in the lower and back part of the epitympanic recess, and lodges the short process of the incus.

The **anterior wall** (paries carotica) is wider above than below; it corresponds with the carotid canal, from which it is separated by a thin plate of bone perforated by the tympanic branch of the internal carotid artery, and by a communicating branch which connects the sympathetic plexus on the internal carotid artery with the tympanic plexus on the promontory. At the upper part of the anterior wall are the orifice of the canal for the Tensor tympani and the orifice of the Eustachian tube, separated from each other by a thin horizontal plate of bone, the *processus cochleariformis* (septum canalis musculotubarii). These canals run from the tympanum forwards, inwards, and a little downwards, to the retiring angle between the squamous and petrous portions of the temporal bone.

The *canal for the Tensor tympani* (semicanalis m. tensoris tympani) is the superior and the smaller of the two; it is cylindrical and lies beneath the forward prolongation of the tegmen tympani. It extends on to the inner wall of the tympanum and ends immediately above the fenestra ovalis. The processus cochleariformis passes backwards below this part of the canal, forming its outer wall and floor; it expands above the anterior extremity of the fenestra ovalis and terminates by curving outwards so as to form a pulley over which the tendon passes.

The *Eustachian tube* (tuba auditiva) is the channel through which the tympanum communicates with the naso-pharynx. Its length is an inch and a half (36 mm.), and its direction is downwards, forwards, and inwards, forming an angle of about forty-five degrees with the sagittal plane and one of from thirty to forty degrees with the horizontal plane. It is formed partly of bone, partly of cartilage and fibrous tissue.

Fig. 859.—The membrana tympani viewed from within. (Testut.)



The malleus has been resected immediately beyond its processus brevis, in order to show the malleolar folds and the membrane of Shrapnell.

1. Membrana tympani. 2. Umbo or navel. 3. Handle of the malleus. 4. Processus brevis. 5. Anterior malleolar fold. 6. Posterior malleolar fold. 7. Membrane of Shrapnell. 8. Anterior pouch of Tröltsch. 9. Posterior pouch of Troltsch. 10. Fibro-cartilaginous ring. 11. Glaserian fissure. 12. Eustachian tube. 13. Iter chordæ posterius. 14. Iter chordæ anterius. 15. Fossa incudis for short process of the incus. 16. Prominentia styloidea.

The *osseous portion* (pars ossea tubæ auditivæ) is about half an inch in length. It commences in the anterior wall of the tympanum, below the processus cochleariformis, and, gradually narrowing, terminates at the angle of junction of the petrous and squamous portions of the temporal bone, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion.

The *cartilaginous portion* (pars cartilaginea tubæ auditivæ), about an inch in length, is formed of a triangular plate of elastic fibro-cartilage, the apex of which is attached to the margin of the inner extremity of the osseous canal, while its base lies directly under the mucous membrane of the naso-pharynx, where it forms an elevation or cushion behind the pharyngeal orifice of the tube. The upper edge of the cartilage is curled upon itself, being bent outwards so as to present on transverse section the appearance of a hook; a groove or furrow is thus produced, which opens below and externally, and this part of the canal is completed by fibrous membrane. The cartilage lies in a groove between the petrous temporal and the greater wing of the sphenoid; this groove ends opposite the middle of the internal pterygoid plate. The cartilaginous and bony portions of the tube are not in the same plane, the former inclining downwards a little more than the latter. The diameter of the tube is not uniform throughout, being greatest at the pharyngeal orifice, least at the junction of the bony and cartilaginous portions, and again expanding as it approaches the tympanic cavity; the narrowest part of the tube is termed the *isthmus*. The position and relations of the pharyngeal orifice are described with the naso-pharynx. The mucous membrane of the tube is continuous in front with that of the naso-pharynx and behind with that of the tympanic cavity; it is covered with ciliated epithelium and is thin in the osseous portion, while in the cartilaginous portion it contains many mucous glands and near the pharyngeal orifice a considerable amount of adenoid tissue, which has been named by Gerlach the *tube-tonsil*. The tube is opened during deglutition by the Salpingo-pharyngeus and Dilatator

tubæ. The latter arises from the hook of the cartilage and from the membranous part of the tube, and blends below with the Tensor palati.

The **membrana tympani** (fig. 859) separates the cavity of the tympanum from the bottom of the external meatus. It is a thin, semi-transparent membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downwards and inwards so as to form an angle of about fifty-five degrees with the floor of the meatus. Its longest diameter is directed from above and behind, downwards and forwards, and measures from nine to ten millimetres; its shortest diameter measures from eight to nine millimetres. The greater part of its circumference is thickened to form an annular ring which is fixed in a groove, the *sulcus tympanicus*, at the inner extremity of the meatus. This sulcus is deficient superiorly at the incisure or notch of Rivinus. From the extremities of this notch two bands, the *anterior* and *posterior malleolar folds*, are prolonged to the short process of the malleus. The small, somewhat triangular part of the membrane situated above these folds is lax and thin, and is named the *pars flaccida* of Shrapnell; in it a small orifice is sometimes seen. The handle of the malleus is firmly attached to the inner aspect of the membrane as far as its centre, which it draws inwards towards the cavity of the tympanum. The outer surface of the membrane is thus concave, and the most depressed part of this concavity is named the *umbo* (umbo membranæ tympani).

Structure.—The membrana tympani is composed of three layers, an external (cuticular), a middle (fibrous), and an internal (mucous). The *cuticular* layer (stratum cutaneum) is derived from the integument lining the meatus. The fibrous layer consists of two strata, an external (stratum radiatum) of *radial fibres*, which diverge from the handle of the malleus, and an internal (stratum circulare) of *circular fibres*, which are plentiful around the circumference but sparse and scattered near the centre of the membrane. Branched or *dendritic* fibres, as pointed out by Grüber, are also present, especially in the posterior half of the membrane.

Vessels and Nerves.—The *arteries* of the membrana tympani are derived from the deep auricular branch of the internal maxillary, which ramifies beneath the cuticular layer: and from the stylo-mastoid branch of the posterior auricular, and tympanic branch of the internal maxillary, which are distributed on the mucous surface. The superficial *veins* open into the external jugular; those on the mucous surface drain partly into the lateral sinus and veins of the dura mater, and partly into a plexus on the Eustachian tube. The membrane receives its *nerve supply* from the auriculo-temporal branch of the inferior maxillary, the auricular branch of the vagus, and the tympanic branch of the glosso-pharyngeal.

Ossicles of the Tympanum (Ossicula Auditus)

The tympanic cavity contains a chain of three movable bones, the *malleus*, *incus*, and *stapes*. The first is attached to the membrana tympani, the last to the circumference of the fenestra ovalis, the incus being placed between the two, and connected to both by delicate articulations.

The **Malleus** (fig. 860), so named from its fancied resemblance to a hammer, consists of a head, neck, and three processes, viz. the handle or manubrium, the processus gracilis, and the processus brevis.

The *head* (capitulum mallei) is the large upper extremity of the bone; it is oval in shape, and articulates posteriorly with the incus, being free in the rest of its extent. The facet for articulation with the incus is constricted near the middle, and consists of an upper larger, and lower lesser part, which form nearly a right angle with each other. Opposite the constriction the lower margin of the facet projects in the form of a process, the *cog-tooth* or *spur* of the malleus.

The *neck* (collum mallei) is the narrow contracted part just beneath the head; below it, is a prominence, to which the various processes are attached.

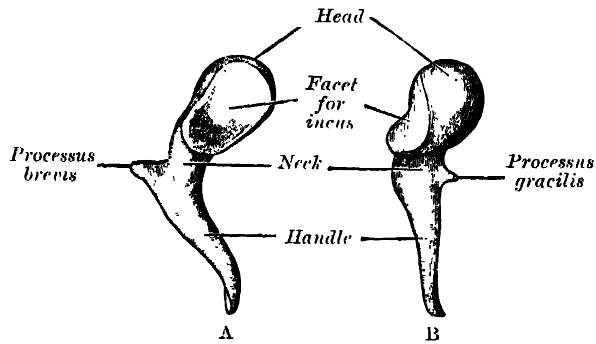
The *handle* (manubrium mallei) is connected by its outer margin with the membrana tympani. It is directed downwards, inwards, and backwards; it decreases in size towards its free extremity, which is curved slightly forwards, and flattened from within outwards. On the inner side, near its upper end, is a slight projection, into which the tendon of the Tensor tympani is inserted.

The *processus gracilis* (processus anterior [Folii]) is a delicate process,

which springs from the eminence below the neck and is directed forwards and outwards to the Glaserian fissure, to which it is connected by ligamentous fibres. In the fœtus this is the longest process of the malleus, and is in direct continuity with the cartilage of Meckel.

The *processus brevis* (processus lateralis) is a slight conical projection, which springs from the root of the manubrium ; it is directed outwards, and is attached to the upper part of the tympanic membrane and, by means of the anterior and posterior malleolar folds, to the extremities of the notch of Rivinus.

FIG. 860.—Left malleus. A. From behind. B. From within.



The **Incus** (fig. 861) has received its name from its supposed resemblance to an anvil, but it is more like a bicuspid tooth, with two roots, which differ in length, and are widely separated from each other. It consists of a body and two processes.

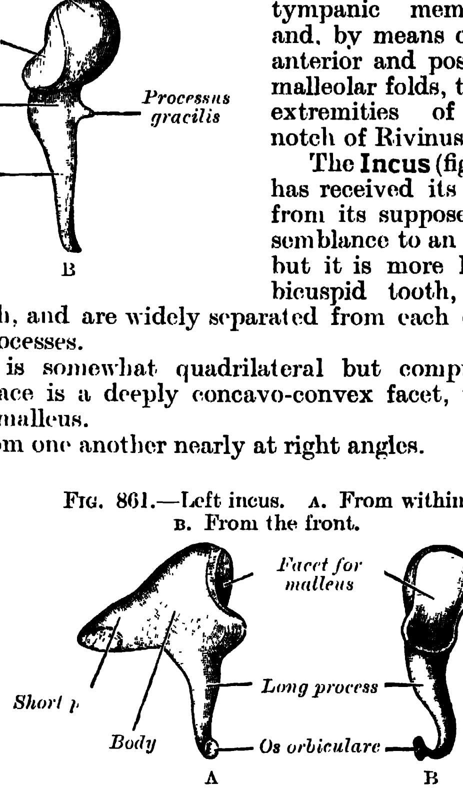
The *body* (corpus incudis) is somewhat quadrilateral but compressed laterally. On its anterior surface is a deeply concavo-convex facet, which articulates with the head of the malleus.

The two processes diverge from one another nearly at right angles.

The *short process* (crus breve) is somewhat conical in shape, projects almost horizontally backwards, and is attached to a depression, the *fossa incudis*, in the lower and back part of the epitympanic recess.

The *long process* (crus longum), longer and more slender than the preceding, descends nearly vertically behind and parallel to the handle of the malleus, and, bending inwards, terminates in a rounded globular projection, the *os orbiculare* or *lenticular process*, which is tipped with cartilage, and articulates with the head of the stapes. In the fœtus the os orbiculare exists as a separate bone.

FIG. 861.—Left incus. A. From within. B. From the front.

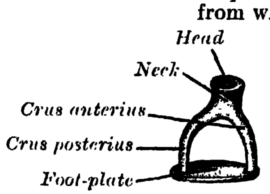


The **Stapes** (fig. 862), so called from its close resemblance to a stirrup, consists of a head, neck, two crura, and a base.

The *head* (capitulum stapedis) presents a depression, tipped with cartilage, which articulates with the os orbiculare.

The *neck* (collum stapedis), the constricted part of the bone succeeding the head, receives the insertion of the Stapedius muscle.

FIG. 862.—A. Left stapes. B. Foot-plate of stapes from within.



The *two crura* (crus anterius et crus posterius) diverge from the neck and are connected at their extremities by a flattened oval-shaped plate (*the base*), which forms the foot-plate of the stirrup and is fixed to the margin of the fenestra ovalis by ligamentous fibres. Of the two crura the anterior is shorter and less curved than the posterior.

Ligaments of the Ossicula.—These small bones are connected with each other, and with the walls of the tympanum, by ligaments, and moved by small muscles. The articular surfaces of the malleus and incus, and the orbicular process of the incus and head of the stapes, are covered with cartilage and connected together by delicate capsular ligaments, lined by synovial membrane. The ligaments connecting the ossicula with the walls of the tympanum are five in number: three for the malleus, one for the incus, and one for the stapes.

The *anterior ligament of the malleus* (lig. mallei anterius) was formerly described as a muscle (*Laxator tympani*). It is now, however, believed by most observers to consist of ligamentous fibres only. It is attached by one extremity to the neck of the malleus, just above the processus gracilis, and by the other to the anterior wall of the tympanum, close to the Glaserian fissure, some of its fibres being prolonged through the fissure to reach the spine of the sphenoid.

The *superior ligament of the malleus* (lig. mallei superius) is a delicate, round bundle of fibres which descends perpendicularly from the roof of the epitympanic recess to the head of the malleus.

The *external ligament of the malleus* (lig. mallei lateralis) is a triangular plane of fibres passing from the posterior part of the notch in the tympanic ring (*incisura Rivini*) to the head of the malleus.

The *posterior ligament of the incus* (lig. incudis posterius) is a short, thick, ligamentous band which connects the extremity of the short process of the incus to the fossa incudis in the epitympanic recess.

The vestibular surface and the circumference of the foot of the stapes are covered with hyaline cartilage; that encircling the base is attached to the margin of the fenestra ovalis by a fibrous ring, the *annular ligament of the stapes* (lig. annulare baseos stapedis).

A *superior ligament of the incus* (lig. incudis superius) has been described, but it is little more than a fold of mucous membrane.

The **muscles of the tympanum** are two:

Tensor tympani.	Stapedius.

The *Tensor tympani*, the larger, is contained in the bony canal above the osseous portion of the Eustachian tube, from which it is separated by the processus cochleariformis. It arises from the cartilaginous portion of the Eustachian tube and the adjoining part of the greater wing of the sphenoid, as well as from the osseous canal in which it is contained. Passing backwards through the canal, it terminates in a slender tendon which enters the tympanum, makes a sharp bend outward round the extremity of the processus cochleariformis, and is inserted into the handle of the malleus, near its root. It is supplied by a branch from the otic ganglion.

The *Stapedius* arises from the side of a conical cavity, hollowed out of the interior of the pyramid; its tendon emerges from the orifice at the apex of the pyramid, and, passing forwards, is inserted into the posterior surface of the neck of the stapes. Its surface is aponeurotic, its interior fleshy; and its tendon occasionally contains a slender bony spine, which is constant in some mammalia. It is supplied by a branch of the facial nerve.

Actions.—The Tensor tympani draws the membrana tympani inwards, and thus increases its tension. The Stapedius draws the head of the stapes backwards, and thus causes the base of the bone to rotate on a vertical axis drawn through its own centre; the back part of the base is pressed inwards towards the vestibule, while the fore part is drawn from it. It probably compresses the contents of the vestibule.

The **mucous membrane of the tympanic cavity** is continuous with that of the pharynx, through the Eustachian tube. It invests the ossicles, and the muscles and nerves contained in the tympanic cavity; forms the internal layer of the membrana tympani, and the outer layer of the membrana tympani secundaria, and is reflected into the mastoid antrum and cells, which it lines throughout. It forms several vascular folds, which extend from the walls of the tympanum to the ossicles; of these one descends from the roof of the tympanum to the head of the malleus and upper margin of the body of the incus, a second invests the Stapedius muscle: other folds invest the chorda

tympani nerve and the Tensor tympani muscle. These folds separate off pouch-like cavities, and give the interior of the tympanum a somewhat honeycomb appearance. One of these pouches is well marked, viz. the *pouch of Prussak*, which lies between the neck of the malleus and the membrana flaccida. Two other folds may be mentioned : they are formed by the mucous membrane which envelops the chorda tympani nerve and are situated, one in front of, and the other behind the handle of the malleus ; they are named the *anterior* and *posterior recesses of Tröltsch*. In the tympanum this membrane is pale, thin, slightly vascular and covered for the most part with columnar ciliated epithelium, but over the pyramid, ossicula, and membrana tympani it possesses a flattened non-ciliated epithelium. In the antrum and mastoid cells its epithelium is also non-ciliated. In the osseous portion of the Eustachian tube the membrane is thin ; but in the cartilaginous portion it is very thick, highly vascular, and provided with numerous mucous glands ; the epithelium which lines the tube is columnar and ciliated.

Vessels and Nerves.—The *arteries* are six in number. Two of them are larger than the rest, viz. the tympanic branch of the internal maxillary, which supplies the membrana tympani ; and the stylo-mastoid branch of the posterior auricular, which supplies the back part of the tympanum and mastoid cells. The smaller arteries are—the petrosal branch of the middle meningeal, which enters through the hiatus Fallopii ; a branch from the ascending pharyngeal and another from the Vidian, which accompany the Eustachian tube ; and the tympanic branch from the internal carotid, given off in the carotid canal and perforating the thin anterior wall of the tympanum. The *veins* terminate in the pterygoid plexus, the superior petrosal sinus, and the middle meningeal vein. The *nerves* constitute the tympanic plexus, which ramifies upon the surface of the promontory. The plexus is formed by (1) the tympanic branch of the glosso-pharyngeal ; (2) the small deep petrosal nerve ; (3) the small superficial petrosal nerve ; and (4) a branch which joins the great superficial petrosal.

The *tympanic branch of the glosso-pharyngeal* (Jacobson's nerve) enters the tympanic cavity by an aperture in its floor close to the inner wall, and divides into branches which ramify on the promontory and enter into the formation of the plexus. The *small deep petrosal nerve* from the carotid plexus of the sympathetic passes through the wall of the carotid canal, and joins the branches of Jacobson's nerve. The branch to the great superficial petrosal passes through an opening on the inner wall, in front of the fenestra ovalis. The *small superficial petrosal nerve*, from the otic ganglion, passes backwards through a foramen in the middle fossa of the base of the skull (sometimes the foramen ovale), and enters the anterior surface of the petrous bone through a small aperture, situated external to the hiatus Fallopii ; it courses downwards through the bone, past the geniculate ganglion of the facial nerve, receiving a connecting filament from it, and enters the tympanic cavity, where it communicates with Jacobson's nerve, and assists in forming the tympanic plexus.

The *branches of distribution* of the tympanic plexus are supplied to the mucous membrane of the tympanic cavity ; a branch passes to the fenestra ovalis, another to the fenestra rotunda, and a third to the Eustachian tube. The small superficial petrosal may be looked upon as the continuation of the nerve of Jacobson through the plexus to the otic ganglion.

In addition to the tympanic plexus there are the nerves supplying the muscles. The Tensor tympani is supplied by a branch from the third division of the fifth through the otic ganglion, and the Stapedius by the tympanic branch of the facial.

The *chorda tympani* nerve crosses the tympanic cavity. It is given off from the sensory part of the facial, about a quarter of an inch before the nerve emerges from the stylo-mastoid foramen. It runs from below upwards and forwards in a canal, and enters the tympanic cavity through the *iter chordæ posterius*, already described (page 1040), and becomes invested with mucous membrane. It traverses the tympanic cavity, crossing internal to the membrana tympani and over the upper part of the handle of the malleus to the anterior wall, where it emerges through the *iter chordæ anterius*, or *canal of Huguier*.

Applied Anatomy.—The tympanic cavity is very frequently the seat of disease both suppurative and non-suppurative, and in practically every case the inflammation spreads upwards from the nose or throat along the Eustachian tube. The anatomy of the tympanic cavity is of the very greatest practical importance as regards its relations to other parts. Its roof is formed by a thin plate of bone which, with the dura mater, is all that separates it from the temporal lobe of the brain ; its floor is situated immediately above the jugular fossa behind, and the carotid canal in front ; its posterior wall presents the opening of the mastoid antrum, and on its anterior wall is the opening of the Eustachian tube. Acute inflammatory troubles spreading up to the tympanum by the latter tube are usually associated with so much inflammatory swelling of the mucous membrane of the Eustachian tube as to occlude it, and thus the products of inflammation are pent up in the tympanic cavity and directly involve the mastoid antrum. Under such circumstances

the only means of escape for the products is by rupture of the tympanic membrane, which usually occurs spontaneously and is followed by a free discharge of pus and relief to the acute pain which exists in these cases. Should the swelling of the walls of the Eustachian tube then subside, the normal drainage of the cavity will be established and the perforation in the drum will heal, but if not—as is often the case because the opening of the tube may be occluded by adenoid growths in the naso-pharynx or other cause—the pus will continue to accumulate in the middle ear and will overflow through the perforation as a chronic otorrhœa. In the course of time the disease spreads beyond the mucous membrane to the walls of the tympanic cavity, to the ossicles, or to the bone of the mastoid process, and when this has occurred the condition is incurable except by the removal of the carious bone. Further severe intracranial complications are at this time often produced owing to purulent material being retained; thus an abscess may form between the bone and dura mater, (*a*) about the roof of the tympanum, and immediately beneath the dura covering the temporal lobe, or (*b*) between the deep aspect of the mastoid process and the sigmoid bend of the lateral sinus, possibly extending widely and surrounding the sinus. In this latter type of case, thrombosis of the lateral sinus readily occurs, and the clot being also infected tends to disintegrate and be carried into the general circulation, particles often becoming lodged in the capillaries of the lungs and setting up abscesses therein. Pyæmia from lateral sinus thrombosis is probably more common than from any other focus of origin. In addition, bone disease of the tympanum or mastoid antrum may be associated with severe and fatal septic meningitis, or with the formation of abscess in the encephalon, the most common sites being the temporal lobe and the hemisphere of the cerebellum.

Less serious, but more common, is the formation of a subperiosteal mastoid abscess with great swelling behind the ear, and protrusion outwards of the auricle; such a condition demands an early incision down through all the structures, including the periosteum, over the whole length of the mastoid process, and then it will frequently be found that the underlying bone is carious or that a track leads through the bone into the mastoid antrum. In such conditions extensive operations for the removal of bone are often required. In many cases of chronic bone disease in the tympanic cavity the facial nerve becomes exposed as it lies in the aqueduct of Fallopius, and an inflammatory process is set up in the nerve, leading to facial paralysis of the infranuclear type (see page 927). In other cases localised areas of bone disease, most often in the region of the attic, form the points from which aural polypi grow, and the ear polypus, like the nasal polypus, must be considered to have originated in a spot of carious bone, the removal of which is necessary if a cure is to be established. Fractures of the middle fossa of the base of the skull almost invariably involve the tympanic roof, and are accompanied by a rupture of the drum or fracture through the roof of the bony meatus. They are associated with profuse continued bleeding from the ear, and, if the dura has also been lacerated, with discharge of copious amounts of cerebro-spinal fluid. Here the avoidance of infection from the outside is of the utmost importance, as should it occur septic meningitis must inevitably follow with a fatal issue.

Of the non-suppurative conditions which affect the middle ear, chronic catarrh, leading to sclerosis of the whole of the tympanic contents, is again due to spread of inflammation from some nasal or pharyngeal condition. The progress is very slow, but leads to ever-increasing deafness—this deafness in the first instance is in no way connected with any defect in the auditory nerve, and this can be shown by the fact that the hearing by bone conduction over the mastoid process remains normal. In chronic non-suppurative otitis, media treatment must be especially directed towards placing the nose and pharynx in a healthy condition; when this has been accomplished, the aural condition often improves of itself; if not, however, improvement may be induced by forcing air up the Eustachian tube by means of the Politzer bag, or directly into the orifice of the tube by means of the Eustachian catheter.

Internal Ear, or Labyrinth

The **internal ear** (auris interna) is the essential part of the organ of hearing, receiving the ultimate distribution of the auditory nerve. It is called the **labyrinth**, from the complexity of its shape, and consists of two parts: the *osseous labyrinth*, a series of cavities channelled out of the substance of the petrous bone, and the *membranous labyrinth*, the latter being contained within the former.

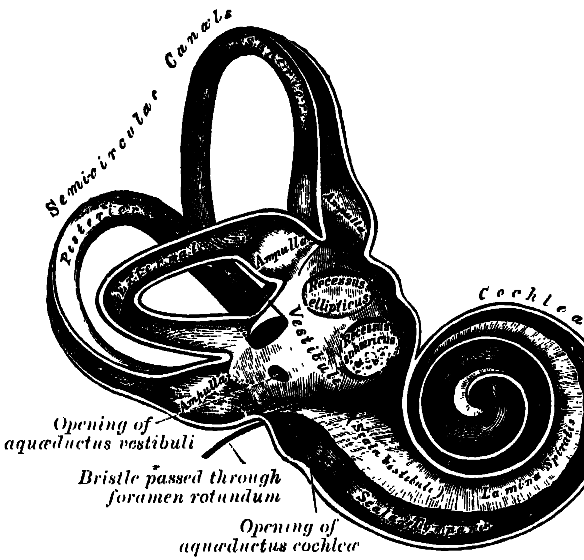
The Osseous Labyrinth (fig. 863)

The **osseous labyrinth** (labyrinthus osseus) consists of three parts: the *vestibule*, *semicircular canals*, and *cochlea*. These are cavities hollowed out of the substance of the bone, and lined by periosteum; they contain a clear fluid, the perilymph, in which the membranous labyrinth is situated.

The **vestibule** (vestibulum) is the central part of the internal ear, and is situated on the inner side of the tympanum, behind the cochlea, and in

front of the semicircular canals. It is somewhat ovoid in shape, flattened from within outwards, and measures about one-fifth of an inch from before backwards, the same from above downwards, and about one-eighth of an inch from without inwards. On its *outer* or *tympanic wall* is the fenestra ovalis, closed, in the recent state, by the base of the stapes and annular ligament. On its *inner wall*, at the fore part, is a small circular depression, the *recessus sphæricus*, which is perforated, at its anterior and inferior part, by several minute holes (*macula cribrosa media*) for the passage of filaments of the auditory nerve to the saccule; and behind this depression is an oblique ridge, the *crista vestibuli*, the anterior end of which is named the *pyramid* (pyramis vestibuli). This ridge bifurcates below to enclose a small depression, the *fossa cochlearis*, which is perforated by a number of holes for the passage of filaments of the auditory nerve which supply the posterior end of the ductus cochlearis. At the hinder part of the inner wall is the orifice of the *aquæductus vestibuli*, which extends to the posterior surface of the petrous portion of the temporal bone. It transmits a small vein, and contains a tubular prolongation of the membranous labyrinth, the *ductus endolymphaticus*, which ends in a *cul-de-sac* between the layers of the dura mater within the cranial cavity. On

Fig. 863.—The osseous labyrinth laid open. (Enlarged.)



the *upper wall* or *roof* is a transversely oval depression, the *recessus ellipticus*, separated from the recessus sphæricus by the crista vestibuli already mentioned. The pyramid and adjoining part of the recessus ellipticus are perforated by a number of holes (*macula cribrosa superior*). The apertures in the pyramid transmit the nerves to the utricle; those in the recessus ellipticus the nerves to the ampullæ of the superior and external semicircular canals. *Behind*, the semicircular canals open into the vestibule by five orifices. In *front* is an elliptical opening, which communicates with the scala vestibuli of the cochlea.

The **bony semicircular canals** (canales semicirculares ossei) are situated above and behind the vestibule. They are of unequal length, compressed from side to side, and each describes the greater part of a circle. Each measures about ·8 mm. in diameter, and presents a dilatation at one end, called the *ampulla*, which measures more than twice the diameter of the tube. They open into the vestibule by five orifices, one of the apertures being common to two of the canals.

The *superior semicircular canal* (canalis semicircularis superior), 15 to 20 mm. in length, is vertical in direction, and is placed transversely to the long axis of the petrous portion of the temporal bone, on the anterior surface of which

its arch forms a round projection. It describes about two-thirds of a circle. Its outer extremity is ampullated, and opens into the upper part of the vestibule; the opposite end joins with the upper part of the posterior canal to form the *crus commune*, which opens into the upper and inner part of the vestibule.

The *posterior semicircular canal* (canalis semicircularis posterior), also vertical, is directed backwards, nearly parallel to the posterior surface of the petrous bone; it is the longest of the three, measuring from 18 to 22 mm.; its lower or ampullated end opens into the lower and back part of the vestibule, its opposite opens into the crus commune already mentioned.

The *external* or *horizontal canal* (canalis semicircularis lateralis) is the shortest of the three. It measures from 12 to 15 mm., and its arch is directed horizontally outwards and backwards; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and outer angle of the vestibule, just above the fenestra ovalis, where it opens close to the ampullary end of the superior canal; its opposite end opens by a distinct orifice at the upper and back part of the vestibule. 'The external canal of one ear is very nearly in the same plane as that of the other; while the superior canal of one ear is nearly parallel to the posterior canal of the other.' *

Perilymphatic space.

The **cochlea** (figs. 865, 866) bears some resemblance to a common snail-shell; it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its apex (cupula) is directed forwards and outwards, with a slight inclination downwards, towards the upper and front part of the inner wall of the tympanum; its base (basis cochleæ) corresponds with the bottom of the internal auditory meatus, and is perforated by numerous apertures for the passage of the cochlear division of the auditory nerve. It measures about 5 mm. from base to apex, and its breadth across the base is somewhat greater (about 9 mm.). It consists of a conical-shaped central axis, the *modiolus*; of a canal, the inner wall of which is formed by the central axis, wound spirally around it for two turns and three-quarters, from the base to the apex; and of a delicate lamina (the *lamina spiralis ossea*) which projects from the modiolus, and, following the windings of the canal, partially subdivides it into two. In the recent state a membrane, the *membrana basilaris*, stretches from the free border of this lamina to the outer wall of the bony cochlea and completely separates the canal into two passages, which, however, communicate with each other at the apex of the modiolus by a small opening, named the *helicotrema*.

The *modiolus* is the central axis or pillar of the cochlea. It is conical in form, and extends from the base to the apex of the cochlea. Its base (basis

* Crum Brown, *Journal of Anatomy and Physiology*, vol. viii.

modioli) is broad, and appears at the bottom of the internal auditory meatus, where it corresponds with the area cochleæ ; it is perforated by numerous orifices, which transmit filaments of the cochlear division of the auditory nerve ; the nerves for the first turn and a half pass through the foramina of the tractus spiralis foraminosus ; those for the apical, turn through the foramen

Fig. 865.—The cochlea and vestibule, viewed from above. (Testut.)

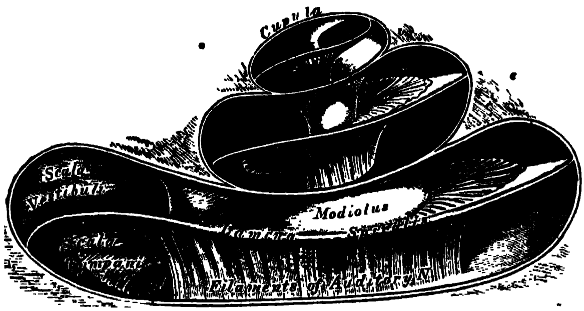
centrale. The canals of the tractus spiralis foraminosus pass up through the modiolus and successively bend outwards to reach the attached margin of the lamina spiralis ossea. Here they become enlarged, and by their apposition form a spiral canal (*canalis spiralis modioli*), which follows the course of the attached margin of the lamina spiralis ossea and lodges the ganglion

Fig. 866.—The cochlea laid open. (Enlarged.)



spirale (*ganglion of Corti*). The foramen centrale is continued into a canal which runs up the middle of the modiolus to its apex. The modiolus diminishes rapidly in size in the second and succeeding coil.

The bony canal of the cochlea takes two turns and three-quarters round the modiolus. It is a little over an inch in length (about 30 mm.) and

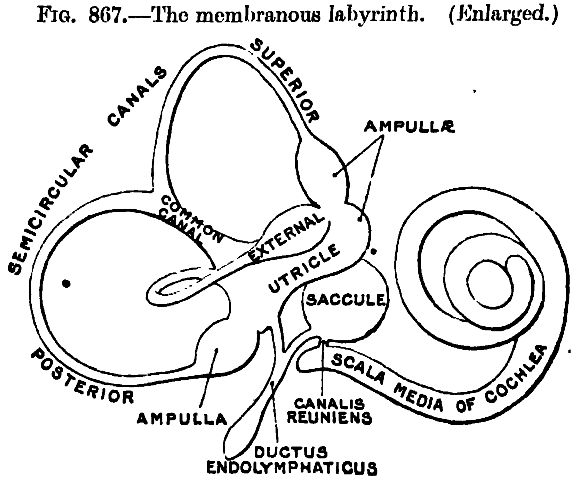
diminishes gradually in size from the base to the summit, where it terminates in the *cupula*, which forms the apex of the cochlea. The commencement of this canal is about the tenth of an inch in diameter; it diverges from the modiolus towards the tympanum and vestibule, and presents three openings. One, the *fenestra rotunda*, communicates with the tympanum—in the recent state this aperture is closed by a membrane, the *membrana tympani secundaria*; another, of an elliptical form, opens into the vestibule. The third is the aperture of the aqueductus cochleæ, leading to a minute funnel-shaped canal, which opens on the basilar surface of the petrous bone and transmits a small vein, and also forms a communication between the subarachnoid space of the skull and the scala tympani.

The *lamina spiralis ossea* is a bony shelf or ledge which projects outwards from the modiolus into the interior of the spiral canal, and, like the canal, takes two and three-quarter turns round the modiolus. It reaches about half-way towards the outer wall of the spiral tube, and partially divides its cavity into two passages or scalæ, of which the upper is named the *scala vestibuli*, while the lower is termed the *scala tympani*. Near the summit of the cochlea the lamina terminates in a hook-shaped process, the *hamulus laminæ spiralis*, which assists in forming the boundary of a small opening, the *helicotrema*, by which the two scalæ communicate with each other. From the canalis spiralis modioli numerous canals pass outwards through the osseous spiral lamina as far as its free edge. In the lower part of the first turn a second bony lamina, the *lamina spiralis secundaria*, projects inwards from the outer wall of the bony tube; it does not, however, reach the primary osseous spiral lamina, so that if viewed from the vestibule a narrow fissure, the *fissura vestibuli*, is seen between them.

The Membranous Labyrinth (figs. 867, 868, 869)

The **membranous labyrinth** (labyrinthus membranaceus) is lodged within the bony cavities just described, and has the same general form as the cavities in which it is contained; it is, however, considerably smaller, and is separated from the bony walls by a quantity of fluid, the *perilymph*. It does not float loosely in this fluid, but in certain places is fixed to the walls of the cavity. The membranous labyrinth contains fluid, the *endolymph*, and on its walls the ramifications of the auditory nerve are distributed.

Fig. 867.—The membranous labyrinth. (Enlarged.)



Within the osseous vestibule the membranous labyrinth does not quite preserve the form of the bony cavity, but presents two membranous sacs, the *utricle* and the *saccule*.

The **utricle** (utriculus), the larger of the two, is of an oblong form, compressed laterally, and occupies the upper and back part of the vestibule, lying in contact with the recessus ellipticus and the part below it. That portion which is lodged in the recess forms a sort of pouch or *cul-de-sac*, the floor

and anterior wall of which are much thicker than elsewhere, and form the *macula acustica utriculi*, which receives the utricular filaments of the auditory

nerve and has attached to its internal surface a layer of calcareous particles (otoliths). The cavity of the utricle communicates behind with the membranous semicircular canals by five orifices. From its anterior wall is given off a small canal, the *ductus utriculosaccularis*, which opens into the ductus endolymphaticus.

The **saccule** (sacculus) is the smaller of the two vestibular sacs; it is globular in form, and lies in the recessus sphæricus near the opening of the scala vestibuli of the cochlea. Its anterior part exhibits an oval thickening, the *macula acustica sacculi*, to which are distributed the saccular filaments of the auditory nerve. Its cavity does not directly communicate with that of the utricle. From the posterior wall is given off a canal, the *ductus endolymphaticus*; this duct is joined by the ductus utriculo-saccularis, and then passes along the aquæductus vestibuli and ends in a blind pouch (saccus endolymphaticus) on the posterior surface of the petrous portion of the temporal bone, where it is in contact with the dura mater. From the lower part of the saccule a short tube, the *canalis reuniens* of Hensen, passes downwards and outwards to open into the ductus cochlearis near its vestibular extremity (fig. 867).

The **membranous semicircular canals** (ductus semicirculares) (fig. 864) are about one-fourth of the diameter of the osseous canals, but in number, shape, and general form they are precisely similar, and each presents at one end an ampulla (ampulla membranacea). They open by five orifices into the utricle, one opening being common to the inner end of the superior and the upper end of the posterior canal. In the ampullæ the wall is thickened, and projects into the cavity as a fiddle-shaped, transversely placed elevation, the *septum transversum*, in which the nerves end.

The utricle, saccule, and membranous canals are held in position by numerous fibrous bands which stretch across the space between them and the bony walls.

Structure.—The walls of the utricle, saccule, and semicircular canals consist of three layers. The *outer layer* is a loose and flocculent structure, apparently composed of ordinary fibrous tissue, containing blood-vessels and some pigment-cells. The *middle layer*, thicker and more transparent, forms a homogeneous membrana propria, and presents on its internal surface, especially in the semicircular canals, numerous papilliform projections, which, on the addition of acetic acid, exhibit an appearance of longitudinal fibrillation and elongated nuclei. The *inner layer* is formed of polygonal nucleated epithelial cells. In the maculæ of the utricle and saccule, and in the transverse septa of the ampullæ of the canals, the middle coat is thickened and the epithelium is columnar, and consists of *supporting cells* and *hair-cells*. The former are fusiform, and their deep ends are attached to the membrana propria, while their free extremities are united to form a thin cuticle. The hair-cells are flask-shaped, and their deep, rounded ends do not reach the membrana propria, but lie between the supporting cells. The deep part of each contains a large nucleus, while its more superficial part is granular and pigmented. The free end is surmounted by a long, tapering, hair-like filament, which projects into the cavity. The filaments of the auditory nerve enter these parts, and having pierced the outer and the thickened middle layers, they lose their medullary sheaths, and their axis cylinders ramify between the hair-cells.

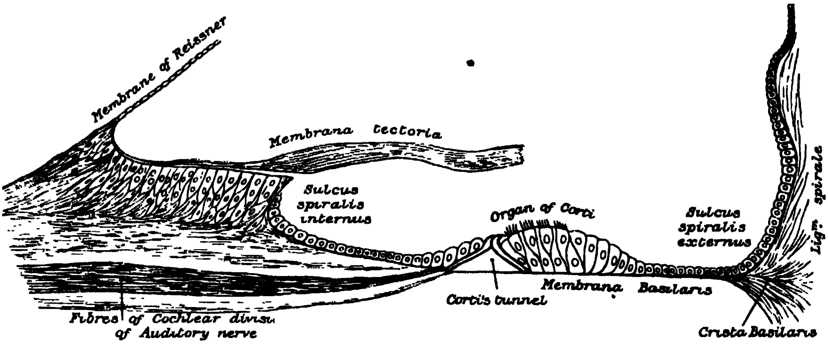
Two small rounded bodies termed *otoconia* (otoliths), and consisting of a mass of minute crystalline grains of carbonate of lime, held together in a mesh of delicate fibrous tissue, are contained in the walls of the utricle and saccule opposite the distribution of the nerves. According to Bowman, a calcareous material is also sparingly scattered in the cells lining the ampullæ of the semicircular canals.

The **membranous cochlea, ductus cochlearis,** or **scala media** consists of a spirally arranged tube enclosed in the bony canal of the cochlea and lying along its outer wall.

As already stated, the osseous spiral lamina extends only part of the distance between the modiolus and the outer bony wall of the cochlea, while a membrane, the *membrana basilaris*, stretches from its free edge to the outer wall of the cochlea, and completes the roof of the scala tympani (fig. 870). A second and more delicate membrane, the *membrane of Reissner* (membrana vestibularis) extends from the thickened periosteum covering the lamina

spiralis ossea to the outer wall of the cochlea, to which it is attached at some little distance from the outer edge of the membrana basilaris. A canal is thus shut off between the scala tympani below and the scala vestibuli above; this is the *membranous canal of the cochlea, ductus cochlearis*, or *scala media.* It is triangular on transverse section, its roof being formed by the membrane of Reissner, its outer wall by the periosteum which lines the bony canal, and

FIG. 870.—Floor of scala media, showing the organ of Corti, &c.



its floor by the membrana basilaris and the outer part of the lamina spiralis ossea. On the membrana basilaris is placed the organ of Corti. Reissner's membrane is thin and homogeneous, and is covered on its upper and under surfaces by a layer of epithelium. The periosteum, supporting the outer wall of the ductus cochlearis, is greatly thickened and altered in character, forming what is called the *ligamentum spirale*. It projects inwards below as a triangular

prominence, the *crista basilaris*, which gives attachment to the outer edge of the membrana basilaris, and immediately above which is a concavity, the *sulcus spiralis externus*. The upper portion of the ligamentum spirale contains numerous capillary loops and small blood-vessels, and forms what is termed the *stria vascularis*.

The lamina spiralis ossea (fig. 872) consists of two plates of bone extending outwards; between these are the canals for the transmission of the filaments of the auditory nerve. On the upper plate of that part of the osseous spiral lamina which is outside Reissner's membrane the periosteum is thickened to form the *limbus laminæ spiralis*, and this terminates externally in a concavity, the *sulcus spiralis internus*, which presents, on section, the form of the letter C; the upper part of the letter, formed by the overhanging extremity of the limbus, is named the *labium vestibulare*; the lower part, prolonged and tapering, is called the *labium tympanicum*, and is perforated by numerous foramina (*foramina nervosa*) for the passage of the cochlear nerves. Externally, the labium tympanicum is continuous with the membrana basilaris. The upper surface of the labium vestibulare is intersected at right angles by a number of furrows, between which are numerous elevations; these present the appearance of teeth along the free surface and margin of the labium, and have been named by Huschke the *auditory teeth*. The limbus is covered by a layer of what appears to be squamous epithelium, but the deeper parts of the cells with their contained nuclei occupy the intervals between the

elevations and between the auditory teeth. This layer is continuous on the one hand with that which lines the sulcus spiralis internus, and on the other with that which covers the under aspect of Reissner's membrane. The basilar membrane may be divided into two areas, inner and outer. The inner is thin, and is named the *zona arcuata*: it supports the organ of Corti. The outer is thicker and striated, and is termed the *zona pectinata*. The under surface of the membrane is covered by a layer of vascular connective tissue. One of the vessels in this tissue is somewhat larger than the rest, and is named the *vas spirale*; it lies below Corti's tunnel.

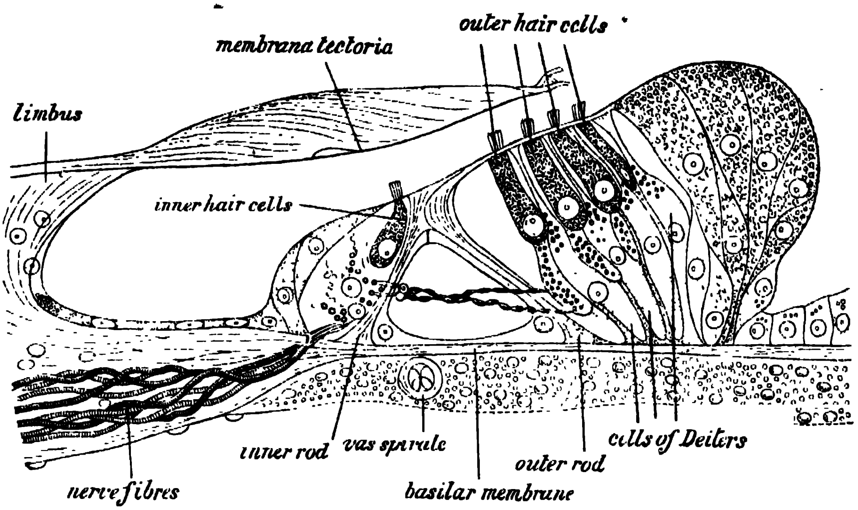
Organ of Corti (organon spirale).—This organ (figs. 871, 873) is situated upon the inner part of the membrana basilaris, and appears at first sight as a papilla, winding spirally throughout the whole length of the ductus cochlearis, from which circumstance it has been designated the *papilla spiralis*. More accurately viewed, it is seen to be composed of a remarkable arrangement of cells, which may be likened to the keyboard of a pianoforte. Of these cells, the central ones are rodlike bodies, and are called the inner and outer *rods of Corti*. Their bases are expanded and placed on the basilar membrane, at some little distance from each other, while their intermediate portions are

inclined towards each other, so that the rods meet at their opposite extremities, and form a series of arches roofing over a minute tunnel, the *tunnel of Corti*, between them and the basilar membrane; this tunnel ascends spirally through the whole length of the cochlea.

The *inner rods*, some 6,000 in number, rest by means of expanded foot-plates on the basilar membrane, close to the labium tympanicum; they project obliquely upwards and outwards, and terminate above in expanded extremities, each of which resembles in shape the upper end of the ulna, with its sigmoid cavity, coronoid and olecranon processes. On the outer side of the rod, in the angle formed between it and the basilar membrane, is a nucleated mass of protoplasm; while on the inner side is a row of epithelial cells (*inner hair-cells*), each surmounted by a brush of fine, stiff, hair-like processes. On the inner side of these cells are two or three rows of columnar supporting cells, which are continuous with the cubical cells lining the sulcus spiralis internus.

The *outer rods*, numbering about 4,000, also rest by broad foot-plates on the basilar membrane; they incline upwards and inwards, and the upper extremity of each resembles the head and bill of a swan; the back of the head

FIG. 873.—Section through the organ of Corti. Magnified. (G. Retzius.)



fitting into the concavity—the analogue of the sigmoid cavity—of one or more of the internal rods, and the bill projecting outwards as a phalangeal process of the membrana reticularis, presently to be described.

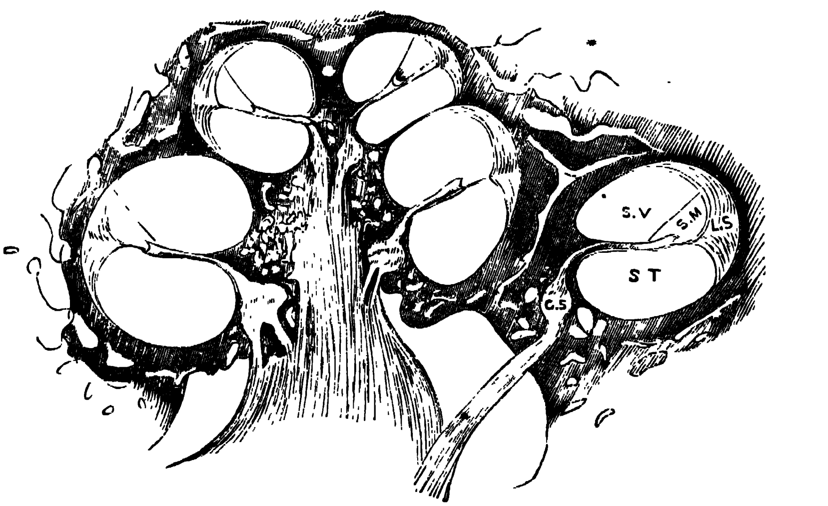
In the head of the outer rod is an oval portion where the fibres of which the rod appears to be composed are deficient; it stains more deeply with carmine than the rest of the rod. At the base of the rod, on its internal side—that is to say, in the angle formed by the rod with the basilar membrane—is a similar protoplasmic mass to that found on the outer side of the base of the inner rod; these masses of protoplasm are probably the undifferentiated portions of the cells from which the rods are developed. External to the outer rod are three or four successive rows of epithelial cells, more elongated than those found on the internal side of the inner rod, but, like them, furnished with minute hairs or cilia. These are termed the *outer hair-cells*, in contradistinction to the *inner hair-cells* above referred to. The outer hair-cells number about 12,000, the inner about 3,500.

The *hair-cells* are somewhat oval in shape; their free extremities are on a level with the heads of Corti's rods, and from each some twenty fine hairlets project and are arranged in the form of a crescent, the concavity of which opens inwards. The deep ends of the cells are rounded and contain large nuclei: they reach only as far as the middle of Corti's rods, and are in contact with the ramifications of the nervous filaments. Between the rows of the outer hair-cells are rows of supporting cells, called the *cells of Deiters*; their expanded bases are planted on the basilar membrane, while the opposite end of each

presents a clubbed extremity or *phalangeal* process. Immediately to the outer side of Deiters' cells are some five or six rows of columnar cells, the *supporting cells of Hensen.* Their bases are narrow, while their upper parts are expanded and form a rounded elevation on the floor of the ductus cochlearis. The columnar cells lying outside Hensen's cells are termed the *cells of Claudius.* A space is seen between the outer rods of Corti and the adjacent hair-cells; this is called the *space of Nuel.*

The *lamina reticularis* or *membrane of Kölliker* is a delicate framework perforated by rounded holes. It extends from the heads of the outer rods of Corti to the external row of the outer hair-cells, and is formed by several rows of 'minute fiddle-shaped cuticular structures,' called *phalanges*, between which are circular apertures containing the free ends of the hair-cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters' cells.

FIG. 874.—Longitudinal section of the cochlea, showing the relations of the scalæ, the ganglion spirale, &c.



S.V. Scala vestibuli. S.T. Scala tympani. S.M. Scala media. L.S. Ligamentum spirale. G.S. Ganglion spirale.

Covering over these structures, but not touching them, is the *membrana tectoria*, or membrane of Corti, which is attached to the limbus laminæ spiralis close to the inner edge of the membrane of Reissner. It is thin near its inner margin, and overlies the auditory teeth of Huschke. Its outer half is thick, and along its lower edge, opposite the inner hair-cells, is a clear band, named *Hensen's stripe.* Externally, the membrane becomes much thinner, and is attached to the outer row of Deiters' cells (Retzius).

The *osseous labyrinth* is lined by an exceedingly thin fibro-serous membrane, analogous to a periosteum, from its close adhesion to the inner surfaces of these cavities, and performing the office of a serous membrane by its free surface. It lines the vestibule, and from this cavity is continued into the semicircular canals and the scala vestibuli of the cochlea, and through the helicotrema into the scala tympani. A delicate tubular process is prolonged along the aqueduct of the vestibule to the inner surface of the dura mater. This membrane is continued across the fenestra ovalis and rotunda, and consequently has no communication with the lining membrane of the tympanum. Its attached surface is rough and fibrous, and closely adherent to the bone; its free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the *perilymph.*

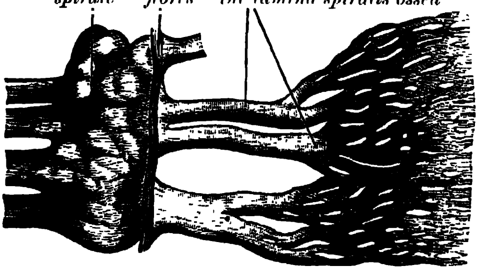
The ductus cochlearis or scala media is closed above and below. The upper blind extremity is termed the *lagena*, and is attached to the cupula at the upper part of the helicotrema; the lower end is lodged in the recessus cochlearis of the vestibule. Near this blind extremity, the scala media receives

the *canalis reuniens of Hensen* (fig. 867), a very delicate canal, by which the ductus cochlearis is brought into continuity with the saccule.

The **auditory nerve,** the special nerve of the sense of hearing, divides, at the bottom of the internal auditory meatus, into two branches, the cochlear and vestibular.

The *vestibular nerve,* the posterior of the two, presents, as it lies in the internal auditory meatus, a ganglion, the *ganglion of Scarpa,* the cells of which constitute the real origin of the nerve; it divides into three branches, which pass through minute openings at the upper and back part of the bottom of the meatus (*area vestibularis superior*), and, entering the vestibule, are distributed to the utricle and to the ampullæ of the external and superior semicircular canals. The nervous filaments enter the ampullary enlargements opposite the septum transversum, and arborise around the hair-cells. In the utricle and saccule the nerve-fibres pierce the membrana propria of the maculæ, and end in arborisations round the hair-cells.

Fig. 875.—Part of the cochlear division of the auditory nerve, highly magnified. (Henle.)



The *cochlear nerve* gives off the branch to the saccule, the filaments of which are transmitted from the internal auditory meatus through the foramina of the *area vestibularis inferior,* which lies at the lower and back part of the floor of the meatus. It also gives off the branch for the ampulla of the posterior semicircular canal, which leaves the meatus through the *foramen singulare.*

The rest of the cochlear nerve divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the tractus foraminosus, those for the apical coil through the canalis centralis, and the nerves bend outwards to pass between the lamellæ of the osseous spiral lamina. Occupying the spiral canal of the modiolus is the *ganglion spirale cochleæ* (fig. 875), consisting of bipolar nerve-cells, which really constitute the true cells of origin of this nerve, one pole being prolonged centrally to the brain and the other peripherally to the hair-cells of Corti's organ. Reaching the outer edge of the osseous spiral lamina, they pass through the foramina in the labium tympanicum; some end by arborising around the bases of the inner hair-cells, while others pass between Corti's rods and through the tunnel, to terminate in a similar manner in relation to the outer hair-cells.

Vessels.—The *arteries of the labyrinth* are the internal auditory, from the basilar, and the stylo-mastoid, from the posterior auricular. The internal auditory divides at the bottom of the internal meatus into two branches: cochlear and vestibular. The cochlear branch subdivides into twelve or fourteen twigs, which traverse the canals in the modiolus, and are distributed, in the form of a capillary network, in the lamina spiralis and basilar membrane. The vestibular branches accompany the nerves, and are distributed, in the form of a minute capillary network, in the substance of the membranous labyrinth.

The *veins* (auditory) of the vestibule and semicircular canals accompany the arteries, and, receiving those of the cochlea at the base of the modiolus, terminate in the posterior part of the superior petrosal sinus or in the lateral sinus.

Applied Anatomy.—The diseased conditions which may be found in the internal ear usually result from the spread of a suppurative process from the middle ear—thus in chronic suppuration of the latter, destruction of the internal ear may take place, with necrosis of parts of the cochlea or vestibule. Such cases will be associated with 'nerve deafness,' and the disease may spread by means of the sheaths of the facial and auditory nerves into the posterior fossa of the skull.

Hæmorrhage occasionally occurs into the labyrinth in certain blood disorders, resulting in complete 'nerve deafness,' and such conditions may be associated with symptoms known as 'Menière's disease,' vertigo, giddiness, and tinnitus. Nerve deafness is diagnosed when all 'bone-conduction' of sound is lost, and is most commonly seen in patients suffering from congenital syphilis, many deaf-mutes being the subjects of this condition.

SPLANCHNOLOGY

UNDER this heading are included the respiratory, digestive and uro-genital organs, and the ductless glands.

RESPIRATORY ORGANS

The respiratory organs (apparatus respiratorius) consist of the larynx or organ of voice, the trachea, bronchi, lungs and pleuræ.

THE LARYNX

The larynx, or organ of voice, is placed at the upper part of the air-passage. It is situated between the trachea and base of the tongue, at the upper and fore part of the neck, where it forms a considerable projection in the middle line. On either side of it lie the great vessels of the neck; it forms the lower part of the anterior wall of the pharynx, and is covered behind by the mucous lining of that cavity. Its vertical extent corresponds to the fourth, fifth, and sixth cervical vertebræ, but it is placed somewhat higher in the female and also during childhood. In infants between six and twelve months of age Symington found that the tip of the epiglottis was a little above the level of the cartilage between the odontoid process and body of the axis, and that between infancy and adult life the larynx descends for a distance equal to two vertebral bodies and two intervertebral discs. According to Sappey the average measurements of the adult larynx are as follows:

	In males	In females
Length	44 mm.	36 mm.
Transverse diameter . . .	43 ,,	41 ,,
Antero-posterior diameter . .	36 ,,	26 ,,
Circumference	136 ,,	112 ,,

Until puberty the larynx of the male and that of the female differ little in size. In the female its further increase at puberty is only slight, whereas in the male it is great; all the cartilages are enlarged and the thyroid becomes prominent in the middle line of the neck, while the length of the glottis is nearly doubled.

The larynx is broad above, where it presents the form of a triangular box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages, which are connected together by ligaments and moved by numerous muscles. It is lined by mucous membrane which is continuous above with that of the pharynx and below with that of the trachea.

The **cartilages of the larynx** (cartilagines laryngis) (fig. 876) are nine in number, three single, and three paired, as follows:

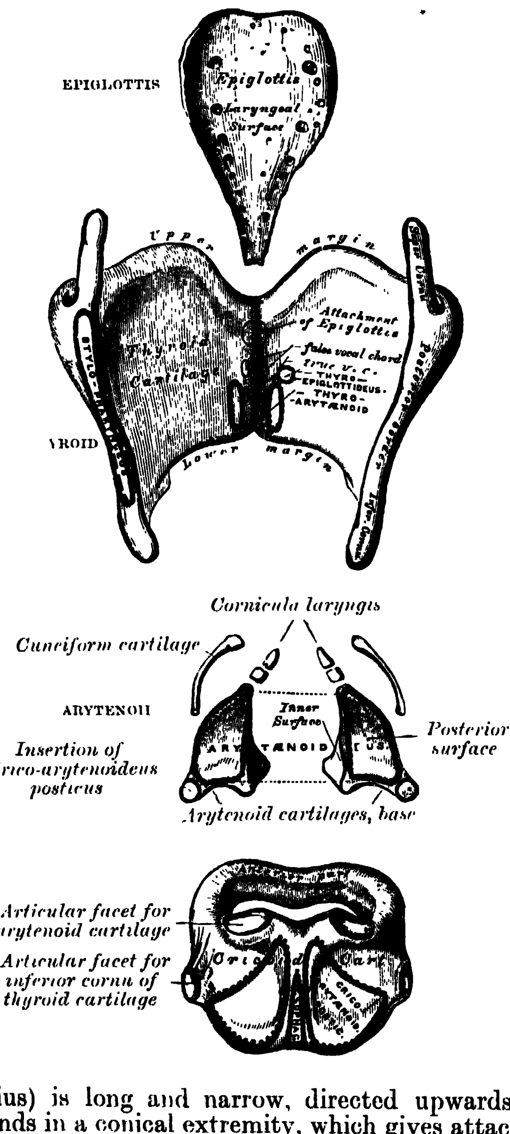
Thyroid.	Two Arytenoid.
Cricoid.	Two Cornicula laryngis.
Epiglottis.	Two Cuneiform.

The **thyroid cartilage** (cartilago thyreoidea) is the largest cartilage of the larynx. It consists of two alæ or laminæ the anterior borders of which are fused with each other at a right angle in the middle line of the neck, and

form a subcutaneous projection named the *pomum Adami* (prominentia laryngea). This prominence is most distinct at its upper part, and is larger in the male than in the female. Immediately above it the alæ are separated by a V-shaped notch, the *thyroid notch* (incisura thyreoidea superior). The alæ are irregularly quadrilateral in shape, their posterior angles being prolonged into processes termed the *superior* and *inferior cornua*.

The *outer surface* of each ala presents an *oblique ridge* (linea obliqua) which runs downwards and forwards from a tubercle situated near the root of the superior cornu, to another on the lower border. This ridge gives attachment to the Sterno-thyroid and Thyro-hyoid, and from the portion of cartilage included between it and the posterior border a part of the Inferior constrictor muscle takes origin.

Fig. 876.—The cartilages of the larynx. Posterior view.



The *inner surface* is smooth; above and behind, it is slightly concave and covered by mucous membrane. In front, in the receding angle formed by the junction of the alæ, are attached the epiglottis, the true and false vocal cords, the Thyro-arytenoideus and Thyro-epiglottideus muscles, and the thyro-epiglottic ligament.

The *upper border* is concave behind and convex in front; it gives attachment to the corresponding half of the thyro-hyoid membrane.

The *lower border* is concave behind, and nearly straight in front, the two parts being separated by the inferior tubercle. A small part of it in and near the median line is connected to the cricoid cartilage by the middle portion of the crico-thyroid membrane.

The *posterior border*, thick and rounded, receives the insertions of the Stylo-pharyngeus and Palato-pharyngeus muscles. It terminates above, in the superior cornu, and below, in the inferior cornu. The *superior cornu* (cornu superius) is long and narrow, directed upwards, backwards, and inwards, and ends in a conical extremity, which gives attachment to the lateral thyro-hyoid ligament. The *inferior cornu* (cornu inferius) is short and thick; it is directed downwards, with a slight inclination forwards and inwards, and presents, on its inner surface, a small oval articular facet for articulation with the side of the cricoid cartilage.

During infancy the alæ of the thyroid cartilage are joined to each other by a narrow, lozenge-shaped strip, named the *intrathyroid cartilage*. This strip extends from the upper to the lower border of the cartilage in the middle

line, and is distinguished from the alæ by being more transparent and more flexible.

The **cricoid cartilage** (cartilago cricoidea) is so called from its resemblance to a signet ring. It is smaller, but thicker and stronger than the thyroid cartilage, and forms the lower and back part of the wall of the larynx. It consists of two parts: a quadrate portion, situated behind. and a narrow ring or arch, one-fourth or one-fifth of the depth of the posterior part, situated in front. The posterior square portion rapidly narrows at the sides of the cartilage, at the expense of the upper border, into the anterior portion.

The *posterior portion* is very deep and broad, and measures from above downwards about an inch (2 to 3 cm.); it presents, on its posterior surface, in the middle line, a vertical ridge for the attachment of the longitudinal fibres of the œsophagus; and on either side of this a broad depression for the Crico-arytenoideus posticus muscle.

The *anterior portion* is narrow and convex, and measures vertically about one-fourth or one-fifth of an inch (7 to 5 mm.); it affords attachment externally in front and at the sides to the Crico-thyroid muscles, and behind, to part of the Inferior constrictor.

At the junction of the posterior quadrate portion with the rest of the cartilage is a small round articular eminence on either side, for articulation with the inferior cornu of the thyroid cartilage.

The *lower border* of the cricoid cartilage is horizontal, and connected to the upper ring of the trachea by a fibrous membrane.

The *upper border* is directed obliquely upwards and backwards, owing to the great depth of the posterior surface. It gives attachment, in front, to the middle portion of the crico-thyroid membrane; at the sides, to the lateral portions of the same membrane and to the Crico-arytenoideus lateralis muscles; behind, it presents, in the middle, a shallow notch, and on either side of this is a smooth, oval, convex surface, directed upwards and outwards, for articulation with the base of an arytenoid cartilage.

The *inner surface* of the cricoid cartilage is smooth, and lined by mucous membrane.

The **arytenoid cartilages** (cartilagines arytænoideæ) are two in number, and situated at the upper border of the cricoid cartilage, at the back of the larynx. Each cartilage is pyramidal in form, and presents for examination three surfaces, a base, and an apex.

The *posterior surface* is triangular, smooth, concave, and gives attachment to the Arytenoideus muscle.

The *antero-external surface* is somewhat convex and rough. It presents rather below its centre a transverse ridge, to the inner extremity of which is attached the false vocal cord; to the outer part, as well as to the surfaces above and below it, the Thyro-arytenoideus muscle is inserted.

The *internal surface* is narrow, smooth, and flattened, covered by mucous membrane, and forms the lateral boundary of the respiratory part of the glottis.

The *base* of each cartilage is broad, and presents a concave smooth surface, for articulation with the cricoid cartilage. Two of its angles require special mention: the *external*, which is short, rounded, and prominent, projects backwards and outwards, and is termed the *processus muscularis*; it gives insertion to the Crico-arytenoideus posticus behind, and to the Crico-arytenoideus lateralis in front. The *anterior angle*, also prominent, but more pointed, projects horizontally forwards, and gives attachment to the true vocal cord. This angle is called the *processus vocalis*.

The *apex* of each cartilage is pointed, curved backwards and inwards, and surmounted by a small conical, cartilaginous nodule, the *corniculum laryngis*.

The **cornicula laryngis** or **cartilages of Santorini** (cartilagines corniculatæ) are two small conical nodules, consisting of yellow elastic cartilage, which articulate with the summits of the arytenoid cartilages and serve to prolong them backwards and inwards. They are situated in the posterior parts of the aryteno-epiglottic folds of mucous membrane, and are sometimes united to the arytenoid cartilages.

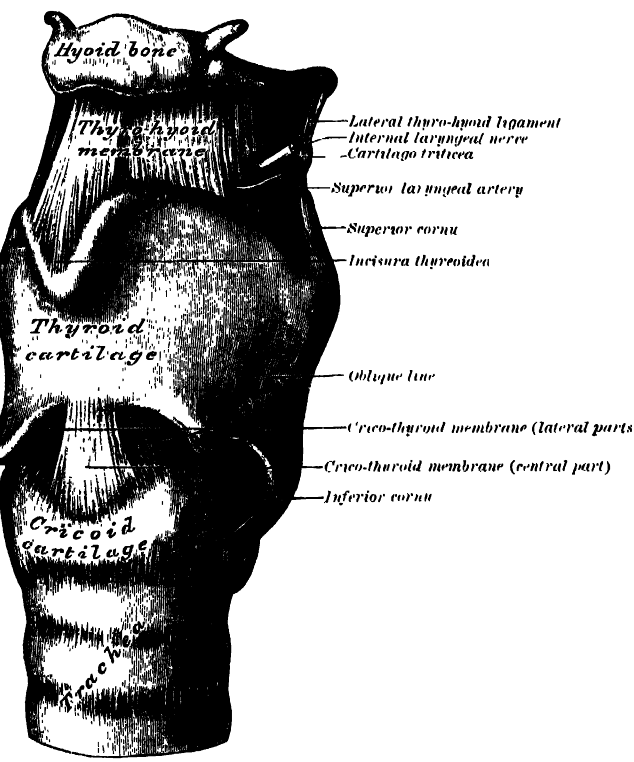
The **cuneiform cartilages** or **cartilages of Wrisberg** (cartilagines cuneiformes) are two small, elongated pieces of yellow elastic cartilage, placed one on either side, in the aryteno-epiglottic fold, where they give rise to small

whitish elevations on the inner surface of the mucous membrane, just in front of the arytenoid cartilages.

The **epiglottis** is a thin lamella of fibro-cartilage, of a yellowish colour, shaped like a leaf, and projecting behind the tongue, in front of the superior opening of the larynx. The projecting extremity is broad and rounded; the attached part or apex is long, narrow, and connected to the receding angle between the two alæ of the thyroid cartilage, just below the median notch, by a ligamentous band, the *thyro-epiglottic ligament* (lig. thyreoepiglotticum). The lower part of its anterior surface is connected to the upper border of the body of the hyoid bone by an elastic ligamentous band, the *hyo-epiglottic ligament.*

The *anterior* or *lingual surface* is curved forwards towards the tongue, and covered on its upper, free part by mucous membrane which is reflected on to the sides and base of the organ, forming a median and two lateral folds, the

FIG. 877.—The ligaments of the larynx. Antero-lateral view.



glosso-epiglottic folds; the lateral folds are partly attached to the wall of the pharynx. The depressions between the epiglottis and the base of the tongue, on either side of the median fold, are named the *valleculæ*. The lower part of the anterior surface lies behind the hyoid bone, the thyro-hyoid membrane, and upper part of the thyroid cartilage, but is separated from these structures by a mass of fatty tissue.

The *posterior* or *laryngeal surface* is smooth, concave from side to side, concavo-convex from above downwards; its lower part projects backwards as an elevation, the *tubercle* or *cushion* (tuberculum epiglotticum). When the mucous membrane is removed, the surface of the cartilage is seen to be indented by a number of small pits, in which mucous glands are lodged. To its sides the aryteno-epiglottic folds are attached.

Structure.—The cornicula laryngis and cuneiform cartilages, the epiglottis, and the apices of the arytenoids at first consist of hyaline cartilage, but later elastic fibres grow in from the perichondrium, and eventually they are converted into yellow fibro-cartilage,

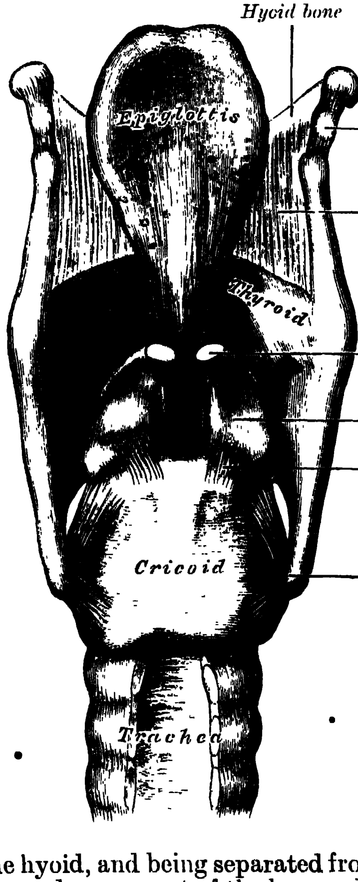
which shows little tendency to calcification. The thyroid, cricoid, and the greater part of the arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, and somewhat later in the cricoid and arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone.

Ligaments.—The ligaments of the larynx (figs. 877, 878) are *extrinsic*, i.e. those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and *intrinsic*, those which connect the several cartilages of the larynx to each other.

Extrinsic ligaments.—The ligaments connecting the thyroid cartilage with the hyoid bone are three in number—the thyro-hyoid membrane, and the two lateral thyro-hyoid ligaments.

The *thyro-hyoid membrane* (membrana hyothyreoidea) is a broad, fibro-elastic membranous layer, attached below to the upper border of the thyroid cartilage, and above to the upper margin of the posterior surface of the body and greater cornua of the hyoid bone, thus passing behind the posterior surface

FIG. 878.—Ligaments of the larynx. Posterior view.



of the body of the hyoid, and being separated from it by a synovial bursa, which facilitates the upward movement of the larynx during deglutition. It is thicker in the middle line than at either side, and is pierced, in the latter situation, by the superior laryngeal vessels and the internal laryngeal nerve. Its anterior surface is in relation with the Thyro-hyoid, Sterno-hyoid, and Omo-hyoid muscles, and with the body of the hyoid bone.

The *lateral thyro-hyoid ligament* (lig. hyothyreoideum laterale) is a round elastic cord, which passes between the superior cornu of the ala of the thyroid cartilage and the extremity of the greater cornu of the hyoid bone. A small cartilaginous nodule (*cartilago triticea*), sometimes bony, is frequently found in it.

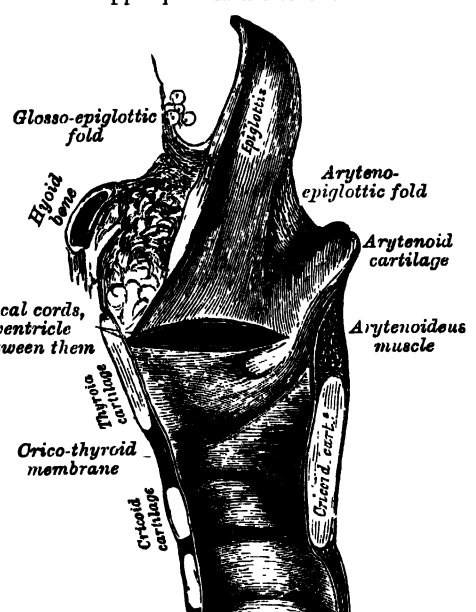
The ligament connecting the epiglottis with the hyoid bone is the *hyo-epiglottic*. In addition to this extrinsic ligament, the epiglottis is connected to the tongue by the three glosso-epiglottic folds of mucous membrane, which may also be considered as extrinsic ligaments of the epiglottis.

The *hyo-epiglottic ligament* (lig. hyoepiglotticum) is an elastic band, which extends from the anterior surface of the epiglottis to the upper border of the body of the hyoid bone.

Intrinsic ligaments.—The ligaments connecting the thyroid cartilage to the cricoid are three in number—the crico-thyroid membrane, and the capsular ligaments.

The *crico-thyroid membrane* is composed mainly of yellow elastic tissue. It consists of three parts, a central, triangular portion and two lateral portions. The *central* part (lig. cricothyreoideum medium) is thick and strong, narrow above and broad below. It connects together the contiguous margins of the thyroid and cricoid cartilages. It is convex, concealed on either side by the Crico-thyroideus, but subcutaneous in the middle line; it is crossed horizontally by a small anastomotic arterial arch, formed by the junction of the two crico-thyroid arteries. The *lateral* portions are thinner and lie close under the mucous membrane of the larynx; they extend from the superior border of the cricoid cartilage to the inferior margin of the true vocal cords, with which they are continuous. These cords may therefore be regarded as the free borders of the lateral portions of the crico-thyroid membrane; they extend from the vocal processes of the arytenoid cartilages to the receding angle of the thyroid cartilage near its centre. The lateral portions are lined internally by mucous membrane, and covered externally by the Crico-arytenoideus lateralis and Thyro-arytenoideus muscles.

FIG. 879.—Sagittal section of the larynx and upper part of the trachea.



A *capsular ligament*, strengthened posteriorly by a well-marked fibrous band, encloses the articulation of the inferior cornu of the thyroid with the cricoid cartilage on each side. The articulation is lined by synovial membrane.

Each arytenoid cartilage is connected to the cricoid by a *capsular* and a *posterior crico-arytenoid ligament*. The *capsular ligament* is thin and loose, and is attached to the margins of the articular surfaces, and lined by synovial membrane. The *posterior crico-arytenoid ligament* (lig. cricoarytænoideum posterius) extends from the cricoid to the inner and back part of the base of the arytenoid.

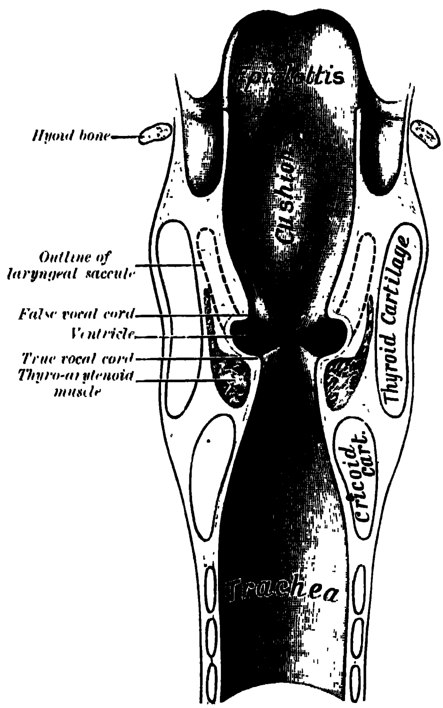
The *thyro-epiglottic ligament* (lig. thyreoepiglotticum) is a long, slender, elastic cord which connects the apex of the epiglottis with the receding angle of the thyroid cartilage, immediately beneath the median notch, above the attachment of the vocal cords.

The *crico-tracheal ligament* (lig. cricotracheale) connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane which connects the cartilaginous rings of the trachea to each other.

Movements.—The articulation between the inferior cornu of the thyroid cartilage and the cricoid cartilage on either side is a diarthrodial one, and

permits of rotatory and gliding movements. The rotatory movement is one in which the inferior cornua of the thyroid cartilage rotate upon the cricoid cartilage around an axis passing transversely through both joints. The gliding movement consists in a limited shifting of the cricoid on the thyroid in different directions.

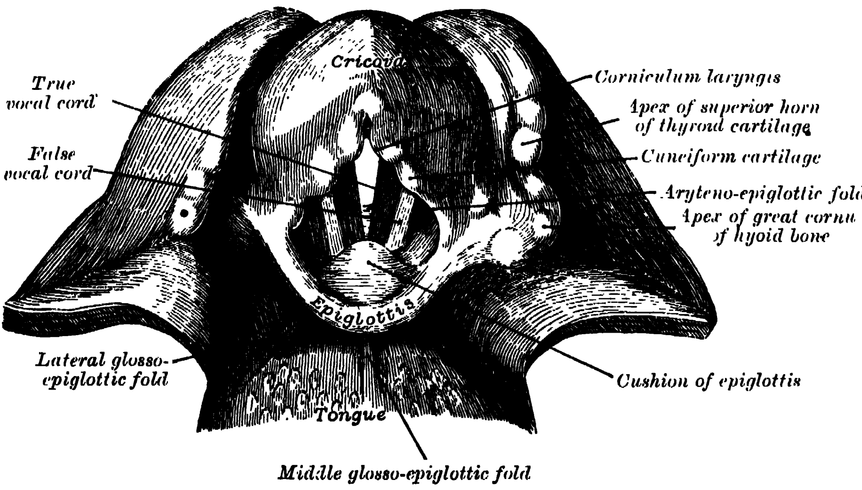
FIG. 880.—Coronal section of larynx and upper part of trachea.



The articulation between the arytenoid cartilages and the cricoid is also a diarthrodial one, and permits of two varieties of movement: one a rotation of the arytenoid on a vertical axis, whereby the vocal process is moved outwards or inwards, and the opening of the rima glottidis increased or diminished; the other is a gliding movement, and allows the arytenoid cartilages to approach or recede from each other; from the direction and slope of the articular surfaces outward gliding is accompanied by a forward and downward movement The two movements of gliding and rotation are associated, the gliding inwards being connected with inward rotation, and the gliding outwards with outward rotation. The posterior crico-arytenoid ligaments limit the forward movement of the arytenoid cartilages on the cricoid.

Interior of the larynx (figs. 879, 880).—The *cavity of the larynx* (cavum laryngis) extends from its superior aperture to the lower border of the cricoid cartilage. It is divided into two parts by the projection inwards of the true vocal cords, between which is a narrow triangular fissure or chink, the *rima glottidis*. The portion of the cavity of the larynx above the true

FIG. 881.—Larynx, viewed from above. (Testut.)



vocal cords, sometimes called the *vestibule* (vestibulum laryngis), is wide and triangular in shape, its base or anterior wall presenting, however, about its centre the backward projection of the cushion of the epiglottis. It contains

the false vocal cords, and between these and the true vocal cords are the ventricles of the larynx. The portion below the true vocal cords is at first of an elliptical form, but lower down it widens out, assumes a circular form, and is continuous with the tube of the trachea.

The *superior aperture of the larynx* (aditus laryngis) (fig. 881) is a triangular or cordiform opening, wide in front, narrow behind, and sloping obliquely downwards and backwards. It is bounded, in front, by the epiglottis; behind, by the apices of the arytenoid cartilages and the cornicula laryngis; and on either side, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the side of the epiglottis and the apex of the arytenoid cartilage; this is the *aryteno-epiglottic fold* (plica aryepiglottica), on the margin of which the cuneiform cartilage forms a more or less distinct whitish prominence.

The *superior* or *false vocal cords* (plicæ ventriculares), so called because they are not directly concerned in the production of the voice, are two thick folds of mucous membrane, each enclosing a narrow band of fibrous tissue, the *superior thyro-arytenoid ligament*. This is attached in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottis, and behind to the antero-external surface of the arytenoid cartilage, a short distance above the vocal process. The lower border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx.

The *inferior* or *true vocal cords* (plicæ vocales), so called from their being concerned in the production of sound, are two strong bands, named the *inferior thyro-arytenoid ligaments*. Each ligament consists of a band of yellow elastic tissue, attached in front to the depression between the two alæ of the thyroid cartilage, and behind to the vocal process of the base of the arytenoid. Its lower border is continuous with the thin lateral part of the crico-thyroid membrane. Its upper border forms the lower boundary of the ventricle of the larynx. Externally the Thyro-arytenoideus muscle lies parallel with it. It is covered internally by mucous membrane, which is extremely thin, and closely adherent to its surface.

The *ventricle of the larynx* or *laryngeal sinus* (ventriculus laryngis) is an oblong fossa, situated between the superior and inferior vocal cords on either side, and extending nearly their entire length. The fossa is bounded, above, by the free crescentic edge of the false vocal cord; below by the straight margin of the true vocal cord; externally, by the mucous membrane covering the corresponding Thyro-arytenoideus muscle. The anterior part of the ventricle leads up by a narrow opening into a cæcal pouch of mucous membrane of variable size, called the laryngeal saccule.

The *laryngeal saccule* (appendix ventriculi laryngis) is a membranous sac, placed between the superior vocal cord and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border or even higher; it is conical in form, and curved slightly backwards. On the surface of its mucous membrane are the openings of sixty or seventy mucous glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule, continuous below with the superior thyro-arytenoid ligament: its laryngeal surface is covered by a few delicate muscular fasciculi, which arise from the apex of the arytenoid cartilage and become lost in the fold of mucous membrane extending between the arytenoid cartilage and the side of the epiglottis (they were named by Hilton the *compressor sacculi laryngis*); while its exterior is covered by the Thyro-arytenoideus and Thyro-epiglottideus muscles. These muscles compress the laryngeal saccule, and express the secretion it contains upon the vocal cords to lubricate their surfaces.

The *rima glottidis* is the elongated fissure or chink between the inferior or true vocal cords in front, and the bases and vocal processes of the arytenoid cartilages behind. It is therefore frequently subdivided into a larger anterior inter-ligamentous or *vocal* portion, the *glottis vocalis* (pars intramembranacea), which measures about three-fifths of the length of the entire aperture, and a posterior intercartilaginous or *respiratory* part, the *glottis respiratoria* (pars intercartilaginea). Posteriorly it is limited by the mucous membrane passing between the arytenoid cartilages. The rima glottidis is the narrowest part of the cavity of the larynx, and its level corresponds with the bases of the

arytenoid cartilages. Its length, in the male, measures rather less than an inch (23 mm.); in the female it is shorter by 5 or 6 mm. The width and shape of the rima glottidis vary with the movements of the vocal cords and arytenoid cartilages during respiration and phonation. In the condition of rest, i.e. when these structures are uninfluenced by muscular action, as in quiet respiration, the glottis vocalis is triangular, with its apex in front and its base behind—the latter being represented by a line, about 8 mm. long, connecting the anterior extremities of the vocal processes, while the inner surfaces of the arytenoids are parallel to each other, and hence the glottis respiratoria is rectangular. During extreme adduction of the cords, as in the emission of a high note, the glottis vocalis is reduced to a linear slit by the apposition of the cords, while the glottis respiratoria is triangular, its apex corresponding to the anterior extremities of the vocal processes of the arytenoids, which are approximated by the inward rotation of the cartilages. Conversely in extreme abduction of the cords, as in forced inspiration, the arytenoids and their vocal processes are rotated outwards, and the glottis respiratoria is triangular in shape but with its apex directed backwards. In this condition the entire glottis is somewhat lozenge-shaped, the sides of the glottis vocalis diverging from before backwards, those of the glottis respiratoria diverging from behind forwards—the widest part of the aperture corresponding with the attachments of the cords to the vocal processes.

Fig. 882.—Side view of the larynx, showing muscular attachments.

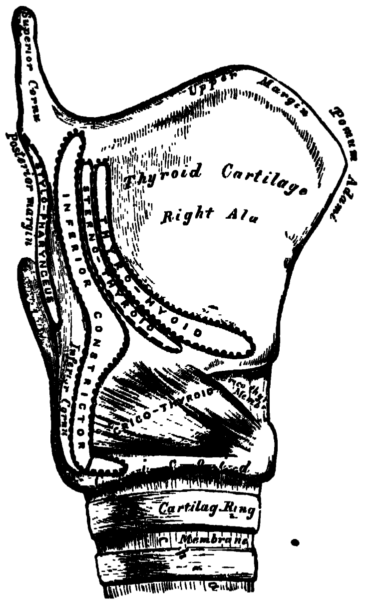


Fig. 883.—Muscles of larynx. Posterior view.

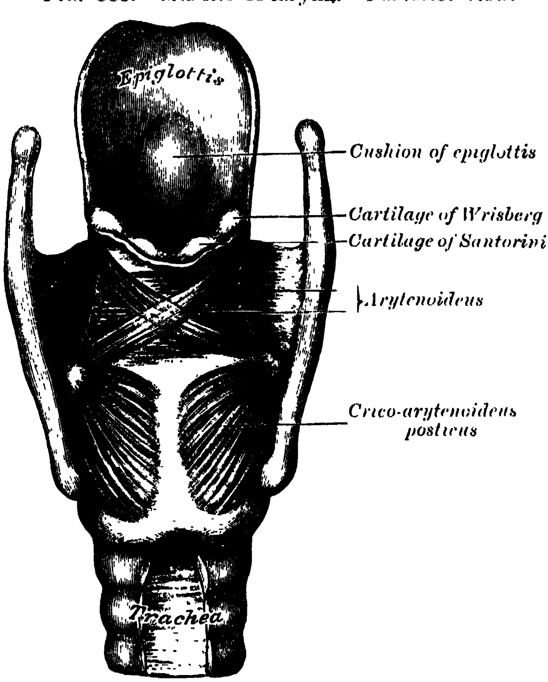


Muscles.—The muscles of the larynx are *extrinsic*, passing between the larynx and parts around—these have been described in the section on Myology; and *intrinsic*, confined entirely to the larynx.

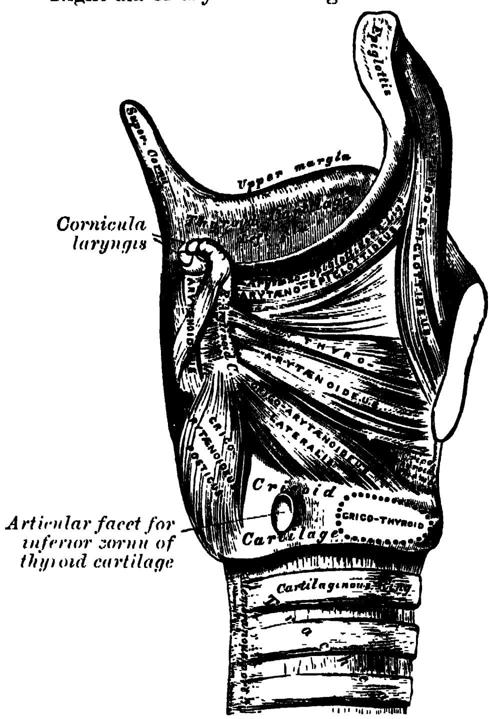
The intrinsic muscles

Crico-thyroideus.
Crico-arytenoideus posticus.
Crico-arytenoideus lateralis.
Arytenoideus.
Thyro-arytenoideus.

The *Crico-thyroideus* (m. cricothyreoideus) (fig. 882) is triangular in form, and situated at the fore part and side of the cricoid cartilage. It arises from the front and lateral part of the cricoid cartilage; its fibres diverge, passing obliquely upwards and

outwards, to be inserted into the lower border of the ala of the thyroid cartilage, and the anterior border of the inferior cornu.

Fig. 884.—Muscles of larynx. Side view. Right ala of thyroid cartilage removed.



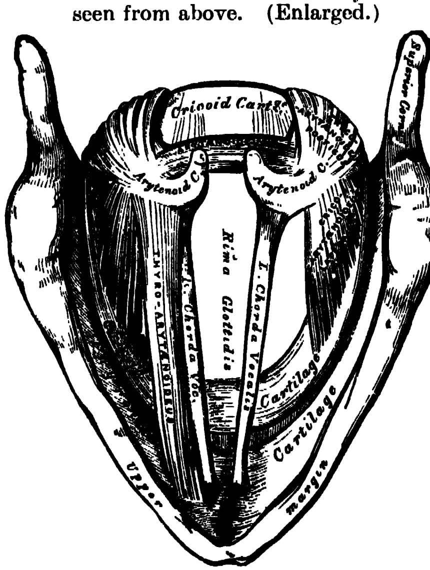
The inner borders of the two muscles are separated in the middle line by a triangular interval, occupied by the central part of the crico-thyroid membrane.

The *Crico-arytenoideus posticus* (m. cricoarytænoideus posterior) (fig. 883) arises from the broad depression on the corresponding half of the posterior surface of the cricoid cartilage; its fibres run upwards and outwards, and converge to be inserted into the posterior surface of the muscular process at the base of the arytenoid cartilage. The uppermost fibres are nearly horizontal, the middle oblique, and the lowest almost vertical.

The *Crico-arytenoideus lateralis* (m. cricoarytænoideus lateralis) (fig. 884) is smaller than the preceding, and of an oblong form. It arises from the upper border of the side of the cricoid cartilage, and, passing obliquely upwards and backwards, is inserted into the front of the muscular process of the arytenoid cartilage.

The *Arytenoideus* (m. arytænoideus) (fig. 883) is a single muscle, filling up the posterior concave surfaces of the arytenoid cartilages. It arises from the posterior surface and outer border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of three planes of fibres, two oblique and one transverse. The *oblique fibres* (m. arytænoideus obliquus), the more superficial, form two fasciculi, which pass from the base of one cartilage to the apex of the opposite one, and which therefore cross each other like the limbs of the letter X. The *transverse fibres*, (m. arytænoideus transversus), the deeper and more numerous, pass transversely across between the two cartilages. A few of the oblique fibres are continued round the outer margin of the cartilage, and are prolonged into the aryteno-epiglottic fold. They are sometimes described as a separate muscle, the *Aryepiglotticus*.

Fig. 885.—Interior of the larynx, seen from above. (Enlarged.)



The *Thyro-arytenoideus* (m. thyreoarytænoideus) (figs. 880, 884, 885) is a broad, flat muscle, which lies parallel with the outer side of the true vocal cord and supports the wall of the ventricle. It arises in front from the lower half of the receding angle of the thyroid cartilage, and from the crico-thyroid membrane.

Its fibres pass backwards and outwards, to be inserted into the base and anterior surface of the arytenoid cartilage. This muscle consists of two fasciculi, an inner and an outer.* The *inner portion* (m. vocalis) is a triangular band which is inserted into the vocal process of the arytenoid cartilage, and into the adjacent portion of its anterior surface; it lies parallel with the true vocal cord, to which it is adherent. The *outer portion* (m. thyreoarytænoideus externus), the thinner, is inserted into the anterior surface and outer border of the arytenoid cartilage above the preceding fibres; it lies on the outer side of the laryngeal saccule, immediately beneath the mucous membrane.

A considerable number of the fibres of the Thyro-arytenoideus are prolonged into the aryteno-epiglottic fold, where some of them become lost, while others are continued forwards to the margin of the epiglottis. They have received a distinctive name, *Thyro-epiglotticus* (m. thyreoepiglotticus), and are sometimes described as a separate muscle.

Actions.—In considering the actions of the muscles of the larynx, they may be conveniently divided into two groups, viz.: 1. Those which open and close the glottis. 2. Those which regulate the degree of tension of the vocal cords.

1. The muscles which open the glottis are the Crico-arytenoidei postici; and those which close it are the Crico-arytenoidei laterales and the Arytenoideus. 2. The muscles which regulate the tension of the vocal cords are the Crico-thyroidei, which elongate and render them tense; and the Thyro-arytenoidei, which relax and shorten them.

The *Posterior crico-arytenoid muscles* separate the vocal cords, and, consequently, open the glottis, by rotating the arytenoid cartilages outwards around a vertical axis passing through the crico-arytenoid joints; so that their vocal processes and the vocal cords attached to them become widely separated.

The *Lateral crico-arytenoid muscles* close the glottis, by rotating the arytenoid cartilages inwards, so as to approximate their vocal processes.

The *Arytenoid muscle* approximates the arytenoid cartilages, and thus closes the opening of the glottis, especially at its back part.

The *Crico-thyroid muscles* produce tension and elongation of the vocal cords by drawing down the lower border of the thyroid cartilage and slightly advancing its inferior cornua; the distance between the vocal processes and the angle of the thyroid is thus increased, and the cords are consequently elongated.

The *Thyro-arytenoid muscles*, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forwards towards the thyroid, and thus shorten and relax the vocal cords. But, owing to the connection of the inner portion with the vocal cord, this part, if acting separately, is supposed to modify its elasticity and tension, and the outer portion, being inserted into the outer part of the anterior surface of the arytenoid cartilage, may rotate it inwards, and thus narrow the rima glottidis by bringing the two cords together.

The manner in which the superior aperture of the larynx is closed during deglutition is referred to on page 486.

Mucous Membrane.—The mucous membrane of the larynx is continuous above with that lining the mouth and pharynx, and is prolonged through the trachea and bronchi into the lungs. It lines the posterior surface and the upper part of the anterior surface of the epiglottis, to which it is closely adherent, and forms the aryteno-epiglottic folds which bound the superior aperture of the larynx. It lines the whole of the cavity of the larynx; forms, by its reduplication, the chief part of the superior, or false vocal cord; and, from the ventricle, is continued into the laryngeal saccule. It is then reflected over the true vocal cords, where it is thin, and very intimately adherent; covers the inner surface of the crico-thyroid membrane and cricoid cartilage; and is ultimately continuous with the lining membrane of the trachea. The upper part of the anterior surface and the upper half of the posterior surface of the epiglottis, the upper part of the aryteno-epiglottic folds, and the true vocal cords are covered by stratified squamous epithelium; all the rest of the laryngeal mucous membrane is covered by columnar ciliated cells.

Glands.—The mucous membrane of the larynx is furnished with numerous muciparous glands, the orifices of which are found in nearly every part; they are very plentiful upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the posterior margin of the aryteno-epiglottic fold, in front of the arytenoid cartilages, where they are termed the *arytenoid glands*. They exist also in large numbers upon the inner surface of the sacculus laryngis. None are found on the free edges of the true vocal cords.

* Henle describes these two portions as separate muscles, under the names of External and Internal thyro-arytenoids.

Vessels and Nerves.—The *arteries of the larynx* are the laryngeal branches derived from the superior and inferior thyroid. The *veins* accompany the arteries: those accompanying the superior laryngeal artery join the superior thyroid vein which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the inferior thyroid vein which opens into the innominate vein. The *lymphatics* consist of two sets, superior and inferior. The former accompany the superior laryngeal artery and pierce the thyro-hyoid membrane, to terminate in the glands situated near the bifurcation of the common carotid artery. Of the latter, some pass through the crico-thyroid membrane and open into a gland lying in front of that membrane or in front of the upper part of the trachea, while others pass to the deep cervical glands and to the glands which accompany the inferior thyroid artery. The *nerves* are derived from the internal and external laryngeal branches of the superior laryngeal nerve, from the inferior or recurrent laryngeal, and from the sympathetic. The internal laryngeal nerve is almost entirely sensory, but some motor filaments are said to be carried by it to the Arytenoideus muscle. It divides into a branch which is distributed to both surfaces of the epiglottis, a second to the aryteno-epiglottic fold, and a third, the largest, which supplies the mucous membrane over the back of the larynx and communicates with the recurrent laryngeal. The external laryngeal nerve supplies the Crico-thyroideus muscle. The recurrent laryngeal passes upwards under the lower border of the Inferior constrictor, and enters the larynx between the cricoid and thyroid cartilages. It supplies all the muscles of the larynx except the Crico-thyroideus, and perhaps a part of the Arytenoideus. The sensory branches of the laryngeal nerves form subepithelial plexuses, from which fibres pass to end between the cells covering the mucous membrane.

Over the posterior surface of the epiglottis, in the aryteno-epiglottic folds, and less regularly in some other parts, taste-buds, similar to those in the tongue, are found.

The Trachea and Bronchi (fig. 886)

The **trachea, or windpipe,** is a cartilaginous and membranous tube, which extends from the lower part of the larynx, on a level with the sixth cervical vertebra, to the upper border of the fifth thoracic vertebra, where it divides into the two bronchi, one for each lung. The trachea is nearly but not quite cylindrical, being flattened posteriorly; it measures about four inches and a half (11 cm.) in length; its diameter, from side to side, is from three-quarters of an inch to an inch (19 to 25 mm.), being always greater in the male than in the female.

Relations.—The anterior surface of the trachea is convex, and covered, *in the neck*, from above downwards, by the isthmus of the thyroid gland, the inferior thyroid veins, the arteria thyreoidea ima (when that vessel exists), the Sterno-thyroid and Sterno-hyoid muscles, the cervical fascia, and, more superficially, by the anastomosing branches between the anterior jugular veins; *in the thorax*, it is covered from before backwards by the first piece of the sternum, the remains of the thymus gland, the left innominate vein, the arch of the aorta, the innominate and left common carotid arteries, and the deep cardiac plexus. Posteriorly it is in relation with the œsophagus; laterally, *in the neck*, it is in relation with the common carotid arteries, the lateral lobes of the thyroid gland, the inferior thyroid arteries, and the recurrent laryngeal nerves; *in the thorax*, it lies in the upper part of the interpleural space (superior mediastinum), and is in relation on the right side to the pleura and right vagus, and near the root of the neck to the innominate artery; on its left side are the recurrent laryngeal nerve, the aortic arch, and the left common carotid and subclavian arteries.

The **right bronchus** (bronchus dexter), wider, shorter, and more vertical in direction than the left, is about an inch in length, and enters the right lung nearly opposite the fifth thoracic vertebra. The vena azygos major arches over it from behind; and the right pulmonary artery lies below and then in front of it. About three-quarters of an inch from its commencement it gives off a branch to the upper lobe of the right lung. This is termed the *eparterial branch* (ramus bronchialis eparterialis), because it is given off above the right pulmonary artery. The bronchus now passes below the artery, and is known as the *hyparterial branch* (ramus bronchialis hyparterialis); it divides into two branches for the middle and lower lobes.

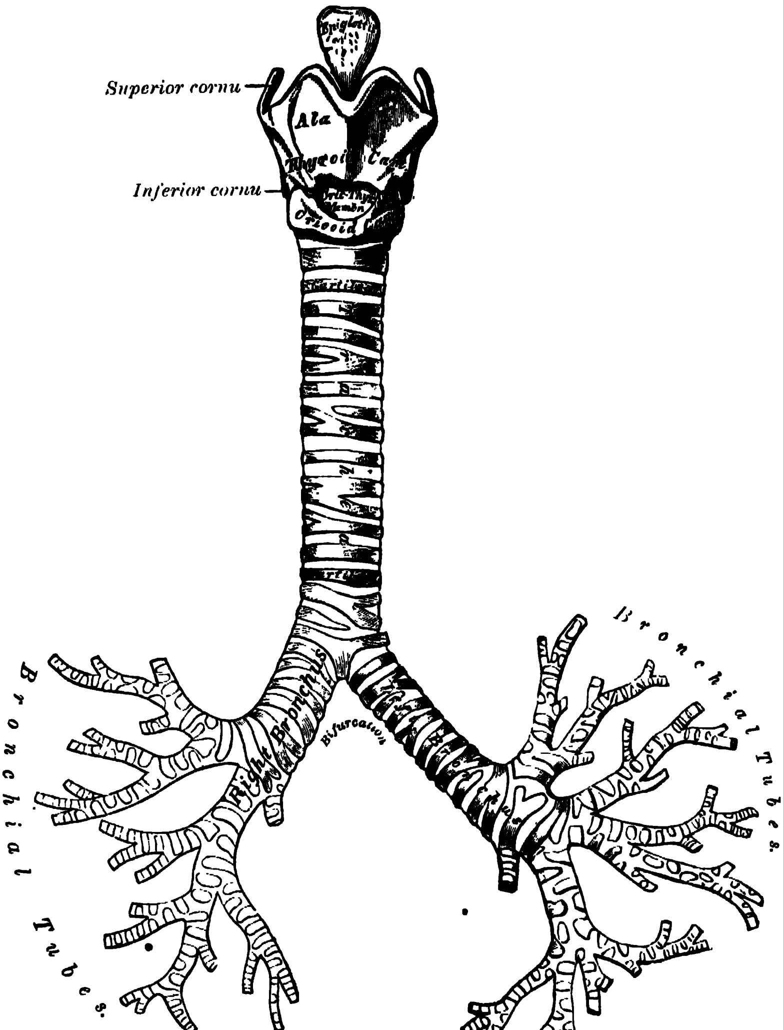
The **left bronchus** (bronchus sinister) is smaller and longer than the right, being nearly two inches in length. It enters the root of the left lung opposite the sixth thoracic vertebra, about an inch lower than the right bronchus. It passes beneath the arch of the aorta, crosses in front of the œsophagus, the thoracic duct, and the descending aorta, and has the left

pulmonary artery lying at first above, and then in front of it. The left bronchus has no eparterial branch, and therefore it has been supposed by some that there is no upper lobe to the left lung, but that the so-called upper lobe corresponds to the middle lobe of the right lung.

The further subdivision of the bronchi will be considered with the anatomy of the lung.

If a transverse section be made across the trachea a short distance above its point of bifurcation, and a bird's-eye view taken of its interior (fig. 887),

FIG. 886.—Front view of cartilages of larynx, trachea, and bronchi.



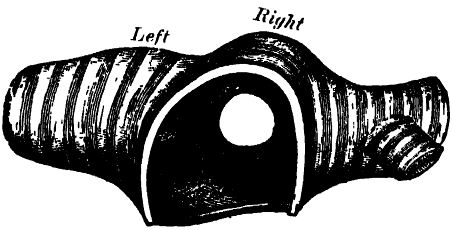
the septum placed at the bottom of the trachea and separating the two bronchi will be seen to occupy the left of the median line, and the right bronchus appears to be a more direct continuation of the trachea than the left, so that any solid body dropping into the trachea would naturally be directed towards the right bronchus. This tendency is aided by the larger size of the right tube as compared with its fellow. This fact serves to explain why a foreign body in the trachea more frequently falls into the right bronchus.*

* Reigel asserts that the entry of a foreign body into the *left* bronchus is by no means so infrequent as is generally supposed. See also *Med.-Chir. Trans.* vol. lxxi. p. 121.

Structure (fig. 888).—The trachea is composed of imperfect rings of hyaline cartilage, fibrous tissue, muscular fibres, mucous membrane, and glands.

The *cartilages* vary from sixteen to twenty in number: each forms an imperfect ring, which occupies the anterior two-thirds or so of the circumference of the trachea, being deficient behind, where the tube is completed by fibrous tissue and unstriped muscular fibres. The cartilages are placed horizontally above each other, separated by narrow intervals. They measure about 4 mm. in depth, and 1 mm. in thickness. Their outer surfaces are flattened, but internally they are convex, from being thicker in the middle than at the margins. Two or more of the cartilages often unite, partially or completely, and they are sometimes bifurcated at their extremities. They are highly elastic, but may become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea. The peculiar tracheal cartilages are the first and the last.

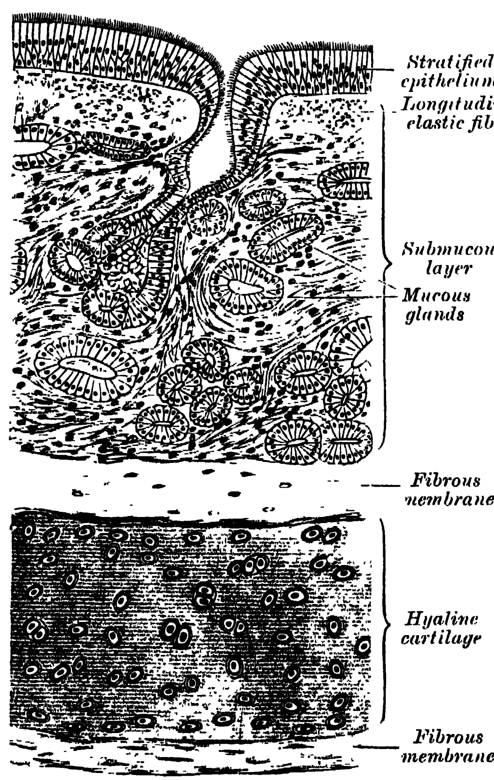
Fig. 887.—Transverse section of the trachea, just above its bifurcation, with a bird's-eye view of the interior.



The *first cartilage* is broader than the rest, and often divided at one end; it is connected by fibrous membrane with the lower border of the cricoid cartilage, with which, or with the succeeding cartilage, it is sometimes blended.

The *last cartilage* is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process, which curves downwards and backwards between the two bronchi. It terminates on each side in an imperfect ring, which encloses the commencement of the bronchi. The cartilage above the last is somewhat broader than the rest at its centre.

Fig. 888.—Transverse section of trachea.



The *fibrous membrane*. — The cartilages are enclosed in an elastic fibrous membrane, which consists of two layers; one, the thicker of the two, passing over the outer surface of the ring, the other over the inner surface: at the upper and lower margins of the cartilages the two layers blend together to form a single membrane, which connects the rings one with another. They are thus, as it were, imbedded in the membrane. In the space behind, between the extremities of the rings, the membrane forms a single distinct layer.

The *muscular tissue* consists of two layers of non-striated muscle, longitudinal and transverse. The *longitudinal fibres* are external, and consist of a few scattered longitudinal bundles. The *transverse fibres* (Trachealis muscle) are internal, and form a thin layer which extends transversely between the ends of the cartilages.

Mucous membrane. — The mucous membrane is continuous above with that of the larynx, and below with that of the bronchi. It consists of areolar and lymphoid tissue, and presents a well-marked basement-membrane, supporting a stratified epithelium, the outer layer of which is columnar and ciliated, while the inner layers are composed of oval or rounded cells. Beneath the basement-membrane there is a distinct layer of longitudinal elastic fibres with a small amount of intervening areolar tissue. The submucous layer is composed of a loose mesh-work of connective tissue, containing large blood-vessels, nerves, and mucous glands; the ducts of the latter pierce the overlying layers and open on the surface.

Vessels and Nerves.—The trachea is supplied with blood by the inferior thyroid *arteries*. The *veins* terminate in the thyroid venous plexus. The *nerves* are derived from the pneumogastric and its recurrent branches, and from the sympathetic.

Surface Form.—In the middle line of the neck, some of the cartilages of the larynx can be readily distinguished. In the receding angle below the chin, the hyoid bone can easily be made out (see page 261), and a finger's breadth below it is the pomum Adami, the prominence between the upper borders of the two alæ of the thyroid cartilage. About an inch below this, in the middle line, is a depression corresponding to the crico-thyroid space, in which the operation of laryngotomy is performed. This depression is bounded below by a prominent arch, the anterior part of the cricoid cartilage, below which the trachea can be felt, though it is only in the emaciated that the separate rings can be distinguished. The lower part of the trachea is not easily made out, for as it descends in the neck it takes a deeper position. The level of the vocal cords corresponds to the middle of the anterior margin of the thyroid cartilage.

With the laryngoscope the following structures can be seen: the base of the tongue, and the upper surface of the epiglottis, with the glosso-epiglottic ligaments; the superior aperture of the larynx, bounded on either side by the aryteno-epiglottic folds, in which may be seen two rounded eminences, corresponding to the cornicula and cuneiform cartilages. Beneath these lie the false and true vocal cords with the ventricle between them. Still deeper are seen the cricoid cartilage and some of the anterior parts of the rings of the trachea, and sometimes, in deep inspiration, the bifurcation of the trachea.

Applied Anatomy.—Foreign bodies often find their way into the air-passages. These may consist of large soft substances, as pieces of meat, which may become lodged in the upper aperture of the larynx, or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of, or unless an opening is made into the air-passages below, so as to enable the patient to breathe. Smaller bodies, frequently of a hard nature, such as cherry or plum stones, small pieces of bone, buttons, &c., may find their way through the rima glottidis into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasm of the glottis which they excite from reflex irritation. When lodged in the ventricle of the larynx, they may produce very few symptoms, beyond sudden loss of voice or alteration in the voice sounds immediately after the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against the vocal cords during expiratory efforts, and produce attacks of dyspnœa from spasm of the glottis. When lodged in the bronchus, they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, and may subsequently lead to purulent bronchitis and gangrene of the lung. Foreign bodies in the air-passages should always be removed as soon as possible. In the less urgent cases a thorough examination of the pharynx, larynx, and bronchi should be made, using one or another of the modern forms of laryngoscope, tracheoscope, or bronchoscope; when discovered, the foreign body should be removed by appropriately shaped forceps. In the cases where urgent dyspnœa is produced and death seems imminent from asphyxia, after digital examination of the back of the throat and inversion with shaking of the patient have failed to give relief, tracheotomy should be rapidly performed.

Beneath the mucous membrane of the upper part of the air-passages there is a considerable amount of submucous tissue, which is liable to become much swollen from effusion in inflammatory affections, constituting the condition known as 'œdema of the glottis.' This effusion does not extend below the level of the vocal cords, on account of the fact that the mucous membrane is closely adherent to these structures without the intervention of any submucous tissue. So that, in cases of œdema of the glottis, in which it is necessary to open the air-passages to prevent suffocation, the operation of laryngotomy is sufficient. Laryngeal or glottidean œdema may be secondary to some local inflammatory affection, such as acute septic laryngitis, syphilitic laryngeal perichondritis, or to malignant disease. Or the œdema may be passive (non-inflammatory), consequent upon renal or cardiac mischief, angioneurotic œdema, or, in unusually susceptible persons, the administration of potassium iodide.

Chronic laryngitis is an inflammation of the mucous glands of the larynx, which occurs in those who speak much in public, and is known as 'clergyman's sore throat.' It is due to the dryness induced by the large amount of cold air drawn into the air-passages during prolonged speaking, which excites increased activity of the mucous glands to keep the parts moist, and this eventually terminates in inflammation of these structures.

Ulceration of the larynx may occur from syphilis, either as a superficial ulceration, or from the softening of a gumma; from tuberculous disease (laryngeal phthisis), or from malignant disease (epithelioma).

The air-passages may be opened in three different situations: by a vertical incision through the centre of the thyroid cartilage (*thyrotomy*); through the crico-thyroid membrane (*laryngotomy*), or in some part of the trachea (*tracheotomy*).

Thyrotomy is usually performed for the purpose of removing growths from the vocal cords or for extracting foreign bodies from the ventricle of the larynx. A median incision

is made from the upper border of the body of the hyoid bone to the lower border of the cricoid cartilage, and is carried through the subcutaneous tissues and deep fascia between the margins of the Sterno-hyoid muscles. An incision is then made in the crico-thyroid membrane, and one blade of a stout, sharp-pointed pair of scissors is introduced beneath the lower border of the thyroid cartilage, and this structure is divided from below upwards. Great care must be taken to cut exactly in the middle line to avoid wounding the vocal cords. If the two halves of the cartilage are now drawn apart, a very good view of the interior of the larynx will be obtained.

Laryngotomy is anatomically a simple operation: it can readily be performed, and should be employed in those cases where the air-passages require opening in an emergency for the relief of some sudden obstruction to respiration. The crico-thyroid membrane is very superficial, being covered only in the middle line by the skin, superficial fascia, and the deep fascia. On either side of the middle line it is also covered by the Sterno-hyoid and Sterno-thyroid muscles, which diverge from each other at their upper parts, leaving a slight interval between them. On these muscles rest the anterior jugular veins. The only vessel of any importance in connection with this operation is the crico-thyroid artery, which crosses the crico-thyroid membrane, and may be wounded, but rarely gives rise to any trouble. The operation is performed thus: the head being thrown back and steadied by an assistant, the finger is passed over the front of the neck, and the crico-thyroid depression felt for. A vertical incision is then made through the skin in the middle line over this spot, and carried down through the fascia until the crico-thyroid membrane is exposed. A cross-cut is then made through the membrane, close to the upper border of the cricoid cartilage, so as to avoid, if possible, the crico-thyroid artery, and a laryngotomy tube inserted. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut through the superficial structures, and thus to open at once the air-passages. It will be seen, however, that in operating in this way the anterior jugular veins are in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid body, or this structure may be divided and the trachea opened behind it.

From the relations already described it must be evident that the trachea can be more readily opened above than below the isthmus of the thyroid body.

Tracheotomy above the isthmus is performed thus: the patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon standing on the right side of his patient makes an incision from an inch and a half to two inches in length in the median line of the neck from the top of the cricoid cartilage. The incision must be made exactly in the middle line so as to avoid the anterior jugular veins, and after the superficial structures have been divided, the interval between the Sterno-hyoid muscles must be found, the raphe divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downwards in the middle line. Bose has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downwards with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed and is saved from all danger of being wounded, and the trachea cleanly exposed. The trachea is now transfixed with a sharp hook and drawn forwards in order to steady it, and is then opened by inserting the knife into it and dividing the upper two or three rings by cutting upwards. If the trachea is to be opened beneath the isthmus, the incision must be made from a little below the cricoid cartilage to the top of the sternum.

In the child the trachea is smaller, more deeply placed, and more movable than in the adult. In fat or short-necked people, or in those in whom the muscles of the neck are prominently developed, the trachea is more deeply placed than in the opposite conditions.

A portion of the larynx or the whole of it may be removed for malignant disease. The results which have been obtained from the removal of the whole of it have not been very satisfactory, and the cases in which the operation is justifiable are very few. It may be removed by a median incision through the soft-parts, freeing the cartilages from the muscles and other structures in front, separating the larynx from the trachea below, and dissecting off the deeper structure from below upwards.

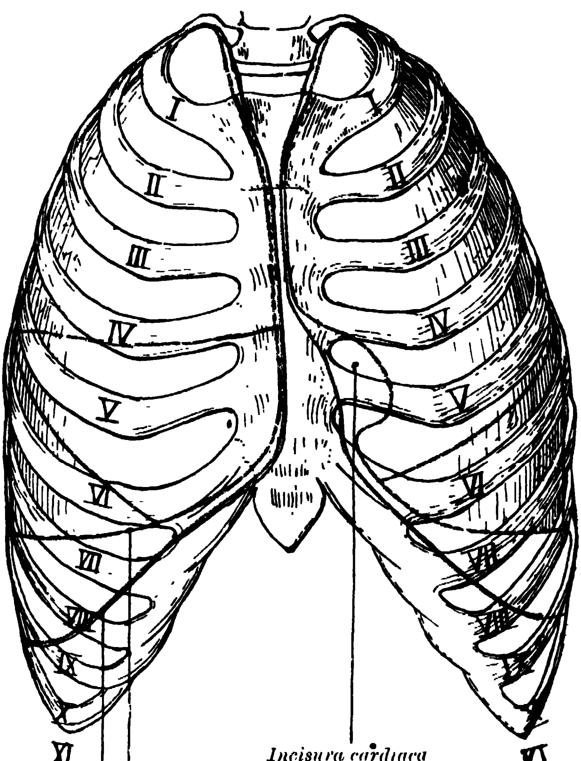
The Pleuræ

Each lung is invested by an exceedingly delicate serous membrane, the **pleura,** which encloses the organ as far as its root, and is then reflected on to the pericardium, chest-wall, and Diaphragm. The portion of the serous membrane investing the surface of the lung and dipping into the fissures between its lobes, is called the *visceral layer of the pleura* (pleura pulmonalis); while that which lines the inner surface of the chest and covers the Diaphragm

and pericardium, is called the *parietal layer of the pleura* (pleura parietalis). The space between these two layers is called the *cavity of the pleura* (cavum pleuræ), but it must be borne in mind that in the healthy condition the two layers are in contact and that there is no real cavity. When the lung becomes collapsed a separation of it from the wall of the chest takes place and a cavity appears. Each pleura is a shut sac, one occupying the right, the other the left half of the thorax; and they are perfectly separate from each other. The two pleuræ do not meet in the middle of the chest, excepting anteriorly opposite the second and third pieces of the sternum. The space left between them contains all the thoracic viscera excepting the lungs, and is named the *mediastinum*.

Different portions of the parietal pleura have received special names which indicate their position: thus, that portion which lines the inner surfaces of the ribs and Intercostal muscles is the *costal pleura* (pleura costalis); that which

FIG. 889.—Front view of chest, showing relations of pleuræ and lungs to the chest-wall: The blue lines indicate the lines of the reflection of the pleuræ; the red, the outlines of the lungs and their fissures.

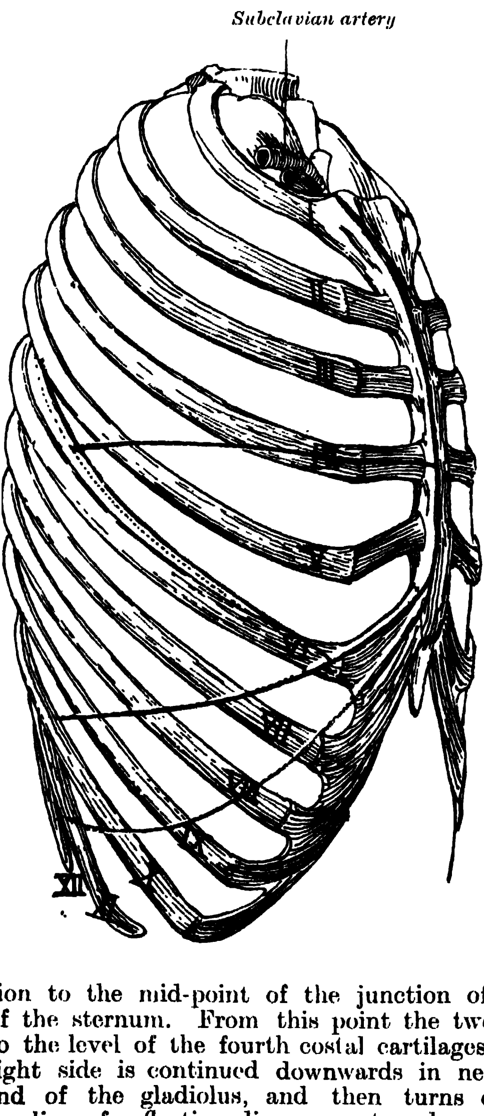


coats the convex surface of the Diaphragm is the *diaphragmatic pleura* (pleura diaphragmatica); that which rises into the neck, over the summit of the lung, is the *cervical pleura* (cupula pleuræ); and that which is applied to the adjacent structures in the mediastinum is the *mediastinal pleura* (pleura mediastinalis).

Reflections of the pleura (figs. 889, 890).—Commencing at the sternum, the pleura passes outwards, lines the costal cartilages, the inner surfaces of the ribs and Intercostal muscles, and at the back part of the thorax passes over the gangliated cord of the sympathetic and its branches, and is reflected upon the sides of the bodies of the vertebræ, where it is separated by a narrow interval, the *posterior mediastinum* (cavum mediastinale posterius), from the opposite pleura. From the vertebral column the pleura passes to the side of

the pericardium, which it covers to a slight extent; it then covers the back part of the root of the lung, from the lower border of which a triangular sheet descends vertically by the side of the posterior mediastinum to the Diaphragm. This sheet is the posterior layer of a wide fold, known as the broad ligament of the lung (*ligamentum pulmonale* or *ligamentum latum pulmonis*). From the posterior aspect of the lung root, the pleura may be traced over the convex surface of the lung, the summit and base, and also over the sides of the fissures between the lobes, on to its inner surface and the front part of its root; it is continued from the lower margin of the root as the anterior layer of the broad ligament, and from this it is reflected on to the pericardium, and from it to the back of the sternum. *Below*, it covers the upper surface of the Diaphragm, and extends, in front, as low as the costal cartilage of the seventh rib; at the side of the chest, to the lower border of the tenth rib on the left side and to the upper border of the same rib on the right side; and behind, it reaches as low as the twelfth rib, and sometimes even as low as the transverse process of the first lumbar vertebra. *Above*, its apex projects, through the superior opening of the thorax into the neck, extending from one to two inches above the anterior extremity of the first rib; this portion of the sac is strengthened by a dome-like expansion of fascia (*Sibson's fascia*), attached in front to the inner border of the first rib, and behind to the anterior border of the transverse process of the seventh cervical vertebra. This is covered and strengthened by a few spreading muscular fibres derived from the Scaleni.

Fig. 890.—Lateral view of chest, showing relations of right pleura and lung to the chest-wall. The blue line indicates the line of pleural reflection; the red lines, the outline of the lung and its fissures.



In the front of the chest, where the parietal layer of the pleura is reflected backwards to the pericardium, the two pleural sacs are in contact for a short distance. At the upper part of the chest, behind the manubrium, they are not in contact; the point of reflection being represented by a line drawn from the sterno-clavicular articulation to the mid-point of the junction of the manubrium with the body of the sternum. From this point the two pleuræ descend in close contact to the level of the fourth costal cartilages, and the line of reflection on the right side is continued downwards in nearly a straight line to the lower end of the gladiolus, and then turns outwards, while on the left side the line of reflection diverges outwards and is continued downwards, close to the left border of the sternum, as far as the sixth costal cartilage. The inferior limit of the pleura is on a considerably lower level than the corresponding limit of the lung, but does not extend to the attachment of the Diaphragm, so that below the line of reflection of the pleura from the chest-

wall on to the Diaphragm the latter is in direct contact with the rib cartilages and the Internal intercostal muscles. Moreover, in ordinary inspiration the thin margin of the base of the lung does not extend as low as the line of the pleural reflection, with the result that the costal and diaphragmatic pleuræ are here in contact, the narrow slit between the two being termed the ***sinus phrenicocostalis***. A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms what is sometimes called the ***sinus costomediastinalis***.

The line along which the right pleura is reflected from the chest-wall to the Diaphragm starts in front, immediately below the seventh costo-sternal joint, and runs downwards and backwards behind the seventh costal cartilage so as to cross the tenth rib in the mid-axillary line, from which it is prolonged to the twelfth dorsal spine. The reflection of the left pleura follows at first the ascending part of the sixth costal cartilage, and in the rest of its course is slightly lower than that of the right side.

The free surface of the pleura is smooth, polished, and moistened by a serous fluid; its attached surface is intimately adherent to the surface of the lung, and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragm: throughout the rest of its extent it may be separated from the adjacent parts with extreme facility.

The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

Ligamentum latum pulmonis.—From the above description it will be seen that the root of the lung is covered in front and behind by pleura, and that at its lower border the investing layers come into contact. Here they form a sort of mesenteric fold, the *ligamentum latum pulmonis* (lig. pulmonale), which extends as far as the Diaphragm between the pericardium and the lower part of the inner surface of the lung, having a free falciform border below, between the lung and the Diaphragm. It serves to retain the lower part of the lung in position.

Vessels and Nerves.—The *arteries of the pleura* are derived from the intercostal, internal mammary, musculo-phrenic, thymic, pericardiac, and bronchial vessels. The *veins* correspond to the arteries. The *lymphatics* are described on page 793. The *nerves* are derived from the phrenic and sympathetic (Luschka). Kölliker states that nerves accompany the ramifications of the bronchial arteries in the pleura pulmonalis.

Applied Anatomy.—Acute inflammation of the pleura, or *pleurisy*, may be either dry or wet, and, if wet, either serous or purulent. *Dry pleurisy* is common in pneumonia, and is often an early manifestation of tuberculosis. It gives rise to much pain, and to friction sounds due to the scraping to and fro over one another of the inflamed and roughened parietal and visceral pleuræ. *Wet pleurisy* occurs if the inflammation causes the effusion of serum into the pleural cavity. The two pleural layers are now separated by the fluid effusion, so the friction sounds are no longer produced. Room is found for the fluid by shrinkage of the supernatant lung due to the retraction of its elastic tissue, and later, when the quantity of serum exceeds about three pints, by shifting over of the heart and unaffected lung towards the sound side. This shifting may be so extensive that the apex beat of the heart comes to lie under the right nipple. Any pleural effusion that is large enough to embarrass respiration seriously, or has remained unabsorbed for two or three weeks, should be removed by tapping (paracentesis thoracis). The trocar is pushed through the chest-wall into the fluid, in the sixth or seventh intercostal space in the mid-axillary line, or in the eighth or ninth space just outside the angle of the scapula. Aspiration is then performed, and as much fluid as possible drawn off: it must be stopped, however, if the patient shows signs of collapse, or if fits of coughing occur and threaten to wound the expanding lung against the sharp end of the trocar. Non-inflammatory or passive effusion into the pleura, called *hydrothorax*, is often seen in the later stages of chronic renal or cardiac disease, and demands treatment on lines similar to the above.

Purulent pleural effusion, or *empyema*, often occurs after such diseases as pneumonia or measles. This condition requires drainage of the cavity, which usually necessitates excision of a portion of a rib. An incision is made down to the seventh or eighth rib in the mid- or posterior axillary line and the periosteum is incised, and separated from the shaft of the rib, carrying with it the structures in the subcostal groove. With bone-cutting forceps about one and a half or two inches of the rib are separated and removed, and the underlying pleura is incised. The pus having been evacuated, a large drainage tube is inserted into the cavity. The pleura should never be irrigated, as sudden death has followed this proceeding, and great care should be taken to prevent the tube from slipping into the cavity, an occurrence which is far from uncommon.

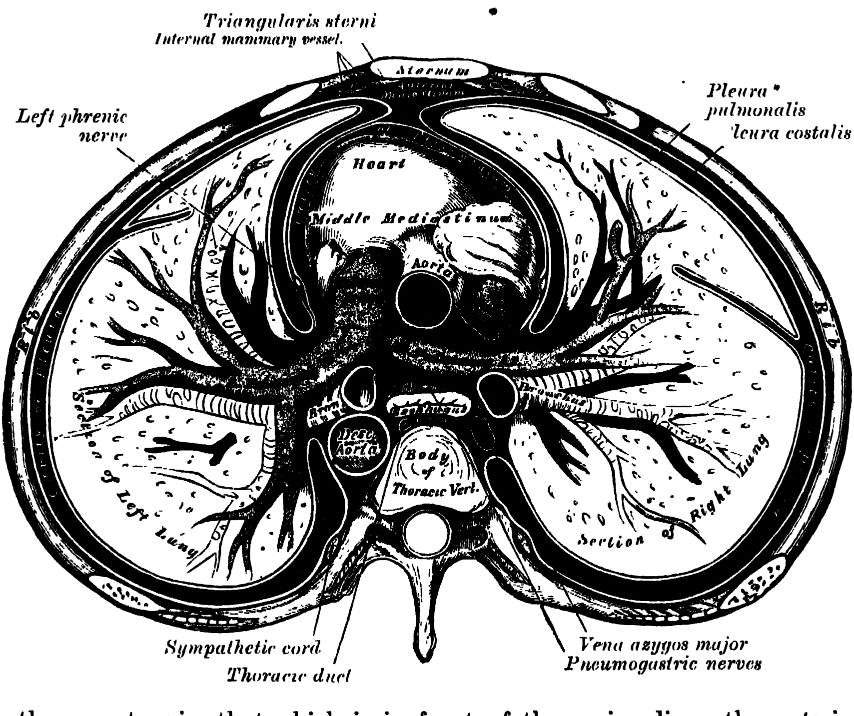
Pneumothorax, or the presence of gas in the pleural cavity, is a common terminal event in tuberculosis of the lungs; less often it is due to trauma—rupture of the lung, for example, when the chest is crushed, or tearing of the lung tissue by the sharp projecting end of a broken rib. Air escapes from the lung into the pleural cavity; the elastic tissue of the lung at once contracts, and finally that organ shrinks away to a dark rounded mass the size of a fist, lying close against the vertebral column. The symptoms of pneumothorax are often very severe; cyanosis, intense dyspnœa, great pain on the affected side, and cardiac failure. Their severity is increased by the fact that the blood-vessels of the collapsed lung offer less resistance to the circulation of the blood than do those of the other lung. Not only, therefore, does the sound lung suddenly have to take over the work—the aeration of the blood—normally performed by both lungs, but it has to do so at the moment when the circulation of blood through it is partially short-circuited by the collapsed lung. If the patient survives for a few days, empyema often complicates the pneumothorax, setting up the condition called *pyopneumothorax*.

In operations upon the kidney, it must be borne in mind that the pleura usually extends below the level of the inner portion of the last rib, and may therefore be opened in these operations, especially when the last rib is removed in order to give more room.

The Mediastinum

The **mediastinum** is the space left in and near the median line of the chest by the non-apposition of the two pleuræ. It extends from the sternum in front to the vertebral column behind, and contains all the thoracic viscera excepting the lungs. The mediastinum may be divided for purposes of description into two parts: an upper portion, above the upper level of the pericardium, which is named the *superior mediastinum* (Struthers); and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided

Fig. 891.—A transverse section of the thorax, showing the relative position of the viscera, and the reflections of the pleuræ.



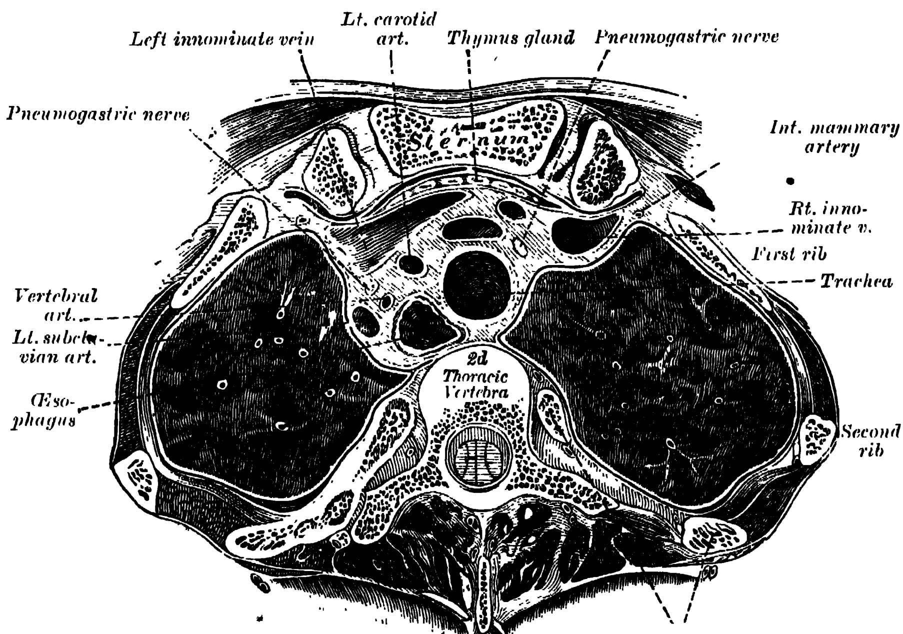
into three parts, viz. that which is in front of the pericardium, the *anterior mediastinum*; that which contains the pericardium and its contents, the *middle mediastinum*; and that which is behind the pericardium, the *posterior mediastinum* (fig. 891).

The **superior mediastinum** (fig. 892) is that portion of the interpleural space which lies between the manubrium sterni in front and the upper thoracic vertebræ behind. It is bounded below by a plane passing backwards from the

junction of the manubrium and gladiolus sterni to the lower part of the body of the fourth thoracic vertebra, and laterally by the pleuræ. It contains the origins of the Sterno-hyoid and Sterno-thyroid muscles and the lower ends of the Longus colli muscles; the arch of the aorta; the innominate artery and the thoracic portions of the left common carotid and the subclavian arteries; the innominate veins and the upper half of the superior vena cava; the left superior intercostal vein; the pneumogastric, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, œsophagus, and thoracic duct; the remains of the thymus gland, and some lymphatic glands.

The **anterior mediastinum** is bounded in front by the sternum, laterally by the pleuræ, and behind by the pericardium. It is narrow above, but widens out a little below, and, owing to the oblique course taken by the left pleura, it is directed from above downwards and to the left. Its anterior wall is formed by the left Triangularis sterni muscle and the fifth, sixth, and seventh left costal cartilages. It contains a quantity of loose areolar tissue, some

Fig. 892.—Transverse section through the upper margin of the second thoracic vertebra. (Braune.)



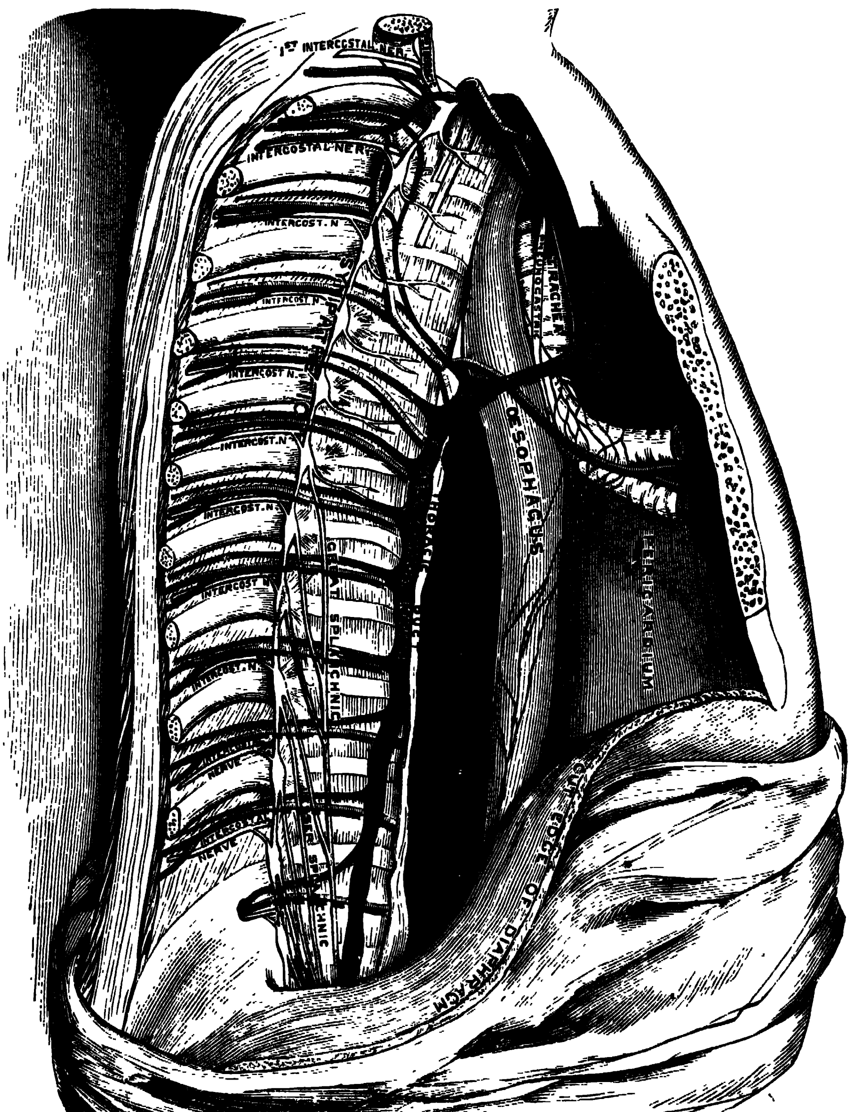
lymphatic vessels which ascend from the convex surface of the liver, two or three lymphatic glands (anterior mediastinal glands), and the small mediastinal branches of the internal mammary artery.

The **middle mediastinum** is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava with the vena azygos major opening into it, the bifurcation of the trachea and the two bronchi, the pulmonary artery dividing into its two branches, the right and left pulmonary veins, the phrenic nerves, and some bronchial lymphatic glands.

The **posterior mediastinum** (fig. 893) is an irregular triangular space running parallel with the vertebral column; it is bounded in front by the pericardium above, and by the posterior surface of the Diaphragm below, behind by the vertebral column from the lower border of the fourth to the twelfth thoracic vertebra, and on either side by the pleura. It contains the descending thoracic aorta, the vena azygos major and minor, the pneumogastric and splanchnic nerves, the œsophagus, the thoracic duct, and some lymphatic glands.

Applied Anatomy.—*Primary tumours* of the mediastinum are usually lymphoma or lymphosarcoma arising from the thymus or from the bronchial or posterior mediastinal lymph-glands: sarcomata, dermoid cysts, and embryomata, occur more rarely. These tumours give rise to pain, deformity of the chest, and symptoms of pressure on the various nerves, blood-vessels, air-passages, lymphatics, and on the œsophagus, as these various structures pass through the thorax. They may produce physical signs very much like those of an aortic aneurysm, so that diagnosis between the two is often difficult. The

Fig. 893.—The posterior mediastinum.



prognosis is bad, life usually ending within a few months or a year of the onset of the symptoms.

Inflammation of the mediastinum due to wounds, or to the spread of inflammation from adjacent parts (e.g. the œsophagus, the pericardium) is sometimes acute, leading to abscess-formation. A more chronic form associated with adhesions and inflammation of the pericardium—the so-called chronic adhesive mediastino-pericarditis—gives rise to obscure symptoms suggesting gradual heart-failure, and leads to death slowly but surely.

The Lungs

The **lungs** (pulmones) are the essential organs of respiration; they are two in number, placed one on either side of the chest, and separated from each other by the heart and other contents of the mediastinum. Each lung is conical in shape, and presents for examination an apex, a base, two borders, and two surfaces.

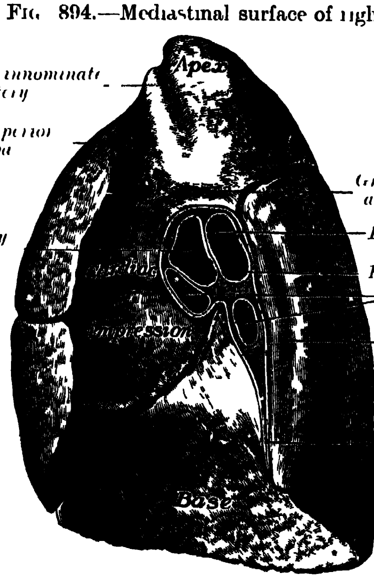
The *apex* (apex pulmonis) is rounded, and extends into the root of the neck, reaching from an inch to an inch and a half above the level of the anterior end of the first rib. A furrow produced by the subclavian artery as it curves outwards in front of the pleura runs upwards and outwards immediately below the apex.

The *base* (basis pulmonis) is broad, concave, and rests upon the convex surface of the Diaphragm which separates the right lung from the right lobe of the liver, and the left lung from the left lobe of the liver, the stomach, and spleen. Since the Diaphragm extends higher on the right than on the left side, it follows that the concavity on the base of the right lung is deeper than that on the left. Laterally and behind, the base is bounded by a thin, sharp margin which projects for some distance into the phrenico-costal sinus of the pleura, between the lower ribs and the costal attachment of the Diaphragm. The base of the lung descends during inspiration and ascends during expiration; its relation to the chest wall is indicated in figs. 889 and 890.

The *external* or *costal surface* (facies costalis) is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper behind than in front. It is in contact with the costal pleura, and presents in a hardened specimen slight grooves corresponding with the overlying ribs.

The *inner* or *mediastinal surface* (facies mediastinalis) is in contact with that portion of the pleura which forms the lateral boundary of the mediastinal space. It presents a deep concavity which accommodates the pericardial sac; this is larger and deeper on the left than on the right lung, on account of the heart

Fig. 894.—Mediastinal surface of right lung.

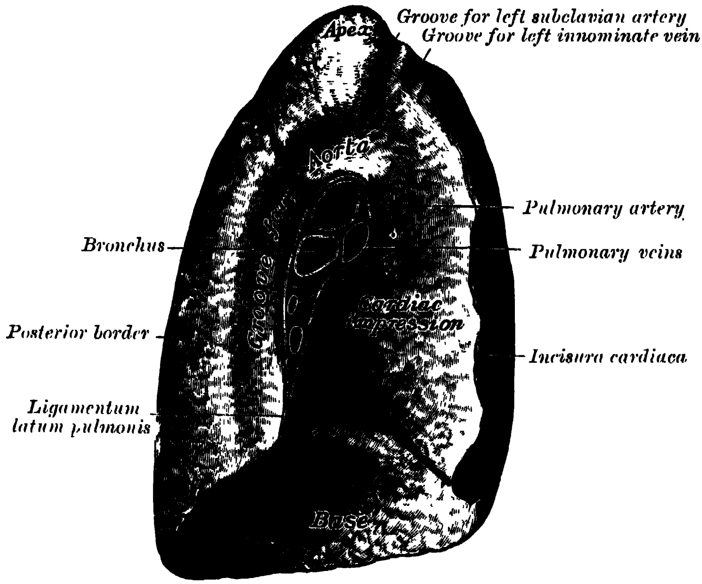


projecting farther to the left than to the right side of the mesial plane. Above and behind this concavity is a triangular depression named the *hilus* (hilus pulmonis), where the structures which form the root of the lung enter and leave the viscus. These structures are invested by pleural membrane, which, below the hilus, forms the ligamentum latum pulmonis. On the *right* lung (fig. 894), immediately above the hilus, is an arched furrow which

accommodates the vena azygos major; while running upwards, and then arching outwards some little distance below the apex, is a wide groove for the superior vena cava and right innominate vein, and behind this, nearer the apex, is a second furrow for the innominate artery. Along the back part of the inner surface is a vertical groove for the œsophagus; this groove becomes less distinct below, owing to the inclination of the lower part of the œsophagus to the left of the middle line. In front and to the right of the lower part of the œsophageal groove(the inner surface is applied to the pleural covering of the right and posterior aspects of the thoracic part of the inferior vena cava—this

Extra pericardiac portion, i.e. the [illegible] part of the infr vena cava.

Fig. 895.—Mediastinal surface of left lung.



vessel being accommodated in a deep concavity. On the *left* lung (fig. 895), immediately above the hilus, is a well-marked curved furrow produced by the aortic arch, and running upwards from this towards the apex is a groove accommodating the left subclavian artery; a slight impression in front of the latter and close to the margin of the lung lodges the left innominate vein. Behind the hilus and pericardial depression is a vertical furrow produced by the descending thoracic aorta, and in front of this, near the base of the lung, the lower part of the œsophagus causes a shallow depression.

The *posterior border* (margo posterior) is broad and rounded, and is received into the deep concavity on either side of the vertebral column. It is much longer than the anterior border, and projects, below, into the upper part of the phrenico-costal sinus.

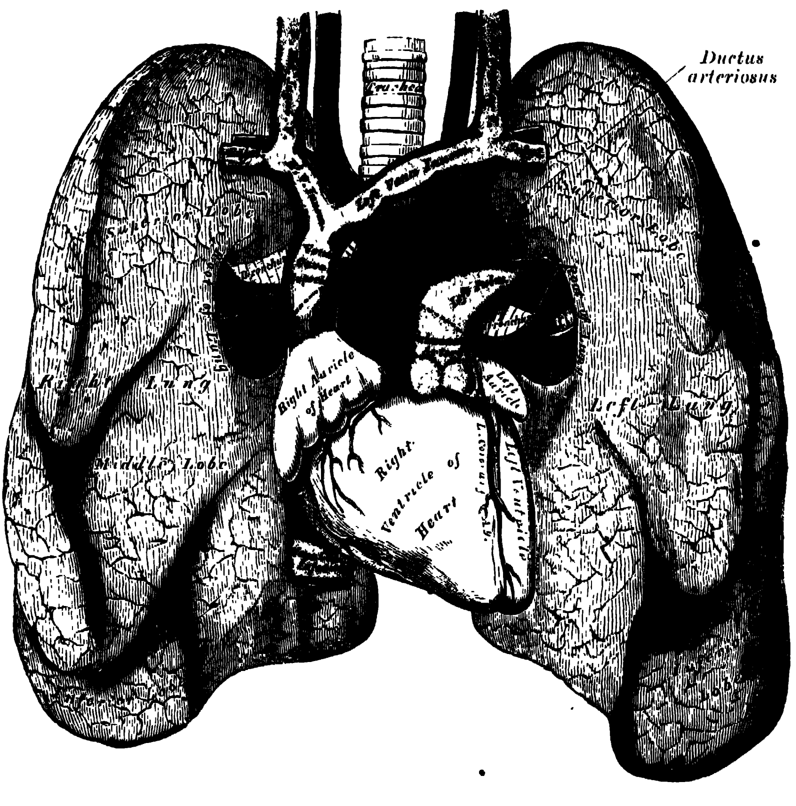
The *anterior border* (margo anterior) is thin and sharp, and overlaps the front of the pericardium. The anterior border of the *right* lung is almost vertical, and projects into the costo-mediastinal sinus of the pleura; that of the *left* presents, below, an angular notch, the *incisura cardiaca*, in which the pericardium is exposed. Opposite this notch the anterior margin of the left lung is situated some little distance to the outer side of the line of reflection of the corresponding part of the pleura.

Fissures and lobes of the lungs.—The *left lung* is divided into two lobes, an upper and a lower, by an *oblique fissure*, which extends from the outer to the inner surface of the lung both above and below the hilus. As seen on the surface, this fissure commences on the inner aspect of the lung at the upper and posterior part of the hilus, and runs backwards and upwards to the posterior border, which it crosses at a point about two and a half inches below the apex. It then extends downwards and forwards over the outer surface, and reaches the lower border a little behind its anterior extremity, and its further course can

be followed upwards and backwards across the inner surface as far as the lower part of the hilus. The *upper lobe* (lobus superior) lies above and in front of this fissure, and includes the apex, the anterior border, and a considerable part of the outer surface and the greater part of the inner surface of the lung. The *lower lobe* (lobus inferior), the larger of the two, is situated below and behind the fissure, and comprises almost the whole of the base, a large portion of the outer surface, and the greater part of the posterior border.

The *right lung* is divided into three lobes, upper, middle, and lower, by an oblique and a horizontal fissure. The *oblique fissure* separates the lower from the middle and upper lobes, and corresponds closely with the fissure in the left lung. Its direction is, however, more vertical, and it cuts the lower border about three inches behind its anterior extremity. The *horizontal fissure* separates the upper from the middle lobe. It begins in the oblique fissure near the posterior border of the lung, and, running horizontally forwards, cuts

FIG. 896.—Front view of heart and lungs.



the anterior border on a level with the sternal end of the fourth costal cartilage ; on the inner surface it may be traced backwards to the hilus. The *middle lobe* (lobus medius), the smallest of the lobes of the right lung, lies between the horizontal fissure and the lower part of the oblique fissure ; it is wedge-shaped, and includes the lower part of the anterior border and the anterior part of the base of the lung.

The *right lung* is the larger and heavier ; it is broader than the *left*, owing to the inclination of the heart to the left side ; it is also shorter by an inch, in consequence of the Diaphragm rising higher on the right side to accommodate the liver.

The **root of the lung** (radix pulmonis).—A little above the middle of the inner surface of each lung, and nearer its posterior than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchus, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexuses of nerves, lymphatics,

bronchial glands, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies behind the superior vena cava and part of the right auricle, and below the vena azygos major. That of the left lung passes beneath the arch of the aorta and in front of the descending aorta; the phrenic nerve, with its accompanying artery and vein, and the anterior pulmonary plexus, lie in front of each, and the pneumogastric and posterior pulmonary plexus behind each; below each is the ligamentum latum pulmonis.

The chief structures composing the root of each lung are arranged in a similar manner from before backwards on both sides, viz. the upper of the two pulmonary veins in front; the pulmonary artery in the middle; and the bronchus, together with the bronchial vessels, behind. From above downwards, on the two sides, their arrangement differs, thus:

On the right side their position is—eparterial bronchus, pulmonary artery, hyparterial bronchus, pulmonary veins; but on the left side their position is—pulmonary artery, bronchus, pulmonary veins. The lower of the two pulmonary veins is situated below the bronchus at the apex or lowest part of the hilus.

Divisions of the bronchi.—Just as the lungs differ from each other in the number of their lobes, so the bronchi differ in their mode of subdivision.

The *right* bronchus gives off, about an inch from the bifurcation of the trachea, a branch for the upper lobe. This branch arises above the level of the pulmonary artery, and is therefore named the *eparterial bronchus*. All the other divisions of the main stem come off below the pulmonary artery, and consequently are termed *hyparterial bronchi*. The first of these is distributed to the middle lobe, and the main tube then passes downwards and backwards into the lower lobe, giving off in its course a series of large ventral and small dorsal branches. The ventral and dorsal branches arise alternately, and are usually eight in number—four of each kind. The branch to the middle lobe is regarded as the first of the ventral series.

The *left* bronchus passes below the level of the pulmonary artery before it divides, and hence all its branches are *hyparterial*; it may therefore be looked upon as equivalent to that portion of the right bronchus which lies on the distal side of its eparterial branch. The first branch of the left bronchus arises about two inches from the bifurcation of the trachea, and is distributed to the upper lobe. The main stem then enters the lower lobe, where it divides into ventral and dorsal branches similar to those in the right lung. The branch to the upper lobe of the left lung is regarded as the first of the ventral series.

Aeby regarded the absence of a left eparterial bronchus as indicating the absence of the corresponding lobe of the lung, and considered the middle lobe of the right lung the homologue of the upper lobe of the left. His conclusions, however, are not universally accepted.

The *weight* of both lungs together is about forty-two ounces, the right lung being two ounces heavier than the left; but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female, their proportion to the body being, in the former, as 1 to 37, in the latter as 1 to 43.

The *colour* of the lungs at birth is a pinkish-white; in adult life it is a dark slaty-grey, mottled in patches; and as age advances, this mottling assumes a black colour. The colouring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. The posterior border of the lung is usually darker than the anterior.

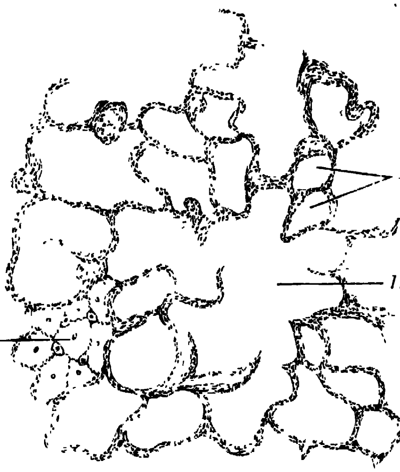
The *surface* of the lung is smooth, shining, and marked out into numerous polyhedral areas, indicating the lobules of the organ: each of these areas is crossed by numerous lighter lines.

The *substance* of the lung is of a light, porous, spongy texture; it floats in water, and crepitates when handled, owing to the presence of air in the air-sacs; it is also highly elastic; hence the retracted state of these organs when they are removed from the closed cavity of the thorax.

Structure.—The lungs are composed of an external serous coat, a subserous areolar tissue, and the pulmonary substance or parenchyma.

The *serous coat* is the visceral layer of the pleura; it is thin, transparent, and invests the entire organ as far as the root.

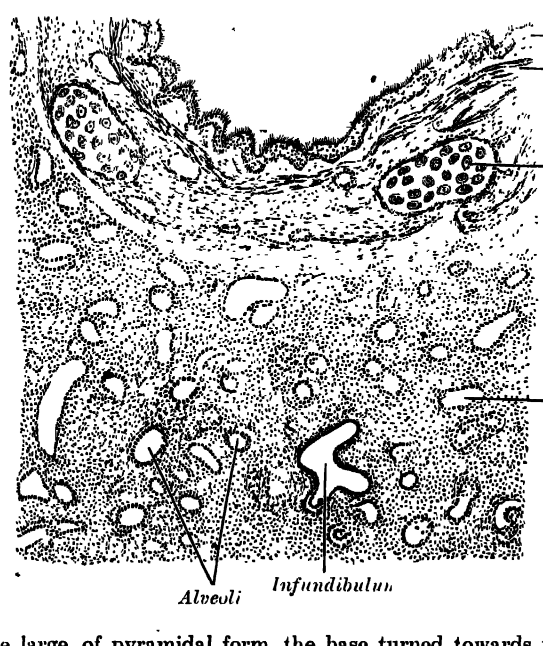
FIG. 897.—Section of lung tissue.



The *subserous areolar tissue* contains a large proportion of elastic fibres; it invests the entire surface of the lung, and extends inwards between the lobules.

The *parenchyma* is composed of lobules which, although closely connected together by an interlobular areolar tissue, are quite distinct from one another, and may be teased asunder without much difficulty in the fœtus. The lobules vary in size: those on the

FIG. 898.—Section of a portion of an atelectic lung of kitten.



surface are large, of pyramidal form, the base turned towards the surface; those in the interior smaller, and of various forms. Each lobule is composed of one of the ramifications of a bronchial tube and its terminal air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves; all of these structures being connected together by areolar tissue.

The primary branches of the *bronchus*, upon entering the substance of the lung, divide and subdivide into smaller tubes throughout the entire organ. Each of the smaller subdivisions of the bronchus enters a pulmonary lobule, and is termed an *intralobular bronchus*. This gives off collateral branches and then bifurcates about the centre of the lobule; these bifurcations divide at right angles to the previous plane of division and the process is repeated until a large number of ultimate bronchi (*bronchioles*) are formed. Each bronchiole now becomes enlarged, and is termed the *atrium* or *alveolar passage*; from it are given off, on all sides, ramifications, called *infundibula*, which are closely beset in all directions by *alveoli* or *air-sacs*.

Changes in the structure of the bronchi in the lungs.—In the lobes of the lungs the following changes take place. The *cartilages* are not segments of rings, but consist of small oval or angular patches scattered irregularly along the sides of the tube, being most distinct at the points of division of the bronchi; as the bronchi approach their terminations the cartilages disappear. The muscular coat (*bronchial muscle*) is disposed in the form of a continuous layer of annular fibres, which may be traced upon the smallest bronchial tubes, and consists of the unstriped variety of muscular tissue; at the termination of the bronchioles in the atria the muscle forms a definite circular band (Miller). The layers of epithelial cells diminish in number and in the terminal bronchioles only a single layer of non-ciliated flattened cells exists.

The air-sacs are small polyhedral recesses, composed of a basement membrane surrounded by a few involuntary muscular and elastic fibres, and lined by flattened squamous epithelium, with sinuous outlines; between these cells are seen small oval granular cells.

Vessels and Nerves.—The *pulmonary artery* conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes and terminate in a dense capillary network upon the walls of the air-sacs. In the lung, the branches of the pulmonary artery are usually above and in front of a bronchial tube, the vein below.

The *pulmonary capillaries* form plexuses which lie immediately beneath the mucous membrane, in the walls and septa of the air-sacs, and of the infundibula. In the septa between the air-sacs the capillary network forms a single layer. The capillaries form a very minute network, the meshes of which are smaller than the vessels themselves; their walls are also exceedingly thin. The arteries of neighbouring lobules are independent of each other, but the veins freely anastomose.

The *pulmonary veins* commence in the pulmonary capillaries, the radicles coalescing into larger branches which run through the substance of the lung, independently of the minute arteries and bronchi. After freely communicating with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilus of the organ. Finally they open into the left auricle of the heart, conveying oxygenated blood to be distributed to all parts of the body by the aorta.

The *bronchial arteries* supply blood for the nutrition of the lung; they are derived from the thoracic aorta or from the upper aortic intercostal arteries, and, accompanying the bronchial tubes, are distributed to the bronchial glands, and upon the walls of the larger bronchial tubes and pulmonary vessels. Those supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat. This plexus communicates with branches of the pulmonary artery, and empties itself into the pulmonary veins. Others are distributed in the interlobular areolar tissue, and terminate partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung, beneath the pleura, where they form a capillary network.

The *bronchial vein* is formed at the root of the lung, receiving superficial and deep veins corresponding to branches of the bronchial artery. It does not, however, receive all the blood supplied by the artery, as some of it passes into the pulmonary veins. It terminates on the right side in the vena azygos major, and on the left side in the superior intercostal or vena azygos minor supérior.

The *lymphatics* are described on page 792.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and pneumogastric. The filaments from these plexuses accompany the bronchial tubes, upon which they are lost. Small ganglia are found upon these nerves.

Surface Form.—The apex of the lung is situated in the neck, behind the interval between the two heads of origin of the Sterno-mastoid. The height to which it rises above the clavicle varies very considerably, but is generally about an inch. It may, however, extend as much as an inch and a half or an inch and three-quarters, or, on the other hand, it may scarcely project, above the level of this bone. In order to mark out the anterior margin of the lung, a line is to be drawn from the apex point, an inch above the level of the clavicle, and rather nearer the posterior than the anterior border of the Sterno-mastoid muscle, downwards and inwards across the sterno-clavicular articulation and manubrium sterni until it meets, or almost meets, its fellow of the other side at the level of the articulation of the manubrium and gladiolus. From this point the two lines are to be drawn downwards, rather to the left of the mesial line but close to it, as far as the level of the articulation of the fourth costal cartilages with the sternum. From here the two lines diverge, the left at first passing outwards with a slight inclination down-

wards, and then taking a bend downwards with a slight inclination outwards to the apex of the heart, and thence to the sixth costo-chondral articulation. The direction of the anterior border of this part of the left lung is denoted with sufficient accuracy by a curved line, with its convexity directed upwards and outwards from the articulation of the fourth right costal cartilage of the sternum to the fifth intercostal space, an inch and a half below, and three-quarters of an inch internal to the left nipple. The continuation of the anterior border of the right lung is marked by a prolongation of its line from the level of the fourth costal cartilages vertically downwards as far as the sixth, when it slopes off along the line of the sixth costal cartilage to its articulation with the rib.

After expiration the lower border of the lung may be marked out by a slightly curved line, with its convexity downwards, from the articulation of the sixth costal cartilage with its rib to the spinous process of the tenth thoracic vertebra. If vertical lines are drawn downwards from the nipple, the mid-axillary line, and the apex of the scapula, while the arms are raised from the sides, they should intersect this convex line, the first at the sixth, the second at the eighth, and the third at the tenth rib. It will thus be seen that the pleura extends farther down than the lung, so that it may be wounded, and a wound pass through both layers into the Diaphragm, and even injure the abdominal viscera, without the lung being involved.

The posterior border of the lung is indicated by a line drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the vertebral column, corresponding to the costo-vertebral joints as low as the spinous process of the tenth thoracic vertebra. The trachea bifurcates opposite the spinous process of the fourth thoracic vertebra, and from this point the two bronchi are directed downwards and outwards.

The position of the oblique fissure in each lung may be indicated by a line drawn from the second thoracic spine round the side of the chest to the sixth rib in the nipple line. The horizontal fissure in the right lung is indicated by a line drawn from the preceding, where it bisects the mid-axillary line, to the junction of the fourth costal cartilage with the sternum.

Applied Anatomy.—The lungs may be wounded or torn in three ways: (1) by compression of the chest, without any injury to the ribs: (2) by a fractured rib penetrating the lung; (3) by stabs, gunshot wounds, &c.

The first form, where the lung is ruptured by external compression without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung, i.e. the most fixed part, and thus, implicating the great vessels, is frequently fatal. It would seem *a priori* a most unusual injury, and its exact mode of causation is difficult to interpret.

In the second variety, when the wound in the lung is produced by the penetration of a broken rib, both the pleura costalis and pleura pulmonalis must necessarily be injured, and consequently the air taken into the wounded air-sacs may find its way through these wounds into the cellular tissue of the parietes of the chest, producing *surgical* emphysema. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air passes straight through from the wounded lung into the subcutaneous tissue. Emphysema constitutes therefore the most important sign of injury to the lung in cases of fracture of the ribs. Pneumothorax, or air in the pleural cavity, is much more likely to occur in injuries of the third variety—that is to say, from external wounds, from stabs, gunshot injuries, and such like—in which case air passes either from the wound of the lung or from the external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air is drawn into the wound during inspiration, and then forced into the cellular tissue around during expiration because it cannot escape from the external wound. Occasionally in wounds of the parietes of the chest no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This takes place where the wound is large, and constitutes one form of *hernia* of the lung. Another form of hernia of the lung occurs, though very rarely, after wounds of the chest-wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscus behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls in during inspiration, and disappears on holding the breath.

An incision into the lung is occasionally required in cases of abscess the result of pneumonia or the presence of a foreign body, and from an abscess in the liver which has made its way through the Diaphragm into the lung substance, and also in cases of hydatid disease. In these cases there is always risk of hæmorrhage, and it has been recommended that the lung tissue should be penetrated by the actual cautery, rather than with the knife. Unless adhesions have formed between the two layers of the pleura, the pleural cavity must necessarily be opened, and there is the further risk of pneumothorax, and possibly of septic infection. It is therefore advisable to suture the lung to the opening in the thoracic wall, and wait for adhesions to form before perforating the lung.

The routine methods of physical examination—inspection, palpation, percussion, and auscultation—are nowhere more important than they are in the diagnosis of diseases of

the lungs. It is essential, too, that in every case the two sides of the chest should be compared with one another, and that the wide variations that may be met with under normal conditions in different persons and at different ages should be kept in mind when the chest is being examined. On *inspection* the thorax will be seen to be enlarged and barrel-shaped in emphysema, in which the volume of the lungs is increased by dilatation of their alveoli, or in an acute attack of asthma, or when a large pleural effusion or mediastinal tumour is present. The chest-wall will be flattened or sunken, on the other hand, over an area of lung that has collapsed or become fibrosed, as often happens in chronic pulmonary tuberculosis. The respiratory movements of the chest-wall will be lessened, or even absent, over a part or the whole of the affected side in such acute disorders as pleurisy, pneumonia, or pleural effusion, or in more chronic disease where the underlying lung is fibrosed, or is crushed to one side by a mediastinal tumour; and by the use of the x-rays a corresponding loss of movement or displacement of the Diaphragm on the affected side can often be observed. Under normal conditions the intercostal spaces are a little depressed; but they may be obliterated or even bulging on that side when a large effusion or new growth fills up one of the pleural cavities.

On *palpation* the hand can be used to verify the eye's impressions as to the degree of movement on respiration of any part of the chest-wall. The facility with which the vibrations produced by the voice are conducted from the larynx by the underlying lung to the hand (in the form of *vocal fremitus*) can also be tested. The vocal fremitus is commonly much increased over the consolidated area in pneumonia or in fibrosis of the lung, and much diminished over a pleural effusion when the lung is pushed up by the fluid towards the top of the pleural cavity. It is also diminished, but to a less extent, in emphysema, and in bronchitis when the bronchi are blocked by secretion. In bronchitis the bubbling of the secretion in the tubes can often be felt by a hand placed on the chest-wall as the patient breathes; and in chronic pleurisy the friction of the two roughened pleural surfaces against one another can sometimes be felt in the same way.

On *percussion*, the normal resonance of the pulmonary tissue is found to be increased in emphysema, and in pneumothorax (page 1078) this hyper-resonance may be still further increased. The resonance is lessened in any condition causing collapse or solidification of the lung-tissue, or when its place is taken by fluid (pleural effusion) or some solid growth (mediastinal tumour). Thus dulness on percussion at the bases of the lungs is common in the hypostatic congestion of the bases seen in heart-failure; dulness at the right base is often due to compression of the lung by enlargement of the liver; some dulness at the apex of a lung is frequently met with in tuberculosis of that part, before the disease has progressed very far. Complete dulness over one side of the chest, back and front alike, except at the apex, is common when a large pleural effusion has taken the lung's place. Von Korányi, Grocco, and others, have drawn attention to a triangular patch of dulness along the vertebral column (the paravertebral triangle of dulness) on the unaffected side in pleural effusion; this triangle of dulness is said to be absent in other conditions causing loss of pulmonary resonance on percussion, and is due to shifting over of the contents of the posterior mediastinum towards the sound side. The apex of this triangle is in the middle line at the upper level of the fluid effusion; its base, some two to four inches in length, runs horizontally outwards from the middle line at the level where the pulmonary resonance normally comes to an end.

On *auscultation* of the lungs, both in health and disease, the variety of sounds to be heard is very great. It is impossible to give adequate consideration to them here, and for further information reference should be made to the text-books dealing with the subject.*

ORGANS OF DIGESTION

The apparatus for the digestion of the food (apparatus digestorius) consists of the alimentary canal and of certain accessory organs.

The **alimentary canal** is a musculo-membranous tube, about thirty feet in length, extending from the mouth to the anus, and lined throughout its entire extent by mucous membrane. It has received different names in the various parts of its course: at its commencement is the *mouth*, where provision is made for the mechanical division of the food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*); beyond this are the organs of deglutition, the *pharynx* and the *œsophagus*, which convey the food into the *stomach* in which the principal chemical changes occur, and in which the reduction and solution of the food take place; the stomach is followed by the *small intestine*, which is divided for purposes of description into three parts, the *duodenum*, the *jejunum*, and *ileum*, and in which the

* See especially *Auscultation and Percussion*, by Samuel Gee. Edit. 5, 1906. Smith, Elder & Co.

nutritive principles of the food are separated and absorbed; finally the small intestine terminates in the *large intestine*, which is made up of *cæcum, colon, rectum*, and *anal canal*, the last terminating on the surface of the body at the *anus*. The *accessory organs* are the *teeth*, for purposes of mastication; the three pairs of *salivary glands*—the *parotid, submaxillary*, and *sublingual*—the secretion from which mixes with the food in the mouth and converts it into a bolus and acts chemically on one of its constituents; the *liver* and *pancreas*, two large glands in the abdomen, the secretions of which, in addition to that of numerous minute glands in the walls of the alimentary canal, assist in the process of digestion.

Alimentary Canal

Salivary glands	Parotid. Submaxillary. Sublingual.	Liver. Pancreas.

The Mouth

The **mouth** (cavum oris) is placed at the commencement of the alimentary canal (fig. 899); it is a nearly oval-shaped cavity, in which the mastication of the food takes place. It consists of two parts: an outer, smaller portion, the vestibule (vestibulum oris), and an inner, larger part, the cavity proper of the mouth (cavum oris proprium).

The *vestibulum oris* is a slit-like space, bounded in front and laterally by the lips and cheeks; behind and internally by the gums and teeth. It communicates with the surface of the body by the *aperture of the mouth*. Above and below, it is limited by the reflection of the mucous membrane from the lips and cheeks to the gum covering the upper and lower alveolar arch respectively. It receives the secretion from the parotid glands, and communicates, when the jaws are closed, with the cavum oris by an aperture on either side behind the wisdom teeth, and by narrow clefts between opposing teeth.

The *cavum oris proprium* is bounded laterally and in front by the alveolar arches with their contained teeth; behind, it communicates with the pharynx by a constricted aperture termed the *isthmus faucium*. It is roofed in by the hard and soft palates, while the greater part of the floor is formed by the tongue, the remainder being completed by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum lining the inner aspect of the mandible. It receives the secretion from the submaxillary and sublingual glands.

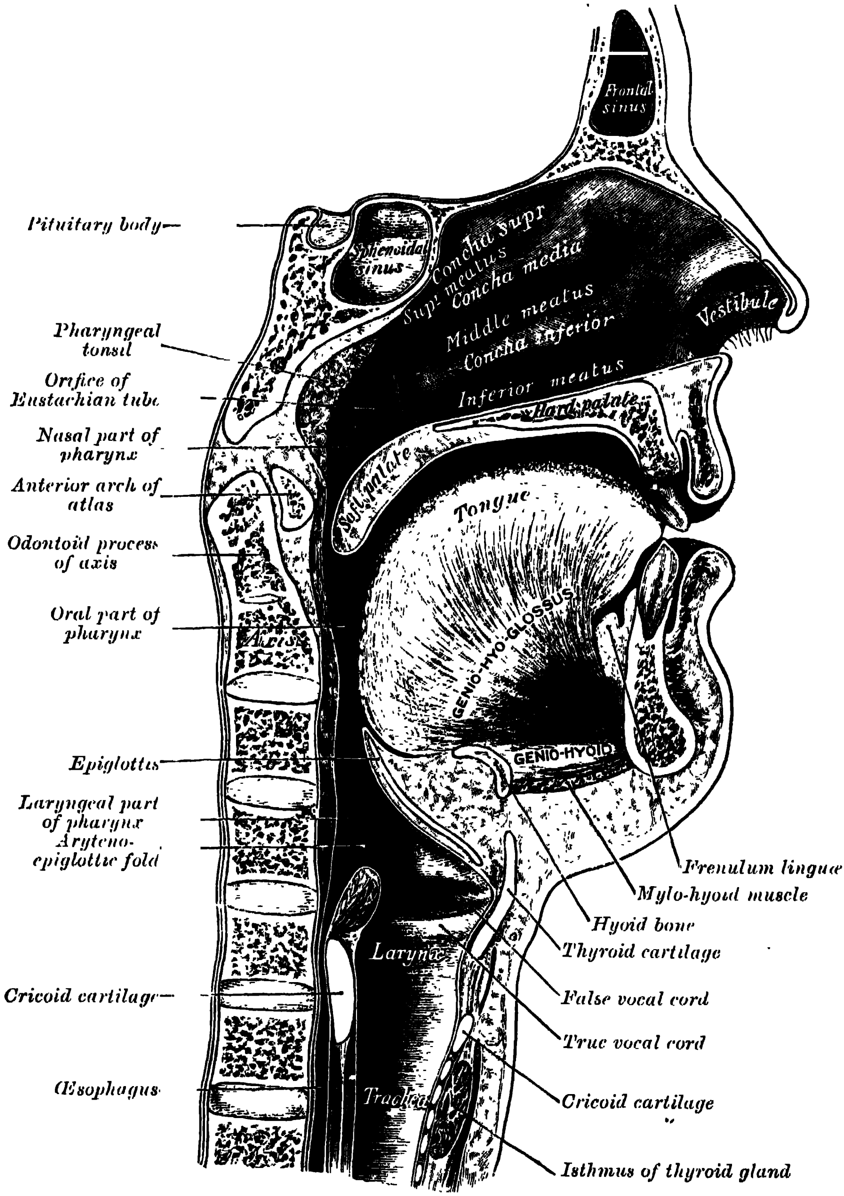
The *mucous membrane* lining the mouth is continuous with the integument at the free margin of the lips, and with the mucous lining of the pharynx behind; it is of a rose-pink tinge during life, and very thick where it overlies the hard parts bounding the cavity. It is covered by stratified epithelium.

The **lips** (labia oris) are two fleshy folds which surround the orifice of the mouth (rima oris), formed externally of integument and internally of mucous membrane, between which are found the Orbicularis oris muscle, the coronary vessels, some nerves, areolar tissue, and fat, and numerous small labial glands. The inner surface of each lip is connected in the middle line to the gum of the corresponding jaw by a fold of mucous membrane, the *frenulum*—the upper being the larger of the two.

The *labial glands* are situated between the mucous membrane and the Orbicularis oris, round the orifice of the mouth. They are circular in form, and about the size of small peas; their ducts opening by minute orifices upon the mucous membrane. In structure they resemble the salivary glands.

The **cheeks** (buccæ) form the sides of the face, and are continuous in front with the lips. They are composed externally of integument; internally

FIG. 899.—Sagittal section of nose, mouth, pharynx, and larynx.



of mucous membrane; and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

The *mucous membrane* lining the cheek is reflected above and below upon the gums, and is continuous behind with the lining membrane of the soft palate. Opposite the second molar tooth of the upper jaw is a papilla, the summit of which presents the aperture of the duct of the parotid gland. The principal muscle of the cheek is the Buccinator; but numerous other muscles enter into its formation, viz. the Zygomatici, Risorius, and Platysma.

The *buccal glands* are placed between the mucous membrane and Buccinator muscle: they are similar in structure to the labial glands, but smaller. About five of larger size than the rest are placed between the Masseter and Buccinator muscles around the distal

extremity of Stenson's duct; their ducts open in the mouth opposite the last molar tooth. They are called *molar glands*.

The **gums** (gingivæ) are composed of a dense fibrous tissue, closely connected to the periosteum of the alveolar processes, and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remarkable for its limited sensibility. Around the necks of the teeth this membrane presents numerous fine papillæ, and is reflected into the alveoli, where it is continuous with the periosteal membrane lining these cavities.

Applied Anatomy.—The gums are occasionally the seat of considerable hypertrophy, forming a lobulated vascular fold growing up in front and behind the teeth, so as almost to bury them. They may also become swollen and congested, bleeding freely, and often becoming ulcerated. The condition is known as *spongy gums*, and may occur in scurvy, in stomatitis and dyspepsia, in ill-fed tuberculous children, and from the administration of mercury; the gums are very tender, mastication is painful, and there is often considerable fœtor. The margin of the gum presents an interrupted blue line in cases of lead-poisoning. The collection of tartar, which consists of the secretion from the gums, mixed with fragments of food and salivary salts, may give rise to a condition known as *pyorrhœa alveolaris*, which is an inflammatory condition of the gums, followed by the gradual absorption of the alveolus and the falling out of the teeth. Fibrous tumours (epulis), myeloid growths and epitheliomata are met with in the gums.

The **palate** (palatum) forms the roof of the mouth: it consists of two portions, the hard palate in front, the soft palate behind.

The **hard palate** (palatum durum) is bounded in front and at the sides by the alveolar arches and gums; behind, it is continuous with the soft palate. It is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent. Along the middle line is a linear ridge or raphe (raphe palati), which terminates anteriorly in a small papilla corresponding with the inferior opening of the anterior palatine fossa. On either side and in front of the raphe the mucous membrane is thick, pale in colour, and corrugated; behind, it is thin, smooth, and of a deeper colour: it is covered with squamous epithelium, and furnished with numerous glands (palatal glands), which lie between the mucous membrane and the surface of the bone.

The **soft palate** (palatum molle) is a movable fold, suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position (i.e. relaxed and pendent) its anterior surface is concave, continuous with the roof of the mouth, and marked by a median ridge or raphe, which indicates its original separation into two lateral halves. Its posterior surface is convex, and continuous with the mucous membrane covering the floor of the nasal fossæ. Its upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its lower border is free.

Hanging from the middle of its lower border is a small, conical, pendulous process, the *uvula* (uvula palatina); and arching outwards and downwards from the base of the uvula on either side are two curved folds of mucous membrane, containing muscular fibres, called the *arches* or *pillars of the soft palate* or *pillars of the fauces*.

The *anterior pillar* (arcus glossopalatinus) on either side runs downwards, outwards, and forwards to the side of the base of the tongue, and is formed by the projection of the Palato-glossus muscle, covered by mucous membrane.

The *posterior pillar* (arcus pharyngopalatinus) is larger and projects farther inwards than the anterior; it runs downwards, outwards, and backwards to the side of the pharynx, and is formed by the projection of the Palato-pharyngeus muscle, covered by mucous membrane. The anterior and posterior pillars are separated below by a triangular interval, in which the tonsil is lodged.

The aperture by which the mouth communicates with the pharynx is called the *isthmus faucium*. It is bounded, above, by the soft palate; below,

by the dorsum of the tongue; and on either side, by the anterior pillar of the fauces.

The *aponeurosis of the soft palate* is a thin but firm fibrous layer attached above to the posterior border of the hard palate, and becoming thinner towards the free margin of the soft palate. Laterally, it is continuous with the pharyngeal aponeurosis. It forms the framework of the soft palate, and is joined by the tendons of the Tensor palati muscles.

The *muscles of the soft palate* are five on each side: the Levator palati, Tensor palati, Azygos uvulæ, Palato-glossus, and Palato-pharyngeus (see pages 484, 485). The following is the relative position of the structures in a dissection of the soft palate from the posterior or pharyngeal to the anterior or oral surface. Immediately beneath the mucous membrane is a thin stratum of muscular fibres, the posterior fasciculus of the Palato-pharyngeus muscle, joining with its fellow of the opposite side in the middle line. Beneath this is the Azygos uvulæ, consisting of two rounded fleshy fasciculi which are in contact with each other in the median line of the soft palate. Next comes the aponeurosis of the Levator palati joining with that of the muscle of the opposite side in the middle line. Fourthly, is the anterior fasciculus of the Palato-pharyngeus, thicker than the posterior, and separating the Levator palati from the next muscle, the Tensor palati. This muscle terminates in a tendon which, after winding round the hamular process, expands into a broad aponeurosis in the soft palate, anterior to the other muscles which have been enumerated. Finally there is a thin muscular stratum, the Palato-glossus muscle, placed in front of the aponeurosis of the Tensor palati, and separated from the oral mucous membrane by glands and adenoid tissue.

The *mucous membrane of the soft palate* is thin, and covered with squamous epithelium on both surfaces, excepting near the orifice of the Eustachian tube, where it is columnar and ciliated.* Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on its posterior surface and round the uvula.

Vessels and Nerves.—The *arteries* supplying the palate are the descending palatine branch of the internal maxillary, the ascending palatine branch of the facial, and the palatine branch of the ascending pharyngeal. The *veins* terminate chiefly in the pterygoid and tonsillar plexuses. The *lymphatic vessels* pass to the deep cervical glands. The *motor nerves* are chiefly derived from the pharyngeal plexus, the Tensor palati, however, receiving a special branch from the otic ganglion. The *sensory* filaments are derived from the descending palatine and naso-palatine nerves and from the glosso-pharyngeal.

Applied Anatomy.—The occurrence of a congenital cleft in the palate has been already referred to as a defect in development (page 285). Acquired perforations of the palate are almost invariably the result of the breaking down of syphilitic gummata. The ensuing ulceration may continue until practically the whole palate, both hard and soft, has been destroyed Tumours of the palate, both innocent and malignant, are occasionally seen.

Paralysis of the soft palate often occurs after diphtheria. It gives rise to a change in the voice, which becomes nasal, and to the regurgitation of fluids down the nose when their swallowing is attempted. On inspection, the palate is seen to hang flaccid and motionless when phonation or deglutition are attempted; it is also anæsthetic.

The Teeth (Dentes) (figs. 900 to 903)

The human subject is provided with two sets of teeth, which make their appearance at different periods of life. Those of the first set appear in childhood, and are called the *temporary, deciduous,* or *milk teeth.* Those of the second set, which also appear at an early period, continue until old age, and are named *permanent.*

The *temporary teeth* are twenty in number: four incisors, two canines, and four molars, in each jaw.

The *permanent teeth* are thirty-two in number: four incisors, two canines, four bicuspids, and six molars, in each jaw.

* According to Klein, the mucous membrane on the nasal surface of the soft palate in the fœtus is covered throughout by columnar ciliated epithelium, which subsequently becomes squamous; some anatomists state that it is covered with columnar ciliated epithelium, except at its free margin, throughout life.

The dental formulæ may be represented as follows :

Temporary Teeth

	mol.	can.	in.	in.	can.	mol.	
Upper jaw . .	2	1	2	2	1	2	Total 20
Lower jaw . .	2	1	2	2	1	2	

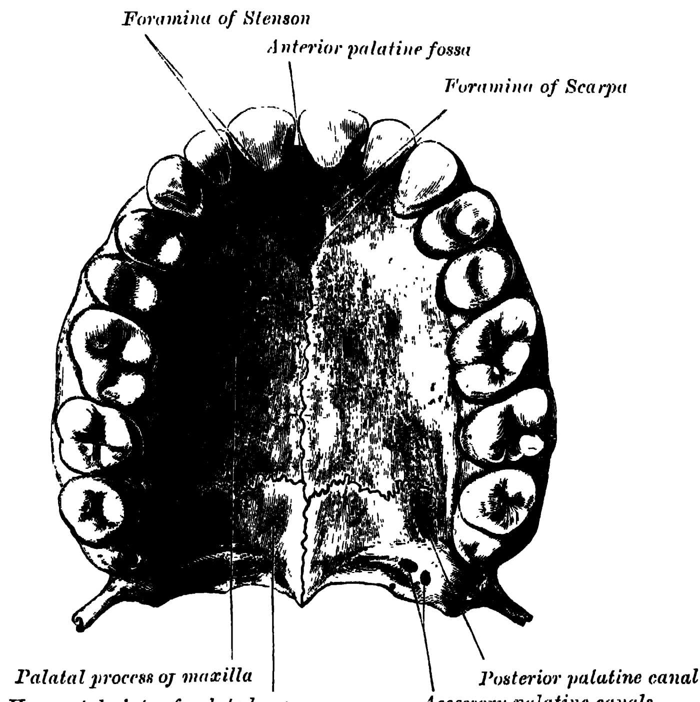
Permanent Teeth

	mol.	bic.	can.	in.	in.	can.	bic.	mol.	
Upper jaw .	3	2	1	2	2	1	2	3	Total 32
Lower jaw .	3	2	1	2	2	1	2	3	

General characters.—Each tooth consists of three portions : the *crown*, or *body* (corona dentis), projecting above the gum ; the *root* (radix dentis), consisting of one or more *fangs*, entirely concealed within the alveolus ; and the *neck* (collum dentis), the constricted portion between the crown and root.

The *roots of the teeth* are firmly implanted within the alveoli ; these depressions are lined with periosteum which is reflected on to the tooth at the point of the fang, and covers it as far as the neck. At the margin of the alveolus, the periosteum becomes continuous with the fibrous structure of the gums.

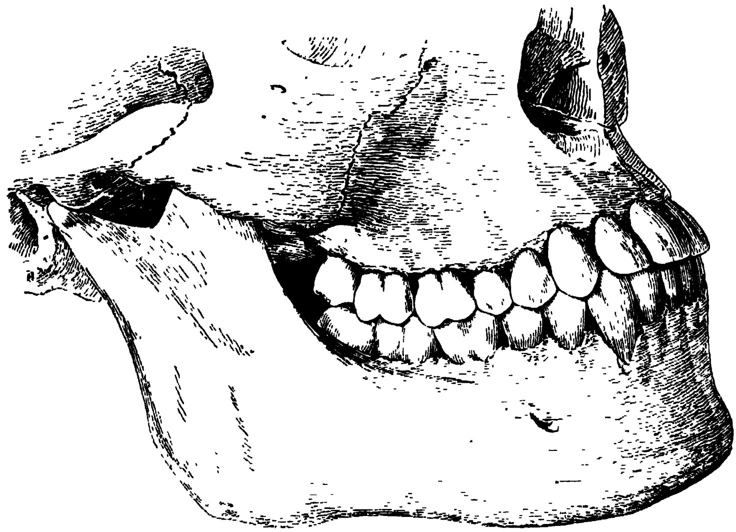
Fig. 900.—Permanent teeth of upper jaw, seen from below.



In consequence of the curve of the dental arch, such terms as anterior, posterior, internal, and external, as applied to the teeth, are misleading and confusing. Special terms are therefore applied to the different surfaces of a tooth : that surface which is directed towards the lips or cheek is known as the *labial* surface (facies labialis) ; that which is directed towards the tongue is described as the *lingual* surface (facies lingualis) ; that surface which is directed towards the mesial line, supposing the teeth were arranged in a straight line outwards from the central incisor, is known as the *proximal* surface ; while that which is directed away from the mesial line is called the *distal* surface.

The teeth in the maxillæ form a larger arch than those in the mandible, so that they slightly overlap those of the mandible both in front and at the sides in the normal condition. Since the upper central incisors are wider than the lower, the other teeth in the upper jaw are thrown somewhat distally, and the two sets do not quite correspond to each other when the mouth is

FIG. 901.—Side views of the teeth and jaws. (Cryer.)



closed: thus the canine tooth of the upper jaw rests partly on the canine of the lower jaw and partly on the first premolar, and the cusps of the molar teeth of the upper jaw lie behind the corresponding cusps of the molar teeth of the lower jaw. The two series, however, terminate at nearly the same point behind; this is mainly because the molars in the upper jaw are the smaller.

PERMANENT TEETH (DENTES PERMANENTES)

The **incisors,** or cutting teeth (dentes incisivi), are so named from their presenting a sharp cutting edge, adapted for biting the food. They are eight in number, and form the four front teeth in each jaw.

The *crown* is directed vertically, and is chisel-shaped, being bevelled at the expense of its lingual surface, so as to present a sharp horizontal cutting edge, which, before being subjected to attrition, presents three small prominent points separated by two slight notches. It is convex, smooth, and highly polished on its labial surface; concave on its lingual surface, where, in the teeth of the upper jaw, it is frequently marked by a V-shaped eminence, situated near the gum, the apex, where the two arms of the eminence meet, being directed upwards. This is known as the *basal ridge* or *cingulum.* The *neck* is constricted. The *fang* is long, single, conical, transversely flattened, thicker in front than behind, and slightly grooved on either side in the longitudinal direction.

The *incisors of the upper jaw* are larger and stronger than those of the lower jaw. They are directed obliquely downwards and forwards. The two central ones are larger than the two lateral, and their roots are more rounded.

The *incisors of the lower jaw* are smaller than those of the upper jaw: the two central ones are smaller than the two lateral, and are the smallest of all the incisor teeth. They are placed vertically and are somewhat bevelled in front, where they have been worn down by contact with the overlapping edge of the upper teeth. The cingulum is absent.

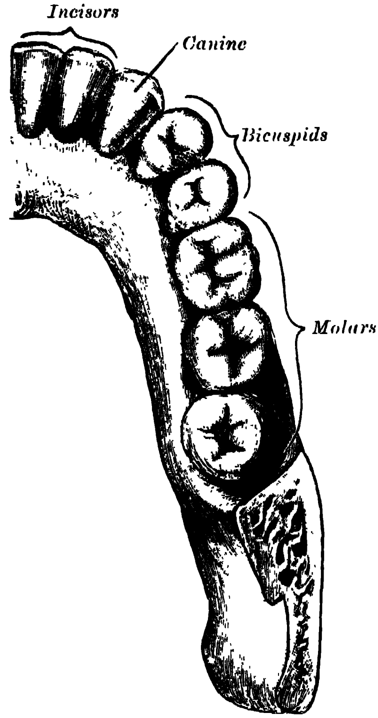
The **canine teeth** (dentes canini) are four in number, two in the upper, and two in the lower jaw; one being placed distally to each lateral incisor. They are larger and stronger than the incisors, and their fangs sink deeply into the jaws, and cause well-marked prominences upon the surface.

The *crown* is large and conical, very convex on its labial surface, a little hollowed and uneven on its lingual surface, and tapering to a blunted point or cusp, which projects beyond the level of the other teeth. The *root* is single, but longer and thicker than that of the incisors, conical in form, compressed laterally, and marked by a slight groove on each side.

The *upper canine teeth* (popularly called *eye-teeth*) are larger and longer than the lower, and situated a little distally to them. They usually present a distinct basal ridge.

The *lower canine teeth* are placed mesially to the upper, so that their summits correspond to the interval between the upper canine teeth and the neighbouring incisors on each side.

FIG. 902.—Permanent teeth of right half of mandible seen from above.



The **bicuspid teeth** or **premolars** (dentes premolares) are eight in number: four in each jaw, two being placed distally to each of the canine teeth. They are smaller and shorter than the canines.

The *crown* is compressed proximodistally, and surmounted by two pyramidal eminences or cusps, a labial and a lingual, separated by a groove: hence their name, *bicuspid*. Of the two cusps the labial is larger and more prominent than the lingual. The *neck* is oval. The *root* is generally single, compressed, and presents on either side a deep groove, which indicates a tendency in the root to become double. The apex is generally bifid.

The *upper bicuspids* are larger, and present a greater tendency to the division of their roots than the lower: this is especially marked in the first upper bicuspid.

FIG. 903.—Permanent teeth. Right side. (Burchard.)

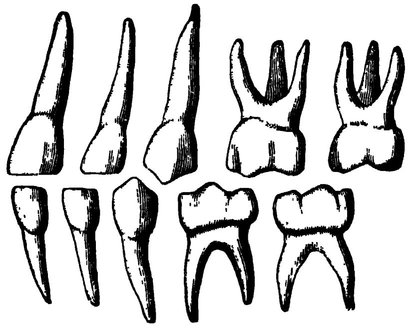
The **molar teeth** (dentes molares) are the largest of the permanent set, and are adapted from the great breadth of their crowns for grinding and pounding the food. They are twelve in number: six in each jaw, three being placed distally to each of the second bicuspids.

The *crown* is nearly cubical in form, convex on its labial and lingual surfaces, flattened on its proximal and distal aspects; the upper surface is surmounted by four or five tubercles, or cusps (four in the upper, five in the lower molars), separated from each other by a crucial depression; hence the molars are sometimes termed *multicuspids*. The *neck* is distinct, large, and rounded. The *root* is subdivided into two or three fangs: three in the teeth of the upper jaw, and two in those of the lower. Each of these fangs presents an aperture at its summit.

The crown of the *first molar tooth* in the *upper jaw* has usually four cusps; the root consists of three fangs, widely separated from one another, two being labial, the other lingual.

The crown of the *first molar tooth* in the *lower jaw* is larger than that of the upper: it has five cusps, and its root consists of two fangs, one being placed proximally, the other distally: they are both compressed from before backwards, and grooved on their contiguous faces, indicating a tendency to division.

Fig. 904.—Temporary teeth. Left side.



The *second molar* is a little smaller than the first. The crown has three or four cusps in the upper, and usually five in the lower jaw. The root has three fangs in the upper jaw, and two in the lower, the characters of which are similar to those of the preceding tooth.

The *third molar tooth* is called the *wisdom-tooth* or *dens sapientiæ* (dens serotinus), from its late appearance through the gum. Its crown is nearly as large as that of the second molar, but is smaller than that of the first. In the upper jaw it is usually furnished with three cusps, the two lingual ones being blended; in the lower jaw there are five cusps as in the other molars. The root is generally single, short, conical, slightly curved, and grooved so as to present traces of a subdivision into three fangs in the upper, and two in the lower jaw.

Temporary Teeth (Dentes decidui) (fig. 904)

The **temporary,** or **milk teeth,** are smaller than, but, generally speaking, resemble in form, the teeth which bear the same names in the permanent set. The hinder of the two temporary molars is the largest of all the milk teeth, and is succeeded by the second permanent bicuspid. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five. The fangs of the temporary molar teeth are smaller and more divergent than those of the permanent set, but in other respects bear a strong resemblance to them.

Structure of the Teeth

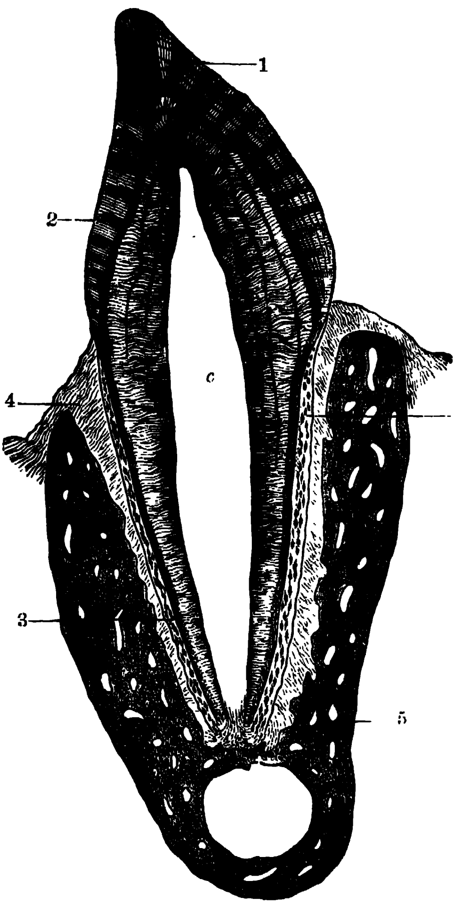
On making a vertical section of a tooth (fig. 905), a cavity will be found in the interior of the crown and the centre of each fang; it opens by a minute orifice at the extremity of the latter. In shape it corresponds somewhat with that of the tooth; it forms what is called the *pulp cavity* (cavum dentis), and contains a soft, highly vascular, and sensitive substance, the *dental pulp* (pulpa dentis). The pulp consists of a loose connective tissue consisting of fine fibres and cells; it is richly supplied with vessels and nerves, which enter the cavity through the small aperture at the point of each fang. Some of the cells of the pulp permeate the matrix, and others are arranged as a layer on the wall of the pulp cavity. The latter cells are named the *odontoblasts of Waldeyer*, and, during the development of the tooth, are columnar in shape, but later on, after the dentine is fully formed, they become flattened and resemble osteoblasts. They have two fine processes, the outer one passing into a dental tubule, the inner being continuous with the processes of the connective-tissue cells of the pulp matrix.

The solid portion of the tooth consists of (1) the *ivory* or *dentine*, which forms the bulk of the tooth; (2) the *enamel*, which covers the exposed part of the crown; and (3) a thin layer, the *cement* or *crusta petrosa*, which is disposed on the surface of the fang.

The *ivory*, or *dentine* (substantia eburnea) (fig. 907), forms the principal mass of a tooth; in its central part is the cavity enclosing the pulp. It is a modification of osseous tissue, from which it differs, however, in structure. On microscopic examination it is seen to consist of a number of minute wavy and branching tubes, the *dentinal tubules*, imbedded in a dense homogeneous substance, the *matrix*.

The *dentinal tubules* (canaliculi dentales) (fig. 908) are placed parallel with one another, and open at their inner ends into the pulp cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. These tubes vary in direction: thus in a tooth of the mandible they are vertical in the upper portion of the crown, becoming oblique and then horizontal in the neck and upper part

Fig. 905.—Vertical section of a tooth *in situ*. (15 diameters.)



is placed in the pulp cavity, opposite the cervix or neck of the tooth; the part above it is the crown, that below is the root (fang). 1. Enamel with radial and concentric markings. 2. Dentine with tubules and incremental lines. 3. Cement or crusta petrosa, with bone corpuscles. 4. Dental periosteum. 5. Mandible.

Fig. 906.—Vertical section of a molar tooth.

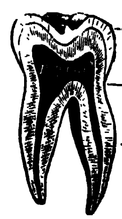


Fig. 907.—Vertical section of a bicuspid tooth. (Magnified.)

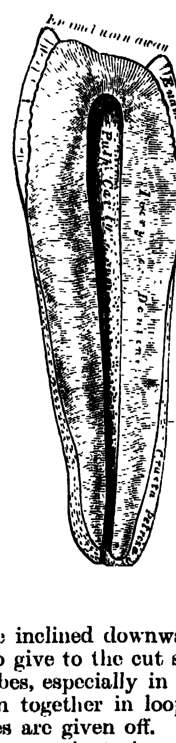
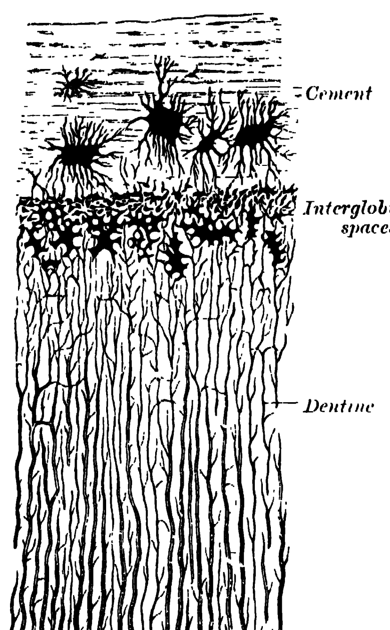


of the root, while towards the lower part of the root they are inclined downwards. In their course they divide and subdivide dichotomously, so as to give to the cut surface of the dentine a striated appearance. From the sides of the tubes, especially in the fang, ramifications of extreme minuteness are given off, which join together in loops in the matrix, or terminate in small dilatations, from which branches are given off. Near the periphery of the dentine, the finer ramifications of the tubules terminate imperceptibly by free ends. The dentinal tubules have comparatively thick walls, consisting, in addition to the intertubular tissue, of an elastic homogeneous membrane, the *dentinal sheath of Neumann*, which resists the action of acids; they contain slender cylindrical prolongations of the odontoblasts, first described by Tomes, and named *Tomes's fibres* or *dentinal fibres*.

The *matrix* is translucent, and contains the chief part of the earthy matter of the dentine. In it are a number of fine fibrils, which are continuous with the fibrils of the dental pulp. After the earthy matter has been removed by steeping a tooth in weak acid, the animal basis remaining may be torn into laminæ which run parallel with the pulp cavity, across the direction of the tubes. A section of dry dentine often displays a series of somewhat parallel lines—the *incremental lines of Salter*. These lines are composed of imperfectly calcified dentine arranged in layers. In consequence of the imperfection in the calcifying process, little irregular cavities are left, termed *interglobular spaces* (spatia interglobularia). Normally a series of these spaces is found towards the outer surface of the dentine, where they form a layer, which is sometimes known as the *granular layer* (fig. 907). They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the *lines of Schreger*, and are due to the optical effect of simultaneous curvature of the dentinal fibres.

Chemical Composition.—According to Berzelius and von Bibra, dentine consists of 28 parts of animal and 72 of earthy matter. The animal matter is converted by boiling into gelatin. The earthy matter consists of phosphate of lime, carbonate of lime, a trace of fluoride of calcium, phosphate of magnesia, and other salts.

FIG. 908.—Transverse section of a portion of the root of a canine tooth. (Magnified 300 diameters.)



The *enamel* (substantia adamantina) is the hardest and most compact part of the tooth, and forms a thin crust over the exposed part of the crown, as far as the commencement of the fang. It is thickest on the grinding surface of the crown, until worn away by attrition, and becomes thinner towards the neck. It consists of minute hexagonal rods or columns termed *enamel fibres* or *enamel prisms* (prismata adamantina). They lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception; and forming the free surface of the crown by the other extremity. The columns are directed vertically on the summit of the crown, horizontally at the sides; they are about $\frac{1}{5600}$ of an inch in diameter, and pursue a more or less wavy course. Each column is a six-sided prism and presents numerous dark transverse shadings; these shadings are probably due to the manner in which the columns are developed in successive stages, producing shallow constrictions, as will be subsequently explained. Another series of lines, having a brown appearance, the *parallel striæ* or *coloured lines of Retzius*, is seen on section. According to Ebner, they are produced by air in the interprismatic spaces; others believe that they are the result of true pigmentation.

Numerous minute interstices intervene between the enamel fibres near their dentinal ends, a provision calculated to allow of the permeation of fluids from the dentinal tubule into the substance of the enamel.

Chemical Composition.—According to von Bibra, enamel consists of 96·5 per cent. of earthy matter, and 3·5 per cent. of animal matter.* The earthy matter consists of phosphate of lime, with traces of fluoride of calcium, carbonate of lime, phosphate of magnesia, and other salts.

The *crusta petrosa*, or *cement* (substantia ossea), is disposed as a thin layer on the roots of the teeth, from the termination of the enamel to the apex of the fang, where it is usually very thick. In structure and chemical composition it resembles bone. It contains, sparingly, the lacunæ and canaliculi which characterise true bone; the lacunæ placed near the surface have the canaliculi radiating from the side of the lacunæ towards the periodontal membrane; and those more deeply placed join with the adjacent dental tubules. In the thicker portions of the crusta petrosa, the lamellæ and Haversian canals peculiar to bone are also found.

* Tomes disputes this, and says that enamel is an inorganic substance, and that what has been regarded as organic matter is in reality merely water in combination with the salts.

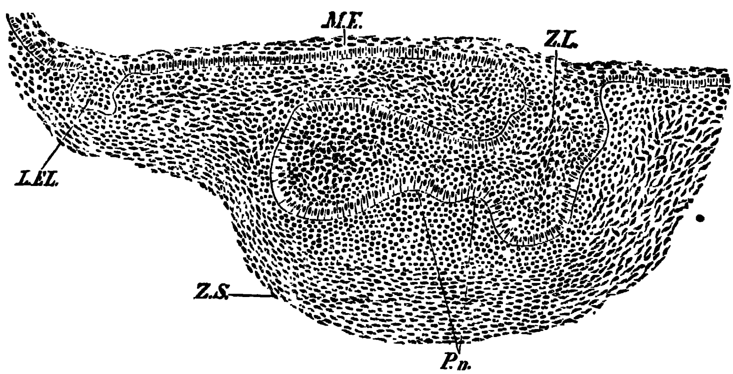
As age advances, the cement increases in thickness, and gives rise to those bony growths, or exostoses, so common in the teeth of the aged; the pulp cavity also becomes partially filled up by a hard substance, intermediate in structure between dentine and bone (*osteo-dentine*, Owen; *secondary dentine*, Tomes). It appears to be formed by a slow conversion of the dental pulp, which shrinks, or even disappears.

Development of the Teeth (figs. 909 to 912)

In describing the development of the teeth, the mode of formation of the temporary or milk teeth must first be considered, and then that of the permanent series.

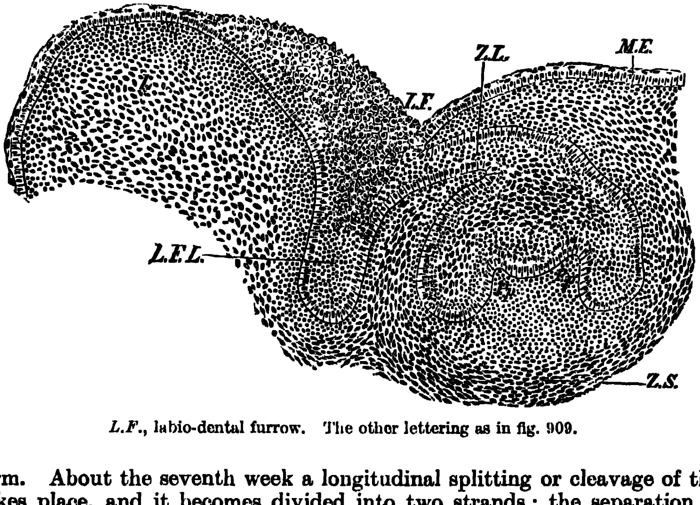
Development of the temporary teeth.—The development of these teeth begins at a very early period of fœtal life—about the sixth week. It commences as a thickening of the epithelium along the line of the future jaw, the thickening being due to a rapid multiplication of the more deeply situated epithelial cells. As the cells multiply they extend into the subjacent mesoderm, and thus form a semicircular ridge or strand of cells imbedded

Fig. 909.—Sagittal section through the first lower temporary molar of a human embryo 30 mm. long. (Röse.) $\frac{100}{1}$.



L.E.L., labio-dental lamina, here separated from and well in advance of the dental lamina; *Z.L.*, placed over the shallow dental furrow, points to the dental lamina, which is spread out below to form the enamel germ of the future tooth; *P.p.*, bicuspidate papilla, capped by the enamel germ; *Z.S.*, condensed tissue forming dental sac; *M.E.*, mouth-epithelium.

Fig. 910.—Similar section through the canine tooth of an embryo 40 mm. long. (Röse.) $\frac{100}{1}$.



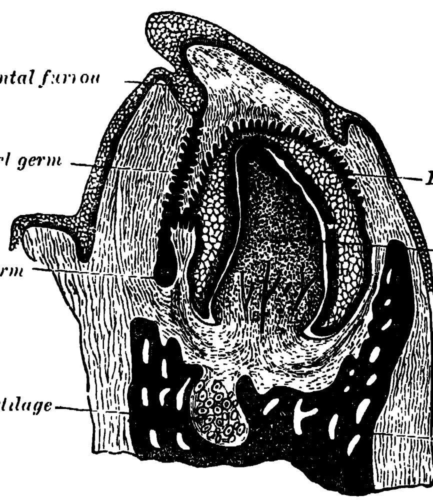
L.F., labio-dental furrow. The other lettering as in fig. 909.

in mesoderm. About the seventh week a longitudinal splitting or cleavage of this strand of cells takes place, and it becomes divided into two strands; the separation begins in front and extends laterally: the process occupying four or five weeks. Of the two strands thus formed, the *outer* or *labial* forms the future labio-dental furrow, and is therefore termed the *labio-dental lamina*; while the other, the *inner* or *lingual*, is the ridge of cells in connection with which the teeth, both temporary and permanent, are developed. Hence it is known as the *dental lamina* or *common dental germ*. It forms a flat band of cells, which

grows into the substance of the embryonic jaw, at first horizontally inwards, and then, as the teeth develop, vertically, i.e. upwards in the upper jaw, and downwards in the lower jaw. While still maintaining a horizontal direction, it has two edges; one, the *attached edge*, which is continuous with the epithelium lining the mouth; the other, the *free edge*, projecting inwards, and imbedded in the mesodermal tissue of the embryonic jaw. Along its line of attachment to the buccal epithelium is a shallow groove, the *dental furrow*.

About the ninth week the dental lamina begins to develop enlargements along its free border. These are ten in number in each jaw, and each corresponds to a future milk tooth. They consist of masses of epithelial cells; and the cells of the deeper part—that is, the part farthest from the margin of the jaw—increase rapidly and spread out in all directions. Each mass thus comes to assume a club shape, connected with the general epithelial lining of the mouth by a narrow neck, embraced by mesoderm. They are now known as *special dental germs*. After a time the lower expanded portion inclines outwards, so as to form an angle with the superficial constricted portion, which is sometimes known as the *neck* of the special dental germ. About the tenth week the mesodermal tissue beneath these special dental germs becomes differentiated into papillæ; these grow upwards, and come in contact with the epithelial cells of the special dental germs, which become folded over them like a hood or cap. There is, then, at this stage a papilla (or papillæ) which has already begun to assume somewhat the shape of the crown of the future tooth, and from which the dentine and pulp of the tooth are formed, surmounted by a dome or cap of epithelial cells, from which the enamel is derived.

FIG. 911.—Vertical section of the mandible of an early human fœtus. (Magnified 25 diameters.)



In the meantime, while these changes have been going on, the dental lamina has been extending backwards behind the special dental germ corresponding to the second molar tooth of the temporary set, and at about the seventeenth week it presents an enlargement, the special dental germ, for the first permanent molar, soon followed by the formation of a papilla in the mesodermal tissue for the same tooth. This is followed, about the sixth month after birth, by a further extension backwards of the dental lamina, with the formation of another enlargement and its corresponding papilla for the second molar. And finally the process is repeated for the third molar, its papilla appearing about the fifth year of life.

After the formation of the special dental germs, the dental lamina undergoes atrophic changes and becomes cribriform, except on the lingual and lateral aspects of each of the special germs of the temporary teeth, where it undergoes a local thickening, forming the special dental germ of each of the successional permanent teeth—i.e. the ten anterior ones in each jaw. Here the same process goes on as has been described in connection with those of the milk teeth: that is, they recede into the substance of the gum behind the germs of the temporary teeth. As they recede they become club-shaped, form an expansion at their distal extremity, and finally meet a papilla, which has been formed in the mesoderm, just in the same manner as was the case in the temporary teeth. The apex of the papilla indents the dental germ, which encloses it, and, forming a cap for it, becomes converted into the enamel, while the papilla forms the dentine and pulp of the permanent tooth.

The special dental germs consist at first of rounded or polyhedral epithelial cells; after the formation of the papillæ, these cells undergo a differentiation into three classes.

Those which are in immediate contact with the papilla become elongated, and form a layer of well-marked columnar epithelium coating the papilla. They are the cells which form the enamel fibres, and are therefore termed *enamel cells* or *adamantoblasts*. The cells of the outer layer of the special dental germ, which are in contact with the inner surface of the dental sac, presently to be described, are much shorter, cubical in form, and are named the *external enamel epithelium*. All the intermediate round cells of the dental germ between these two layers undergo a peculiar change. They become stellate in shape and develop processes, which unite to form a network into which fluid is secreted; this has the appearance of a jelly, and to it the name of enamel pulp is given. This transformed special dental germ is now known under the name of *enamel organ*.

While these changes are going on, a sac is formed around each enamel organ from the surrounding mesodermal tissue. This is known as the *dental sac*, and is a vascular membrane of connective tissue. It grows up from below, and thus encloses the whole tooth germ; as it grows it causes the neck of the enamel organ to atrophy and disappear; so that all communication between the enamel organ and the superficial epithelium is cut off. At this stage there are vascular papillæ surmounted by inverted caps of epithelial cells, the whole being surrounded by membranous sacs. The cap consists of an internal layer of cells—the enamel cells or adamantoblasts—in contact with the papilla; of an external layer of cells—the external enamel epithelium—lining the interior of the dental sac; and of an intermediate mass of stellate cells, with anastomosing processes—the enamel pulp (fig. 912).

Fig. 912.—Dental sac of a human embryo at an advanced stage of development. Partly diagrammatic.

Dentine cells. *f*. Dental papilla. *g*, *i*. Transition of the wall of the follicle into the tissue of the dental germ.

Formation of the enamel.—The enamel is formed exclusively from the enamel cells or adamantoblasts of the special dental germ, either by direct calcification of the columnar cells, which become elongated into the hexagonal rods of the enamel; or, as is believed by some, as a secretion from the adamantoblasts, within which calcareous matter is subsequently deposited.

The process begins at the apex of each cusp, at the ends of the enamel cells, in contact with the dental papilla. Here a fine globular deposit takes place, being apparently shed from the end of the adamantoblasts. It is known by the name of *enamel droplet*, and resembles keratin in its resistance to the action of mineral acids. This droplet then calcifies and forms the first layer of the enamel; a second droplet now appears and calcifies, and so on; successive droplets of keratin-like material are shed from the adamantoblasts and form successive layers of enamel, the adamantoblasts gradually receding as each layer is produced, until at the termination of the process they have almost disappeared. The intermediate cells of the enamel pulp atrophy and disappear, so that the newly formed calcified material and the external enamel epithelium come into apposition. This latter layer, however, soon disappears on the emergence of the tooth beyond the gum. After its disappearance the crown of the tooth is still covered by a distinct membrane, which remains persistent for some time. This is known as the *cuticula dentis*, or *Nasmyth's membrane*, and is believed to be the last-formed layer of enamel derived from the adamantoblasts, which has not become calcified. It forms a horny layer, which may be separated from the subjacent calcified mass by the action of strong acids. It is marked by the hexagonal impressions of the enamel prisms, and, when stained by nitrate of silver, shows the characteristic appearance of epithelium.

Formation of the dentine.—While these changes are taking place in the epithelium to form the enamel, contemporaneous changes occurring in the differentiated mesoderm of the dental papillæ result in the formation of the dentine. As before stated, the first germs of the dentine are the papillæ, corresponding in number to the teeth, formed from the soft mesodermal tissue which bounds the depressions containing the special enamel germs. The papillæ grow upwards into the enamel germs and become covered by them, both being enclosed in a vascular connective tissue, the dental sac, in the manner above described. Each papilla then constitutes the formative pulp from which the dentine and permanent pulp are developed; it consists of rounded cells, and is very vascular, and soon begins to assume the shape of the future tooth. The next step is the appearance of the *odontoblasts*, which have a relation to the development of the teeth similar to that of

the osteoblasts to the formation of bone. They are formed from the cells of the periphery of the papilla—that is to say, from the cells in immediate contact with the adamantoblasts of the special dental germ. These cells become elongated, one end of the elongated cell resting against the epithelium of the special dental germs, the other being tapered and often branched. By the direct transformation of the peripheral ends of these cells, or by a secretion from them, a layer of uncalcified matrix is formed which caps the cusp or cusps, if there are more than one, of the papillæ. In this matrix islets of calcification make their appearance, and coalescing give rise to a continuous layer of calcified material which covers each cusp and constitutes the first layer of dentine. The odontoblasts, having thus formed the first layer, retire towards the centre of the papilla, and as they do so produce successive layers of dentine from their peripheral extremities—that is to say, they form the dentinal matrix in which calcification subsequently takes place. As they thus recede from the periphery of the papilla, they leave behind them filamentous processes of cell protoplasm, provided with finer side processes; these are surrounded by calcified material, and thus form the dentinal tubules, and, by their side branches, the anastomosing tubules, whereby the dentinal tubules communicate: the processes of protoplasm contained within them, constitute the dentinal fibres (Tomes's fibres) which, as mentioned above, are found within the tubules. In this way the entire thickness of the dentine is developed, each tubule being completed throughout its whole length by a single odontoblast. The central part of the papilla does not undergo calcification, but persists as the pulp of the tooth. In this process of formation of dentine it has been shown that an uncalcified matrix is first developed, and that in this matrix islets of calcification appear which subsequently blend together to form a cap to each cusp: in like manner successive layers are produced, which ultimately become blended with each other. In certain places this blending is not complete, portions of the matrix remaining uncalcified between the successive layers; this gives rise, in the macerated tooth, to little spaces, which are the interglobular spaces alluded to above.

Formation of the cement.—The root of the tooth begins to be formed shortly before the crown emerges through the gum, but is not completed until some time afterwards. It is produced by a downgrowth of the epithelium of the dental germ, which extends almost as far as the situation of the apex of the future fang, and determines the form of this portion of the tooth. This fold of epithelium is known as the *epithelial sheath*, and on its papillary surface odontoblasts appear, which in turn form dentine, so that the dentine formation is identical in the crown and root of the tooth. After the dentine of the root has been developed, the vascular tissues of the dental sac begin to break through the epithelial sheath, and spread over the surface of the fang as a layer of bone-forming material. In this osteoblasts make their appearance, and the process of ossification goes on in identically the same manner as in the ordinary intra-membranous ossification of bone. In this way the cement is formed, and consists of ordinary bone, containing canaliculi and lacunæ.

Formation of the alveoli.—About the fourteenth week of embryonic life the dental lamina becomes enclosed in a trough or groove of mesodermal tissue, which at first is common to all the dental germs but subsequently becomes divided by bony septa into loculi, each loculus containing the special dental germ of a temporary tooth and its corresponding permanent tooth. After birth each cavity becomes subdivided, so as to form separate loculi (the future alveoli) for the milk tooth and its corresponding permanent tooth. Although at one time the whole of the growing tooth is contained in the cavity of the alveolus, the latter never completely encloses it, since there is always an aperture over the top of the crown filled by soft tissue, by which the dental sac is connected with the surface of the gum, and which in the permanent teeth is called the *gubernaculum dentis*.

Development of the permanent teeth.—The permanent teeth as regards their development may be divided into two sets: (1) those which replace the temporary teeth, and which, like them, are ten in number in each jaw; these are the *successional permanent teeth*; and (2) those which have no temporary predecessors, but are superadded distal to the temporary dental series. These are three in number on either side in each jaw, and are termed *superadded permanent teeth*. They are the three molars of the permanent set, the molars of the temporary set being replaced by the premolars or bicuspids of the permanent set. The development of the successional permanent teeth—the ten anterior ones in either jaw—has already been indicated. During their development the permanent teeth, enclosed in their sacs, come to be placed on the lingual side of the temporary teeth and more distant from the margin of the future gum, and, as already stated, are separated from them by bony partitions. As the crown of the permanent tooth grows, absorption of these bony partitions and of the fang of the temporary tooth takes place, through the agency of *osteoclasts*, which appear at this time, and finally nothing but the crown of the temporary tooth remains. This is shed or removed, and the permanent tooth takes its place.

The superadded permanent teeth are developed in the manner already described, by extensions backward of the posterior part of the dental lamina in each jaw.

Eruption.—When the calcification of the different tissues of the tooth is sufficiently advanced to enable it to bear the pressure to which it will be

afterwards subjected, eruption takes place, the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is itself pressed up by the increasing size of the fang. At the same time the septa between the dental sacs, at first fibrous in structure, ossify, and constitute the alveoli; these firmly embrace the necks of the teeth, and afford them a solid basis of support.

The eruption of the temporary teeth commences at the seventh month after birth, and is completed about the end of the second year, those of the lower jaw preceding those of the upper.

The following, according to C. S. Tomes, are the most usual times of eruption:

Lower central incisors	6 to 9 months.
Upper incisors	8 to 10 months.
Lower lateral incisors and first molars	15 to 21 months.
Canines	16 to 20 months.
Second molars	20 to 24 months.

Calcification of the permanent teeth proceeds in the following order in the lower jaw (in the upper jaw it takes place a little later): the first molar, soon after birth; the central and lateral incisors, and the canine, about six months after birth; the bicuspids, at the second year, or a little later; the second molar, about the end of the second year; the third molar, about the twelfth year.

The eruption of the permanent teeth takes place at the following periods, the teeth of the lower jaw preceding those of the upper by a short interval:

First molars	6th year.
Two central incisors	7th year.
Two lateral incisors	8th year.
First bicuspids	9th year.
Second bicuspids	10th year.
Canines	11th to 12th year.
Second molars	12th to 13th year.
'Wisdom' teeth	17th to 25th year.

Towards the sixth year, before the shedding of the temporary teeth begins, there are twenty-four teeth in each jaw, viz. the ten temporary teeth and the crowns of all the permanent teeth except the third molars.

Applied Anatomy. — As a consequence of local irritation or of chronic digestive disturbances occurring during their eruption, both the temporary and the permanent teeth may show defective development or irregular transverse furrowing and erosions; this is particularly the case with the incisors. Quite distinct from, and much less common than this, is a characteristic malformation of the two upper central permanent incisors seen in patients with inherited syphilis, and first described by Hutchinson. Here there is a crescentic notch in the anterior surface and at the cutting edge of the tooth, which is peg-shaped, stunted, and often also set obliquely in the gum, pointing either inwards or outwards. Numerous forms of innocent *tumour* arising from the teeth, or from their constituent layers, have been described under the general name of *odontoma*. *Infection* of the pulp of a tooth by bacteria gaining access thereto in consequence of dental caries gives rise to the common and very painful *alveolar abscess*; starting in the apical space between the root of the tooth and its alveolar socket, the pus from such an abscess may make its way into the antrum, or burst through the hard palate or cheek. A more superficial abscess forming between the root of a tooth and the gum is known as a *gum-boil*.

The Tongue

The **tongue** is the principal organ of the sense of taste, and is an important organ of speech; it also assists in the mastication and deglutition of the food. It is situated in the floor of the mouth, within the curve of the body of the mandible.

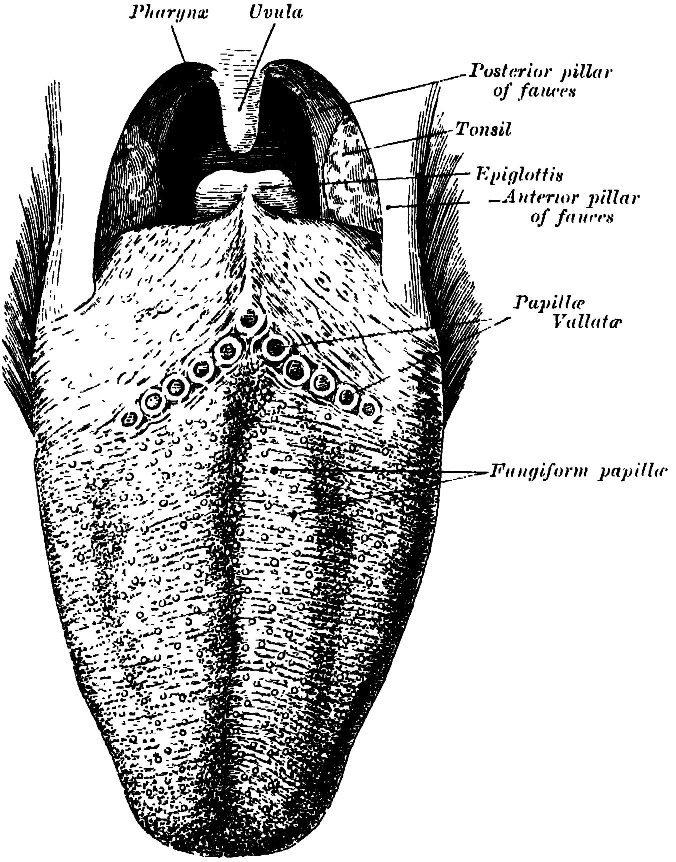
Its *base*, or *root* (radix linguæ), is directed backwards, and connected with the hyoid bone by the Hyo-glossi and Genio-hyo-glossi muscles and the hyo-glossal membrane; with the epiglottis by three folds (*glosso-epiglottic*) of mucous membrane; with the soft palate by means of the anterior pillars of the fauces; and with the pharynx by the Superior constrictors and the

mucous membrane. Its *apex* (apex linguæ), thin and narrow, is directed forwards against the inner surfaces of the lower incisor teeth. Its *under surface* (facies inferior) is connected with the mandible by the Genio-hyo-glossus muscles; from its sides, the mucous membrane is reflected to the inner surface of the gums; and from its under surface on to the floor of the mouth, where, in the middle line, it is elevated into a distinct vertical fold, the *frenulum linguæ*. To the outer side of the frenulum is a slight fold of the mucous membrane, the *plica fimbriata*, the free edge of which exhibits a series of fringe-like processes.

The tip of the tongue, part of the under surface, its sides, and dorsum are free.

The *dorsum* of the tongue (dorsum linguæ) (fig. 913) is convex, marked along the middle line by a furrow (sulcus medianus), which divides it into symmetrical

FIG. 913.—Upper surface of the tongue.



halves; this furrow terminates behind, about an inch from the base of the organ, in a depression, the *foramen cæcum*, from which a shallow groove, the *sulcus terminalis*, runs outwards and forwards on either side to the lateral margin of the tongue. The part of the dorsum of the tongue in front of this groove, forming about two-thirds of its surface, looks upwards, and is rough and covered with papillæ; the posterior third looks backwards, and is smoother, and contains numerous muciparous glands and lymphoid follicles. The foramen cæcum is the remains of the upper part of the *thyroglossal duct* or diverticulum, from which the median rudiment of the thyroid gland is developed; the pyramidal lobe of the thyroid gland indicates the position of the lower part of the duct.

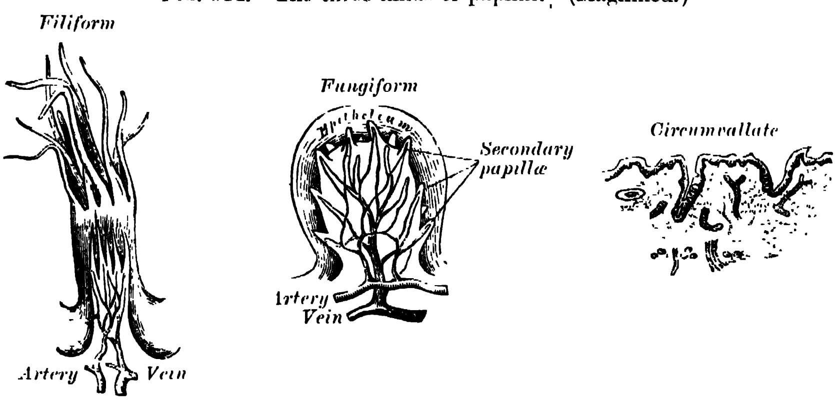
The papillæ of the tongue (papillæ linguæ) (fig. 914).—These are papillary projections of the corium. They are thickly distributed over the anterior

two-thirds of its upper surface, giving to it its characteristic roughness. The varieties of papillæ met with are the papillæ vallatæ, papillæ fungiformes, papillæ filiformes, and papillæ simplices.

The *papillæ vallatæ* are of large size, and vary from eight to twelve in number. They are situated on the dorsum of the tongue immediately in front of the foramen cæcum and sulcus terminalis, forming a row on either side; the two rows run backwards and inwards, and meet in the middle line, like the limbs of the letter V inverted. Each papilla consists of a projection of mucous membrane from $\frac{1}{20}$ to $\frac{1}{12}$ of an inch wide, attached to the bottom of a circular depression of the mucous membrane; the papilla is shaped like a truncated cone; the smaller end being directed downwards and attached to the tongue, the broader part or base projecting a little above the surface of the tongue and being studded with numerous small secondary papillæ and covered by stratified squamous epithelium. The cup-shaped depression forms a kind of fossa round the papilla, and the mucous membrane outside the fossa forms a circular elevation, named the wall (vallum).

The *papillæ fungiformes*, more numerous than the preceding, are found chiefly at the sides and apex, but are scattered irregularly and sparingly over the dorsum. They are easily recognised, among the other papillæ, by their large size, rounded eminences, and deep red colour. They are narrow at their attachment to the tongue, but broad and rounded at their free extremities, and covered with secondary papillæ.

Fig. 914.—The three kinds of papillæ. (Magnified.)



The *papillæ filiformes* cover the anterior two-thirds of the dorsum of the tongue. They are very minute, more or less conical or filiform in shape, and arranged in lines parallel with the two rows of the papillæ circumvallatæ; excepting at the apex of the organ, where their direction is transverse. Projecting from their apices are numerous filiform processes, or secondary papillæ; these are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated into dense, imbricated, brush-like processes. They contain also a number of elastic fibres, which render them firmer and more elastic than the papillæ of mucous membrane generally.

Simple papillæ, similar to those of the skin, cover the whole of the mucous membrane of the tongue, as well as the larger papillæ. They consist of closely set microscopic elevations of the corium, containing a papillary loop, covered by a layer of epithelium.

Structure of the tongue.—The tongue is partly invested by mucous membrane and a submucous fibrous layer. It consists of symmetrical halves, separated from each other in the middle line by a fibrous septum (septum linguæ). Each half is composed of muscular fibres arranged in various directions (page 480), containing much interposed fat, and supplied by vessels and nerves.

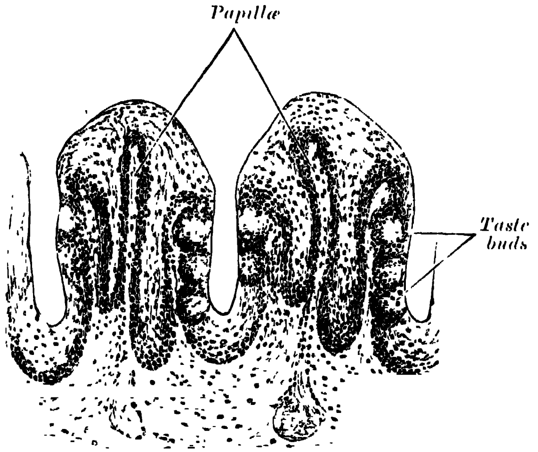
The mucous membrane differs in different parts. That covering the under surface of the organ is thin, smooth, and identical in structure with that lining the rest of the

oral cavity. The mucous membrane of the dorsum of the tongue behind the foramen cæcum and sulcus terminalis is thick and freely movable over the subjacent parts. It contains a large number of lymphoid follicles, which together constitute what is sometimes termed the *lingual tonsil* (tonsilla lingualis). Each follicle forms a rounded eminence, the centre of which is perforated by a minute orifice leading into a funnel-shaped cavity or recess; around this recess are grouped numerous oval or rounded nodules of lymphoid tissue, each enveloped by a capsule derived from the submucosa, while opening into the bottom of the recesses are also seen the ducts of mucous glands. The mucous membrane on the anterior part of the dorsum of the tongue is thin, intimately adherent to the muscular tissue, and presents numerous minute surface eminences, the *papillæ* of the tongue. It consists of a layer of connective tissue, the *corium* or *mucosa*, covered with epithelium.

The epithelium is of the scaly variety, like that of the epidermis, but is much thinner than that of the skin: the intervals between the large papillæ are not filled up by it, but each papilla has a separate investment from root to summit. The deepest cells may sometimes be detached as a separate layer, corresponding to the rete mucosum, but they never contain colouring matter.

The *corium* consists of a dense felt-work of fibrous connective tissue, with numerous elastic fibres, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels and nerves from which the papillæ are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

Fig. 915.—Section of papilla foliata of a rabbit. (Magnified.)



Structure of the papillæ (fig. 915).—The papillæ apparently resemble in structure those of the cutis, consisting of cone-shaped projections of connective tissue, covered with a thick layer of squamous epithelium, and containing one or more capillary loops, among which nerves are distributed in great abundance. If the epithelium be removed, it will be found that they are not simple elevations like the papillæ of the skin, for the surface of each is studded with minute conical processes which form secondary papillæ. In the papillæ circumvallatæ, the nerves are numerous and of large size; in the papillæ fungiformes they are also numerous, and terminate in a plexiform network, from which brush-like branches proceed; in the papillæ filiformes, their mode of termination is uncertain.

Glands of the tongue.—The tongue is provided with mucous and serous glands.

The *mucous glands* are similar in structure to the labial and buccal glands. They are found especially at the back part behind the circumvallate papillæ, but are also present at the apex and marginal parts. In this connection the glands of Blandin or Nuhn require special notice. They are situated on the under surface of the apex of the tongue, one on either side of the frenulum, where they are covered by a fasciculus of muscular fibres derived from the Stylo-glossus and Inferior lingualis. They are from half an inch to nearly an inch long, and about the third of an inch broad, and each opens by three or four ducts on the under surface of the apex (fig. 916).

The *serous glands* occur only at the back of the tongue in the neighbourhood of the taste-buds, their ducts opening for the most part into the fossæ of the circumvallate papillæ. These glands are racemose, the duct branching into several minute ducts, which terminate in alveoli, lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in the distribution of the substance to be tasted over the taste area. (Ebner.)

The *fibrous septum* consists of a vertical layer of fibrous tissue, extending throughout the entire length of the middle line of the tongue, from the base to the apex, though not quite reaching the dorsum. It is thicker behind than in front, and occasionally contains a small fibro-cartilage, about a quarter of an inch in length. It is well displayed by making a vertical section across the organ.

The *hyoglossal membrane* is a strong fibrous lamina, which connects the under surface of the base of the tongue to the body of the hyoid bone. This membrane receives, in front, some of the fibres of the Genio-hyo-glossus muscles.

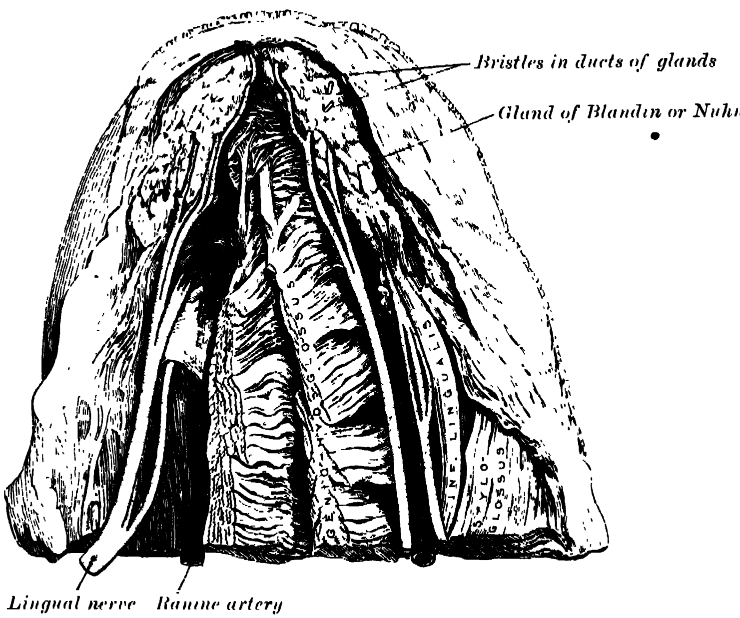
Muscles.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets, extrinsic and intrinsic, which have already been described (pages 479 to 482).

Vessels and Nerves.—The main artery of the tongue is the lingual branch of the external carotid, but the facial and ascending pharyngeal also give branches to it. The *veins* open into the internal jugular.

The *lymphatics of the tongue* have been described on page 770

The *nerves of the tongue* are: (1) the lingual branch of the third division of the fifth, which is distributed to the papillæ at the fore-part and sides of the tongue, and forms the nerve of ordinary sensibility for its anterior two-thirds; (2) the chorda tympani branch of the facial nerve, which runs in the sheath of the lingual, and is generally regarded as the nerve of taste for the anterior two-thirds; this nerve is a continuation of the sensory root of the facial (pars intermedia of Wrisberg); (3) the lingual branch of the glosso-pharyngeal, which is distributed to the mucous membrane at the base and sides of the tongue, and to the papillæ vallatæ, and which supplies both sensory and gustatory filaments to this region; (4) the hypoglossal nerve, which is the motor nerve to the muscular substance of the tongue; (5) the superior laryngeal, which sends some fine branches to the root near the epiglottis.

FIG. 916.—Under surface of tongue, showing position and relations of glands of Blandin or Nuhn. (From a preparation in the Museum of the Royal College of Surgeons of England.)



Applied Anatomy.—The diseases to which the tongue is liable are numerous, and any or all of the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of vertical cleft have been recorded, and it is occasionally, though much more rarely than is commonly supposed, the seat of 'tongue tie,' from shortness of the frenulum.

There is one condition which may be regarded as congenital, the so-called macroglossia, though sometimes it does not evidence itself until a year or two after birth. This is an enlargement of the tongue which is due primarily to a dilatation of the lymph-channels and a greatly increased development of the lymphatic tissue throughout the organ. This is often aggravated by inflammatory changes induced by injury or exposure, and the tongue may assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression. The treatment consists in excising a V-shaped portion and bringing the cut surfaces together with deeply placed sutures.

Acute inflammation of the tongue, which may be caused by injury and the introduction of some septic or irritating matter, is attended by great swelling from infiltration of its connective tissue, which is in considerable quantity. This renders the patient incapable of swallowing or speaking, and may seriously impede respiration. It may run on to suppuration, and the formation of an acute abscess.

In all ages the mucous membrane of the tongue has received much sedulous consideration in disease, and it is certain that the amount and the distribution of the 'fur' with which it may be covered often give valuable help in diagnosis. The fur consists of proliferating or desquamated epithelium, bound up with inspissated mucus, the débris of food, and bacteria of all sorts. The mucous membrane of the tongue may become chronically inflamed, and presents different appearances in the various stages of the disease, to which the terms leucoplakia and psoriasis linguæ have been given. They are usually the result of syphilis.

The tongue, being very vascular, is often the seat of nævoid growths, and these have a tendency to increase rapidly.

The tongue is frequently the seat of ulceration, which may arise from many causes, as from the irritation of jagged teeth, dyspepsia, tuberculosis, syphilis, and cancer. Of these the cancerous ulcer is the most important and also the most common. The variety is the squamous epithelioma, which soon develops into an ulcer with an indurated edge. It causes great pain, which speedily extends to all parts supplied with sensation by the fifth nerve, especially to the region of the ear (auriculo-temporal branch).

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the écraseur or the scissors. Probably the better method is by the scissors, usually known as Whitehead's method. The mouth is widely opened with a gag, the tongue transfixed with a stout silk ligature, by which to hold and make traction on it; the reflection of mucous membrane from the tongue to the jaw, and the insertion of the Genio-hyo-glossus are first divided with a pair of curved, blunt-pointed scissors. The Palato-glossus is also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the main artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells' forceps, the tongue removed, and the vessel secured. In the event of the artery being accidentally injured, hæmorrhage can be at once controlled by passing the forefinger over the tongue till it touches the epiglottis, and then turning it towards the side on which the artery is to be compressed, and pushing it forcibly against the jaw (Heath). In cases where the disease is confined to one side of the tongue, this operation may be modified by splitting the tongue down the centre and removing only the affected half.

In cases where the submaxillary lymphatic glands are involved, Kocher's operation should be resorted to. Having performed a preliminary tracheotomy, Kocher removes the tongue from the neck by an incision from near the lobule of the ear, down the anterior border of the Sterno-mastoid to the level of the great cornu of the hyoid bone, then forwards to the body of the hyoid bone, and upwards to near the symphysis of the jaw. The lingual artery is now secured, and by a careful dissection the submaxillary lymphatic glands and the tongue are removed. If the lymphatic glands in the submaxillary region are in any way affected, an extensive dissection of these will be required if there is any chance of eradicating the disease, and for this purpose it will be found necessary to remove the submaxillary salivary gland.

The more recent operations aim at, first, clearing the neck thoroughly of affected glands, both in the submaxillary region and along the carotid sheath, and secondly removal of the tongue from within the mouth, leaving if possible the mucous membrane of the floor of the mouth intact, so as to avoid soiling the large wound in the neck by the discharges from the mouth.

The Salivary Glands (fig. 917)

The principal salivary glands communicating with the mouth, and pouring their secretion into its cavity, are the parotid, submaxillary, and sublingual.

Parotid gland.—The parotid gland (gl. parotis) is the largest of the three salivary glands, varying in weight from half an ounce to an ounce. ~~It lies~~ upon the side of the face, immediately below and in front of the external ear. The main portion of the gland is superficial, somewhat flattened and quadrilateral in form, and is placed between the ramus of the mandible in front and the mastoid process and Sterno-mastoid muscle behind, overlapping, however, both boundaries. Above, it is limited by the zygoma; below, it extends to about the level of a line joining the tip of the mastoid process to the angle of the jaw. The remainder of the gland is wedge-shaped, and extends deeply inwards towards the pharyngeal wall.

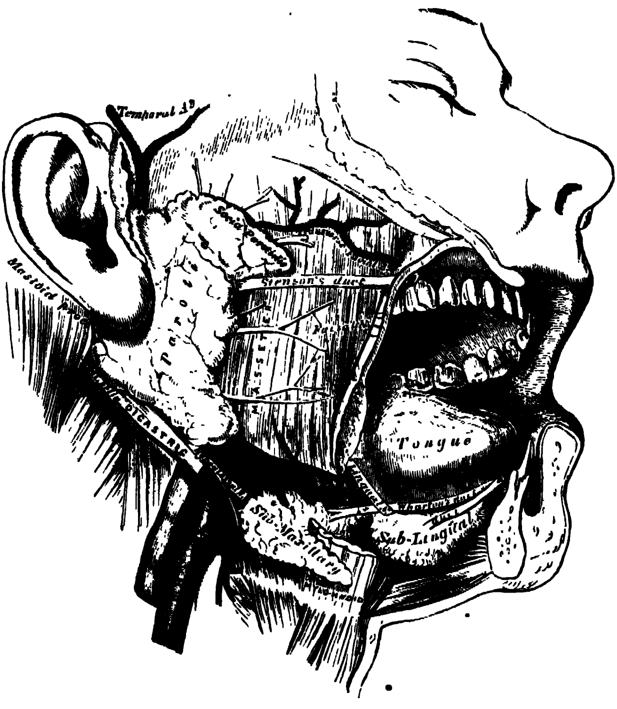
The gland is enclosed within a capsule continuous with the deep cervical fascia; the layer covering the outer surface is dense and closely adherent to the gland; a portion of the fascia, attached to the styloid process and the angle of the mandible, is thickened to form the ~~stylo-mandibular ligament~~ which intervenes between the parotid and submaxillary glands.

The *anterior surface* of the gland is moulded on the posterior border of the ramus of the mandible, clothed by the Internal pterygoid and Masseter muscles. The inner lip of the groove dips, for a short distance, between the two Pterygoid muscles, while the outer lip extends for some distance over the superficial surface of the Masseter; a small portion of this lip immediately below the zygoma is usually detached, and is named the *socia parotidis*.

The *outer* or *superficial surface*, slightly lobulated, is covered by the integument, the superficial fascia containing the facial branches of the great auricular nerve and some small lymphatic glands, and the fascia which forms the capsule of the gland.

The *inner* or *deep surface* extends inwards by means of two processes, one of which lies on the styloid process and the styloid group of muscles and projects under the mastoid process and Sterno-mastoid muscle; the other is situated in front of the styloid process, and passes into the posterior part of the glenoid fossa behind the temporo-mandibular joint. The deep surface is in contact with the internal and external carotid arteries, the internal jugular vein, and the vagus and glosso-pharyngeal nerves.

FIG. 917.—The salivary glands.



The *anterior border* lies on the superficial surface of the Masseter; the *posterior* abuts on the external auditory meatus and the mastoid process, and overlaps the anterior edge of the Sterno-mastoid. The *superior* border is in contact with the zygomatic arch, and the *inferior* overlaps the posterior belly of the Digastric. The *inner border*, at the junction of the anterior and inner surfaces, is separated from the pharyngeal wall by some loose connective tissue.

Structures within the gland.—The external carotid artery lies at first on the deep surface, and then in the substance of the gland. The artery gives off its posterior auricular branch which emerges from the gland behind; it then divides into its terminal branches, the internal maxillary and superficial temporal; the former runs inwards behind the neck of the mandible; the latter runs upwards across the zygoma and gives off its transverse facial branch which emerges from the front of the gland. Superficial to the arteries are the temporal and internal maxillary veins, uniting to form the

Post facial vein

temporo-maxillary vein; in the lower part of the gland this vein splits into anterior and posterior divisions. The anterior division emerges from the gland to join the facial vein; the posterior unites in the gland with the posterior auricular to form the external jugular vein. On a still more superficial plane is the facial nerve, the branches of which emerge at the upper and anterior borders of the gland. Branches of the great auricular nerve pierce the gland to join the facial, while the auriculo-temporal branch of the inferior maxillary nerve issues from the upper part of the gland.

The **duct of the parotid gland,** or **Stenson's duct** (ductus parotideus), is about two inches and a half in length. It commences by numerous branches from the anterior part of the gland, crosses the Masseter muscle, and at its anterior border turns inwards nearly at a right angle and passes into the substance of the Buccinator muscle, which it pierces; it then runs for a short distance obliquely forwards between the Buccinator and mucous membrane of the mouth, and opens upon the inner surface of the cheek by a small orifice, opposite the second molar tooth of the upper jaw. While crossing the Masseter it receives the duct of *socia parotidis*; in this position it has the transverse facial artery above it and some branches of the facial nerve below it.

Structure.—The parotid duct is dense, its wall being of considerable thickness; its canal is about the size of a crow-quill, but at its orifice on the inner aspect of the cheek its lumen is greatly reduced in size. It consists of a thick external fibrous coat which contains contractile fibres, and of an internal or mucous coat lined with short columnar epithelium.

Surface Form.—The direction of the duct corresponds to a line drawn across the face about a finger's breadth below the zygoma—that is, from the lower margin of the concha to midway between the red margin of the upper lip and the ala of the nose.

Vessels and Nerves.—The *arteries* supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The *veins* empty themselves into the external jugular, through some of its tributaries. The *lymphatics* terminate in the superficial and deep cervical glands, passing in their course through two or three lymphatic glands, placed on the surface and in the substance of the parotid. The *nerves* are derived from the plexus of the sympathetic on the external carotid artery, the facial, the auriculo-temporal, and the great auricular nerves. It is probable that the branch from the auriculo-temporal nerve is derived from the glosso-pharyngeal through the otic ganglion. At all events, in some of the lower animals this has been proved experimentally to be the case.

Submaxillary gland.—The submaxillary gland (gl. submaxillaris) is irregular in form and about the size of a walnut. A considerable part of it is situated in the submaxillary triangle, reaching forwards to the anterior belly of the Digastric and backwards to the stylo-hyoid ligament, which intervenes between it and the parotid gland. Above, it extends under cover of the body of the mandible; below, it usually overlaps the intermediate tendon of the Digastric and the insertion of the Stylo-hyoid, while from its deep surface a tongue-like *deep process* extends forwards and inwards above the Mylo-hyoid muscle.

Its *superficial surface* consists of an upper and a lower part. The *upper part* is directed outwards, and lies against the submaxillary fossa on the inner surface of the body of the mandible. The *lower part* is directed downwards and outwards, and is covered by the skin, superficial fascia, Platysma, and deep cervical fascia; it is crossed by the facial vein and by filaments of the facial nerve; in contact with it, near the mandible, are the submaxillary lymphatic glands.

The *deep surface* is in relation with the Mylo-hyoid, Hyo-glossus, Stylo-glossus, Stylo-hyoid, and posterior belly of the Digastric; in contact with it are the mylo-hyoid nerve and the mylo-hyoid and submental vessels.

The facial artery is imbedded in a groove in the posterior border of the gland.

The *deep process* of the gland extends forwards and inwards between the Mylo-hyoid below and externally, and the Hyo-glossus and Stylo-glossus internally; above it, is the lingual nerve; below it, the hypoglossal nerve and the ranine vein.

The **duct of the submaxillary gland,** or **Wharton's duct** (ductus submaxillaris) is about two inches in length, and its wall is much thinner than that of the parotid duct. It begins by numerous branches from the

deep surface of the gland, and runs forwards and inwards between the Mylo-hyoid and the Hyo-glossus and Genio-hyo-glossus muscles, then between the sublingual gland and the Genio-hyo-glossus, and opens by a narrow orifice on the summit of a small papilla, at the side of the frenulum linguæ. On the Hyo-glossus muscle it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it is crossed by the lingual nerve.

Vessels and Nerves.—The *arteries* supplying the submaxillary gland are branches of the facial and lingual. Its *veins* follow the course of the arteries. The *nerves* are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani of the facial and lingual branch of the inferior maxillary, sometimes from the mylo-hyoid branch of the inferior dental, and from the sympathetic.

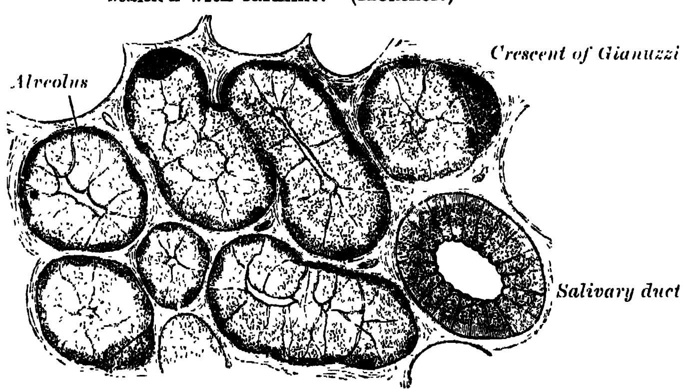
Sublingual gland.—The sublingual gland (gl. sublingualis) is the smallest of the salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frenulum linguæ, in contact with the inner surface of the lower jaw, close to the symphysis. It is narrow, flattened, shaped somewhat like an almond, and weighs about a drachm. It is in relation, *above*, with the mucous membrane; *below*, with the Mylo-hyoid muscle; *in front*, with the mandible, and its fellow of the opposite side; *behind*, with the deep part of the submaxillary gland; and *internally*, with the Genio-hyo-glossus, from which it is separated by the lingual nerve and Wharton's duct. Its excretory ducts (*ducts of Rivinus*) are from eight to twenty in number; some join Wharton's duct; others open separately into the mouth, on the elevated crest of mucous membrane (*plica sublingualis*), caused by the projection of the gland, on either side of the frenulum linguæ. One or more join to form a tube, which opens into the Whartonian duct: this is called the *duct of Bartholin.*

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual, the chorda tympani, and the sympathetic.

Structure of the salivary glands.—The salivary glands are compound racemose glands, consisting of numerous lobes, which are made up of smaller lobules, connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct, the branches terminating in dilated ends or alveoli on which the capillaries are distributed. The alveoli are enclosed by a basement-membrane, which is continuous with the membrana propria of the duct. It presents a peculiar reticulated structure, and consists of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ in the appearance of their secreting cells, in their size, and in the nature of their secretion. (1) The mucous

FIG. 918.—A highly magnified section of the submaxillary gland of the dog, stained with carmine. (Kölliker.)



variety secretes a viscid fluid, which contains mucin; (2) the serous variety secretes a thinner and more watery fluid. The sublingual gland consists of mucous, the parotid of serous alveoli. The submaxillary contains both mucous and serous alveoli, the latter, however, preponderating.

The cells in the *mucous alveoli* are spheroidal in shape, glassy and transparent. The nucleus is usually situated near the basement-membrane, and is flattened. The cells contain a quantity of mucinogen, to which their clear, transparent appearance is due.

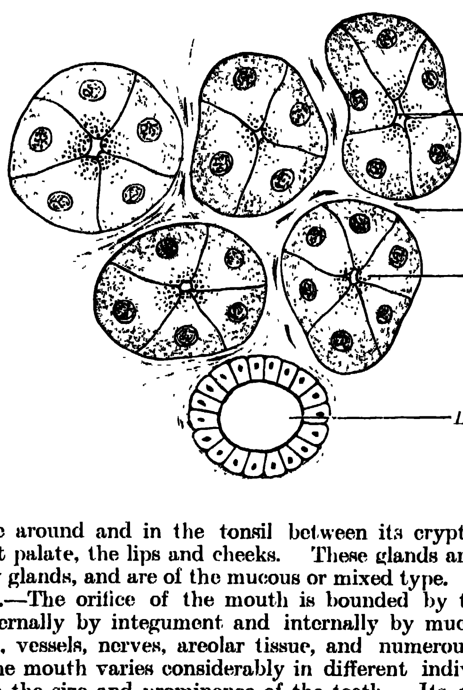
In some alveoli are seen peculiar crescentic bodies, lying between the cells and the membrana propria. They are termed the *crescents of Gianuzzi*, or the *demilunes of Heidenhain* (fig. 918), and are composed of polyhedral granular cells, which Heidenhain regards as young epithelial cells destined to supply the place of those salivary cells which have undergone disintegration. This view, however, is not accepted by Klein.

In the *serous alveoli* the cells almost completely fill the cavity, so that there is hardly any lumen perceptible; they contain granules imbedded in a closely reticulated protoplasm (fig. 919).

The ducts are lined at their origins by epithelium which differs little from the pavement type. As the ducts enlarge, the epithelial cells change to the columnar type, and the part of the cell next the basement-membrane is finely striated. The lobules of the salivary glands are richly supplied with blood-vessels which form a dense network in the inter-alveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. The nerve-fibrils pierce the basement-membrane of the alveoli, and end in branched varicose filaments between the secreting cells. In the hilus of the submaxillary gland there is a collection of nerve-cells termed *Langley's ganglion.*

Mucous glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. Many of these glands are found at the posterior part of the dorsum of the tongue, behind the circumvallate papillæ, and also along its margins as far forwards as the apex. Others lie around and in the tonsil between its crypts, and large numbers are present in the soft palate, the lips and cheeks. These glands are of the same structure as the larger salivary glands, and are of the mucous or mixed type.

Fig. 919.—Section of a serous salivary gland.



Surface Form.—The orifice of the mouth is bounded by the lips, two thick, fleshy folds covered externally by integument and internally by mucous membrane, and consisting of muscles, vessels, nerves, areolar tissue, and numerous small glands. The size of the orifice of the mouth varies considerably in different individuals, but seems to bear a close relation to the size and prominence of the teeth. Its corners usually correspond to the outer border of the canine teeth. In the Mongolian tribes, where the front teeth are large and inclined forward, the mouth is large; and this, combined with the thick and everted lips, which appear to be associated with prominent teeth, gives to the Negro's face much of the peculiarity by which it is characterised. The smaller teeth, and the slighter prominence of the alveolar arch of the more highly civilised races, render the orifice of the mouth much smaller, and thus a small mouth is an indication of intelligence, and is regarded as an evidence of the higher civilisation of the individual.

Upon looking into the mouth, the first thing to be noted is the tongue, the upper surface of which will be seen occupying the floor of the cavity. This surface is convex, and is marked along the middle line by a raphe, which divides it into two symmetrical portions. The anterior two-thirds are rough and studded with papillæ; the posterior third, smooth and tuberculated, is covered by numerous glands which project from the surface. Upon raising the tongue, the mucous membrane which invests its upper surface may be traced over its sides on to its under surface, from which it is reflected over the floor of the mouth on to the inner surface of the mandible, a part of which it covers. As it passes over the borders of the tongue it changes its character, becoming thin and smooth, and losing the papillæ which are to be seen on the upper surface. In the middle line the mucous membrane on the under surface of the tip of the tongue forms a distinct

fold, the *frenulum linguæ*, by which this organ is connected to the symphysis menti. Occasionally it is found that this frenulum is rather shorter than natural, and, acting as a bridle, prevents the complete protrusion of the tongue. When this condition exists and an attempt is made to protrude the organ, the tip will be seen to remain buried in the floor of the mouth, and the dorsum of the tongue is rendered very convex, and more or less extruded from the mouth; at the same time a deep furrow will be noticed to appear in the middle line of the anterior part of the dorsum. Sometimes, a little external to the frenulum, the ranine vein may be seen immediately beneath the mucous membrane. The corresponding artery, being more deeply placed, does not come into view, nor can its pulsation be felt with the finger. On either side of the frenulum, in the floor of the mouth, is a longitudinal elevation or ridge, produced by the projection of the sublingual gland, which lies immediately beneath the mucous membrane. Close to the attachment of the frenulum to the tip of the tongue may be seen on either side the slit-like orifice of Wharton's duct, into which a fine probe may be passed without much difficulty. In the middle line, both of the upper and lower lip, small folds of mucous membrane pass from the lip to the bone, constituting the *frenula*; these are not so large as the frenulum linguæ. By pulling outwards the angle of the mouth the mucous membrane lining the cheeks can be seen, and on it may be perceived a little papilla which marks the position of the orifice of Stenson's duct—the duct of the parotid gland. The exact position of the orifice of the duct is opposite the second molar tooth of the upper jaw. The introduction of a probe into this duct is attended with considerable difficulty.

At the back of the mouth is seen the *isthmus of the fauces*, or, as it is popularly called, 'the throat': this is the space between the pillars of the fauces on either side, and is the means by which the mouth communicates with the pharynx. Above, it is bounded by the soft palate, the anterior surface of which is concave and covered with mucous membrane which is continuous with that lining the roof of the mouth. Projecting downwards from the middle of its lower border is a conical projection, the *uvula*. On either side of the isthmus of the fauces are the anterior and posterior pillars, formed by the Palato-glossus and Palato-pharyngeus muscles respectively, covered by mucous membrane. Between the two pillars on either side is situated the tonsil.

When the mouth is wide open a prominent tense fold of mucous membrane may be seen and felt extending upwards and backwards from the position of the fang of the last molar tooth to the posterior part of the hard palate. This is caused by the pterygo-mandibular ligament which is attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the mylo-hyoid ridge of the lower jaw. It intervenes between the Buccinator and the Superior constrictor of the pharynx. The fang of the last molar tooth indicates the position of the lingual (gustatory) nerve, where it is easily accessible, and can with readiness be divided in cases of cancer of the tongue (see page 920). On the inner side of the last molar tooth one can feel the hamular process of the internal pterygoid plate of the sphenoid bone, around which the tendon of the Tensor palati plays. About one-third of an inch in front of the hamular process and the same distance directly inwards from the last molar tooth is the situation of the opening of the posterior palatine canal, through which emerges the posterior or descending palatine branch of the internal maxillary artery, and one of the descending palatine nerves from Meckel's ganglion. The exact position of the opening on the subject may be ascertained by driving a needle through the tissues of the palate in this situation, when it will be at once felt to enter the canal. The artery emerging from the opening runs forwards in a groove in the bone, just internal to the alveolar border of the hard palate, and may be wounded in the operation for the cure of cleft palate. Under these circumstances the palatine canal may require plugging. By introducing the finger into the mouth the anterior border of the coronoid process of the jaw can be felt, and is especially prominent when the jaw is dislocated. By throwing the head well back a considerable portion of the posterior wall of the pharynx may be seen through the isthmus faucium, and on introducing the finger the anterior surface of the bodies of the upper cervical vertebræ may be felt immediately beneath the thin muscular stratum forming the wall of the pharynx. The finger can be hooked round the posterior border of the soft palate, and, by turning it forwards, the posterior nares, separated by the septum, can be felt, or the presence of any adenoid or other growths in the naso-pharynx ascertained.

Applied Anatomy.—The parotid glands, and much less often the other salivary glands, are liable to an acute infectious inflammation, known in the case of the parotid as *mumps*. The affected glands swell up, becoming tense, tender, and painful; much pain is felt when swallowing or mastication is attempted, and salivation may or may not occur. The inflammation goes down after a few days; suppuration in the affected glands is very rare.

THE PHARYNX

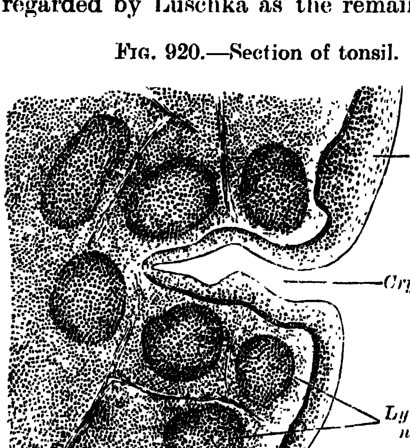
The pharynx is that part of the alimentary canal which is placed behind the nose, mouth, and larynx. It is a musculo-membranous tube, somewhat conical in form, with the base upwards, and the apex downwards, extending

from the under surface of the skull to the level of the cricoid cartilage in front, and that of the sixth cervical vertebra behind.

The cavity of the pharynx (cavum pharyngis) is about five inches in length, and broader in the transverse than in the antero-posterior diameter. Its greatest breadth is immediately below the base of the skull, where it projects on either side, behind the orifice of the Eustachian tube, as a recess termed the fossa of Rosenmüller; its narrowest point is at its termination in the œsophagus. It is limited, *above*, by the body of the sphenoid and basilar process of the occipital bone; *below*, it is continuous with the œsophagus; *posteriorly*, it is connected by loose areolar tissue with the cervical portion of the vertebral column, and the Longus colli and Rectus capitis anticus muscles; *anteriorly*, it is incomplete, and is attached in succession to the internal pterygoid plate, pterygo-mandibular ligament, mandible, tongue, hyoid bone, and thyroid and cricoid cartilages; *laterally*, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, and the glosso-pharyngeal, pneumogastric, hypoglossal, and sympathetic nerves, and above with a small part of the Internal pterygoid muscles. Seven openings communicate with it, viz. the two posterior nares, the two Eustachian tubes, the mouth, the larynx, and the œsophagus. The cavity of the pharynx may be subdivided from above downwards into three parts: nasal, oral, and laryngeal (fig. 899).

The *nasal part*, or naso-pharynx (pars nasalis), lies behind the nose and above the level of the soft palate: it differs from the two lower parts of the tube in that its cavity always remains patent. In front it communicates through the choanæ with the nasal fossæ. On its lateral wall is the *pharyngeal orifice of the Eustachian tube* (ostium pharyngeum tubæ), somewhat triangular in shape, and bounded behind by a firm prominence, the *cushion* (torus tubarius), caused by the inner extremity of the cartilage of the tube which elevates the mucous membrane. A vertical fold of mucous membrane, the *plica salpingopharyngea*, stretches from the lower part of the cushion; it contains the Salpingo-pharyngeus muscle. A second and smaller fold, the *plica salpingopalatina*, stretches from the upper part of the cushion to the palate. Behind the orifice of the Eustachian tube is a deep recess, the *fossa of Rosenmüller* (recessus pharyngeus), which represents the remains of the upper part of the second visceral cleft. On the posterior wall is a prominence, best marked in childhood, produced by a mass of lymphoid tissue, which is known as the *pharyngeal tonsil* (tonsilla pharyngea). Above the pharyngeal tonsil, in the middle line, an irregular flask-shaped depression of the mucous membrane is sometimes seen extending up as far as the basilar process of the occipital bone. It is known as the *bursa pharyngea*, and was regarded by Luschka as the remains of the diverticulum which is concerned in the development of the anterior lobe of the pituitary body. Some anatomists believe it to be connected with the formation of the pharyngeal tonsil.

Fig. 920.—Section of tonsil.



The *oral part* (pars oralis) reaches from the soft palate to the level of the hyoid bone. It opens anteriorly, through the isthmus faucium, into the mouth, while in its lateral wall, between the two pillars of the fauces, is the tonsil.

The **tonsils** (tonsillæ palatinæ) are two prominent bodies situated one on either side between the anterior and posterior pillars of the fauces. They are of a rounded form, and vary considerably in size in different individuals. A recess, the *fossa supratonsillaris*, may be seen, directed upwards and backwards, above the tonsil. His regards this as the remains of the lower

part of the second visceral cleft. It is covered by a fold of mucous membrane termed the *plica triangularis*. *Externally* the tonsil is in relation with the inner surface of the Superior constrictor, to the outer side of which are the ascending palatine and tonsillar arteries and the Internal pterygoid muscle. The internal carotid artery lies behind and to the outer side of the tonsil, and nearly an inch (twenty to twenty-five millimetres) distant from it. The outer surface of the tonsil corresponds in position to the angle of the mandible. Its *inner surface* presents from twelve to fifteen orifices, leading into small crypts or recesses, from which numerous follicles branch out into the substance of the gland (fig. 920). These follicles are lined by a continuation of the mucous membrane of the pharynx, covered with epithelium; around each follicle is a layer of closed capsules consisting of adenoid tissue imbedded in the submucous tissue. Surrounding each follicle is a close plexus of lymphatics, from which the lymphatic vessels pass to the deep cervical glands in the neighbourhood of the greater cornu of the hyoid bone, behind and below the angle of the mandible; these glands frequently become enlarged in affections of the tonsils.

The tonsils form part of a circular band of adenoid tissue which guards the opening into the digestive and respiratory tubes. The anterior part of the ring is formed by the submucous adenoid collections on the posterior part of the tongue; the lateral portions consist of the tonsils and the adenoid collections in the vicinity of the Eustachian tubes, while the ring is completed behind by the pharyngeal tonsil on the posterior wall of the pharynx. In the intervals between these main masses are smaller collections of adenoid tissue.

Vessels and Nerves. – The *arteries* supplying the tonsil are the dorsalis linguæ from the lingual, the ascending palatine and tonsillar from the facial, the ascending pharyngeal from the external carotid, the descending palatine branch of the internal maxillary, and a twig from the small meningeal.

The *veins* terminate in the tonsillar plexus, on the outer side of the tonsil.

The *nerves* are derived from Meckel's ganglion, and from the glosso-pharyngeal.

Applied Anatomy.– The tonsils can be easily inspected by instructing the patient to throw the head back and open his mouth widely; the tongue at the same time being depressed by a spatula or tongue-depressor. The normal tonsil should not project beyond the plane of the anterior pillar of the fauces. They are prone to become enlarged, especially in tuberculous children; and when much increased in size they cause great trouble, owing to obstruction to respiration and deglutition. The tonsils may be the seat of acute inflammation, which may run on to suppuration, requiring evacuation of the pus. The incision into the tonsil should always be made from in front backwards and inwards. Another form of acute inflammation of the tonsil is follicular tonsillitis, due to the lodgment of micro-organisms in the crypts of the tonsil. The removal of an enlarged tonsil is, as a rule, a very simple operation, and is not usually attended with much hæmorrhage, unless the patient is suffering from hæmophilia. The tonsil may be the seat of malignant growth, either an epithelioma or a lymphosarcoma.

The *laryngeal part* of the pharynx (pars laryngea) reaches from the hyoid bone to the lower border of the cricoid cartilage, where it is continuous with the œsophagus. In front it presents the triangular aperture of the larynx, the base of which is directed forwards and is formed by the epiglottis, while its lateral boundaries are constituted by the aryteno-epiglottic folds. On either side of the laryngeal orifice is a recess, termed the *sinus pyriformis*; it is bounded internally by the aryteno-epiglottic fold, externally by the thyroid cartilage and thyro-hyoid membrane.

Structure.—The pharynx is composed of three coats: mucous, fibrous, and muscular.

The *pharyngeal aponeurosis*, or *fibrous coat*, is situated between the mucous and muscular layers. It is thick above where the muscular fibres are wanting, and is firmly connected to the basilar process of the occipital and petrous portions of the temporal bones. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band, which is attached above to the pharyngeal spine on the under surface of the basilar portion of the occipital bone, and passes downwards, forming a median raphe, which gives attachment to the Constrictor muscles of the pharynx.

The *mucous coat* is continuous with that lining the Eustachian tubes, the nasal fossæ, the mouth, and the larynx. In the naso-pharynx it is covered by columnar ciliated epithelium; in the buccal and laryngeal portions the epithelium is stratified. Beneath the mucous membrane are found racemose mucous glands; they are especially numerous at the upper part of the pharynx around the orifices of the Eustachian tubes.

The *muscular coat* has been already described (pages 482 to 484).

Applied Anatomy.—Hypertrophy of the lymphatic tissue in the naso-pharynx, commonly known as 'adenoids,' is a frequent cause of mouth-breathing and all its attendant disadvantages and dangers in children. It entails a proneness to inflammation of all parts of the air-passages and of the Eustachian tubes, and leads to deformed development of the palate and dental arch. In many cases adenoids tend to atrophy about the age of puberty, by which time their presence is likely to have caused permanent injury to the health and development of the patient. No certain remedy for adenoids exists excepting operation.

The pharynx is sometimes the seat of a pouch-like dilatation of its walls, in which the food collects when the patient swallows. A cure is effected by removing the diverticulum and accurately suturing the opening in the pharynx which has been made. The internal carotid artery is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments, introduced into the mouth and thrust through the wall of the pharynx. In aneurysm of this vessel in the neck, the tumour necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscle, whereas on the outer side there are the dense cervical fascia, the muscles descending from the styloid process, and the margin of the Sterno-mastoid.

The mucous membrane of the pharynx is very vascular, and is often the seat of inflammation, frequently of a septic character, since the numerous recesses are prone to lodge micro-organisms. And, in addition, owing to its exposed situation, the mucous membrane is liable to be irritated by agents introduced during inspiration. The inflammation may be attended with serious consequences: it may extend up the Eustachian tube and involve the middle ear; it may spread to the entrance of the larynx, causing œdema and seriously interfering with respiration; or, invading the lymphatics, it may spread to the loose areolar tissue surrounding the pharyngeal wall, and may extend far and wide, sometimes into the posterior mediastinum along the œsophagus. Abscess may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as *retro-pharyngeal abscess*. This is most commonly due to caries of the cervical vertebræ; but may also be caused by suppuration of a lymphatic gland, which is situated in this position opposite the axis, and which receives lymphatics from the nasal fossæ; by a gumma; or by acute pharyngitis. In these cases the pus may be easily evacuated by incision with a guarded bistoury, through the mouth, but, for aseptic reasons, it is desirable that the abscess should be opened from the neck. In some instances this is perfectly easy: the abscess can be felt bulging at the side of the neck, and merely requires an incision for its relief; but this is not always so, and then an incision should be made along the posterior border of the Sterno-mastoid and the deep fascia divided. A director is now to be inserted into the wound, the forefinger of the left hand being introduced into the mouth and pressure made upon the swelling. This acts as a guide, and the director is to be pushed onwards until pus appears in the groove. A pair of sinus forceps is now inserted along the director and the opening into the cavity dilated.

Abscess also occurs in children, underneath the mucous membrane, between it and the pharyngeal aponeurosis. The condition usually arises from a peritonsillar inflammation, which spreads backwards. In some cases an enormous swelling may form, which pushes forwards the soft palate and gives rise to respiratory obstruction. In such the abscess should be opened through the mouth with the child in the inverted position, so as to prevent the first gush of pus from entering the superior opening of the larynx.

Foreign bodies not infrequently become lodged in the pharynx, and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the œsophagus is about six inches.

The Œsophagus

The **œsophagus,** or **gullet,** is a muscular canal, about nine or ten inches in length, extending from the pharynx to the stomach. It commences at the upper border of the cricoid cartilage, opposite the sixth cervical vertebra, descends along the front of the vertebral column, through the posterior mediastinum, passes through the Diaphragm, and, entering the abdomen, terminates at the cardiac orifice of the stomach, opposite the eleventh thoracic vertebra. The general direction of the œsophagus is vertical; but it presents two slight curves in its course. At its commencement it is placed in the median line; but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again at the level of the fifth thoracic vertebra, and finally deviates to the left as it passes forwards to the œsophageal opening of the Diaphragm. The œsophagus also presents antero-posterior flexures corresponding to the curvatures of the cervical and thoracic

portions of the vertebral column. It is the narrowest part of the alimentary canal, and is most contracted at its commencement, and at the point where it passes through the Diaphragm.

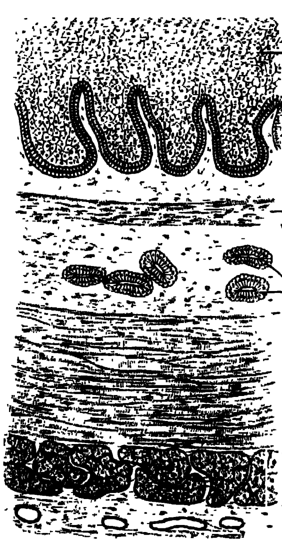
Relations.—The *cervical portion* (pars cervicalis) of the œsophagus is in relation, *in front*, with the trachea; and at the lower part of the neck, where it projects to the left side, with the thyroid gland; *behind*, it rests upon the vertebral column and Longus colli muscles; *on either side* it is in relation with the common carotid artery (especially the left, as it inclines to that side), and part of the lateral lobe of the thyroid gland; the recurrent laryngeal nerves ascend between it and the trachea; to its left side is the thoracic duct.

The *thoracic portion* (pars thoracalis) of the œsophagus is at first situated a little to the left of the median line; it passes behind the aortic arch, separated from it by the trachea, and descends in the posterior mediastinum, along the right side of the aorta, then runs in front and a little to the left of the aorta, and enters the abdomen through the Diaphragm at the level of the tenth thoracic vertebra. Just before it perforates the Diaphragm it presents a distinct dilatation or *bulb*. It is in relation, *in front*, with the trachea, the left bronchus, the pericardium, and the Diaphragm; *behind*, it rests upon the vertebral column, the Longus colli muscles, the right intercostal arteries, the thoracic duct, and azygos minor veins; and below, near the Diaphragm, upon the front of the aorta. On its *left* side, in the superior mediastinum, are the terminal part of the arch of the aorta, the left subclavian artery, the thoracic duct, and left pleura, while running upwards in the angle between it and the trachea is the left recurrent laryngeal nerve; below, it is in relation with the descending thoracic aorta. On its *right* side are the right pleura, and the vena azygos major which it overlaps. The pneumogastric nerves descend in close contact with it, the right nerve passing down behind, and the left nerve in front of it; the two nerves uniting to form a plexus (the *plexus gulæ*) around the tube.

In the lower part of the posterior mediastinum the thoracic duct lies to the right side of the œsophagus; higher up, it is placed behind it, and, crossing about the level of the fourth thoracic vertebra, is continued upwards on its left side.

The *abdominal portion* (pars abdominalis) of the œsophagus lies in the œsophageal groove on the posterior surface of the left lobe of the liver. It measures about half an inch in length, and its front and left aspects only are covered by peritoneal membrane. It is somewhat conical with its base applied to the upper orifice of the stomach, and is known as the *antrum cardiacum*.

Fig. 921.—Section of œsophagus



Structure (fig. 921).—The œsophagus has three coats: an external or muscular; a middle or areolar; and an internal or mucous coat.

The *muscular coat* is composed of two planes of considerable thickness: an external longitudinal and an internal circular.

The *longitudinal fibres* are arranged, at the commencement of the tube, in three fasciculi: one in front, which is attached to the vertical ridge on the posterior surface of the cricoid cartilage; and one at either side, which is continuous with the muscular fibres of the pharynx: as they descend they blend together, and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscular fibres pass between the œsophagus and the left pleura, where the latter covers the thoracic aorta, or the root of the left bronchus, or the back of the pericardium.

The *circular fibres* are continuous above with the Inferior constrictor; their direction is transverse at the upper and lower parts of the tube, but oblique in the central part.

The muscular fibres in the upper part of the œsophagus are of a red colour, and consist chiefly of the striped variety; but below, they consist for the most part of involuntary fibres.

The *areolar* or *submucous coat* connects loosely the mucous and muscular coats.

The *mucous coat* is thick, of a reddish colour above, and pale below. It is disposed in longitudinal folds, which disappear on distension of the tube. Its surface is studded with minute papillæ, and it is covered throughout with a thick layer of stratified pavement epithelium. Beneath the mucous membrane, between it and the areolar coat, is a layer of longitudinally arranged non-striped muscular fibres. This is the *muscularis mucosæ*. At the commencement of the œsophagus it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

The *œsophageal glands* are small compound racemose glands of the mucous type: they are lodged in the submucous tissue, and each opens upon the surface by a long excretory duct.

Vessels and Nerves.—The arteries supplying the œsophagus are derived from the inferior thyroid branch of the thyroid axis of the subclavian, from the descending thoracic aorta, from the gastric branch of the cœliac axis, and from the left inferior phrenic of the abdominal aorta. They have for the most part a longitudinal direction.

The nerves are derived from the pneumogastric and from the sympathetic; they form a plexus, in which are groups of ganglion-cells, between the two layers of the muscular coats, and also a second plexus in the submucous tissue.

Applied Anatomy.—The œsophagus may be obstructed by foreign bodies, and also by changes in its coats producing stricture, or by pressure on it from without of new growths or aneurysm, &c. The different forms of stricture are: (1) the fibrous, due to cicatrisation following destruction of tissue, the result of swallowing boiling or corrosive fluids—here dilatation of the stricture may be carried out; and (2) malignant, usually epitheliomatous in its nature. This may be situated either at the upper end of the tube, opposite the cricoid cartilage, or at its lower end at the cardiac orifice, but is most commonly found at that part of the tube where it is crossed by the left bronchus. In these cases, if the patient is losing weight from insufficient nourishment, the operation of gastrostomy may be performed in order to avoid death from starvation; death, however, most commonly occurs from ulceration of the growth into the mediastinum or air-passages. In cases of stricture of the œsophagus it may be necessary to dilate the canal by a bougie, when it is of importance that the direction of the œsophagus and its relations to surrounding parts should be remembered. In cases of malignant disease of the œsophagus, where its tissues have become softened from infiltration of the growth, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinum or into one or other pleural cavity, or even into the pericardium.

In cases of obstruction of the œsophagus, and consequent symptoms of stricture, produced by an aneurysm of some part of the aorta pressing upon this tube, the passage of a bougie could only hasten the fatal issue.

In passing a bougie the left forefinger should be introduced into the mouth, and the epiglottis felt for, care being taken not to throw the head too far backwards. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently onwards, all violence being carefully avoided.

It occasionally happens that a foreign body becomes impacted in the œsophagus, which can neither be brought upwards nor moved downwards. When all ordinary means for its removal have failed, excision is the only resource. This, of course, can only be performed when it is not very low down. If the foreign body is allowed to remain, extensive inflammation and ulceration of the œsophagus may ensue. In one case the foreign body ultimately penetrated the intervertebral substance, and destroyed life by inflammation of the membranes and substance of the cord.

THE ABDOMEN

The **abdomen** is the largest cavity in the body. It is of an oval shape, the extremities of the oval being directed upwards and downwards. The upper extremity is formed by the Diaphragm which extends as a dome over the abdomen, so that the cavity extends high into the bony thorax, reaching on the right side, in the nipple line, to the upper border of the fifth rib; on the left side it falls below this level by about an inch. The lower extremity is formed by the structures which clothe the inner surface of the bony pelvis, principally the Levatores ani and Coccygei muscles on either side. These muscles are sometimes termed the Diaphragm of the pelvis. The cavity is wider above than below, and measures more in the vertical than in the

transverse diameter. In order to facilitate description, it is artificially divided into two parts: an upper and larger part, the *abdomen proper*; and a lower and smaller part, the *pelvis*. These two cavities are not separated from each other, but the limit between them is marked by the brim of the true pelvis.

The **abdomen proper** differs from the other great cavities of the body in being bounded for the most part by muscles and fasciæ, so that it can vary in capacity and shape according to the condition of the viscera which it contains; but, in addition to this, the abdomen varies in form and extent with age and sex. In the adult male, with moderate distension of the viscera, it is oval or barrel-shaped, but at the same time flattened from before backwards. In the adult female, with a fully developed pelvis, it is conical with the apex above, and in young children it is conical with the apex below.

It is bounded *in front* and *at the sides* by the lower ribs, the abdominal muscles, and the iliac fossæ; *behind* by the vertebral column and the Psoas and Quadratus lumborum muscles; *above* by the Diaphragm; *below* by the plane of the brim of the pelvis. The muscles forming the boundaries of the cavity are lined upon their inner surfaces by a layer of fascia, differently named according to the part it covers.

The abdomen contains the greater part of the alimentary canal; some of the accessory organs to digestion, viz. the liver and pancreas; the spleen, the kidneys, and suprarenal glands. Most of these structures, as well as the wall of the cavity in which they are contained, are more or less covered by an extensive and complicated serous membrane, the *peritoneum*.

The *apertures* found in the walls of the abdomen, for the transmission of structures to or from it, are, the *umbilicus* (in the fœtus), for the transmission of the umbilical vessels; the *caval opening* in the Diaphragm, for the transmission of the inferior vena cava; the *aortic opening*, for the passage of the aorta, vena azygos major, and thoracic duct; and the *œsophageal opening*, for the œsophagus and pneumogastric nerves. *Below*, there are two apertures on either side: one for the passage of the femoral vessels, and the other for the transmission of the spermatic cord in the male, and the round ligament in the female.

Regions.—For convenience of description of the viscera, as well as of reference to the morbid conditions of the contained parts, the abdomen is artificially divided into nine regions by imaginary planes, two horizontal and two sagittal, passing through the cavity, the edges of the planes being indicated by lines drawn on the surface of the body. Of the horizontal planes the upper or *infracostal* is indicated by a line encircling the body at the level of the lowest points of the tenth costal cartilages, the lower by a line carried round the trunk at the level of the highest points of the iliac crests as seen from the front. The latter is the *intertubercular plane* of Cunningham, who has pointed out* that its level corresponds with the prominent and easily defined tubercle on the iliac crest about two inches behind the anterior superior iliac spine. By means of these imaginary planes the abdomen is divided into three zones, which are named from above downwards the *subcostal*, *umbilical*, and *hypogastric* zones. Each of these is further subdivided into three regions by the two sagittal planes, which are indicated on the surface by lines drawn vertically through points halfway between the anterior superior iliac spines and the symphysis pubis.†

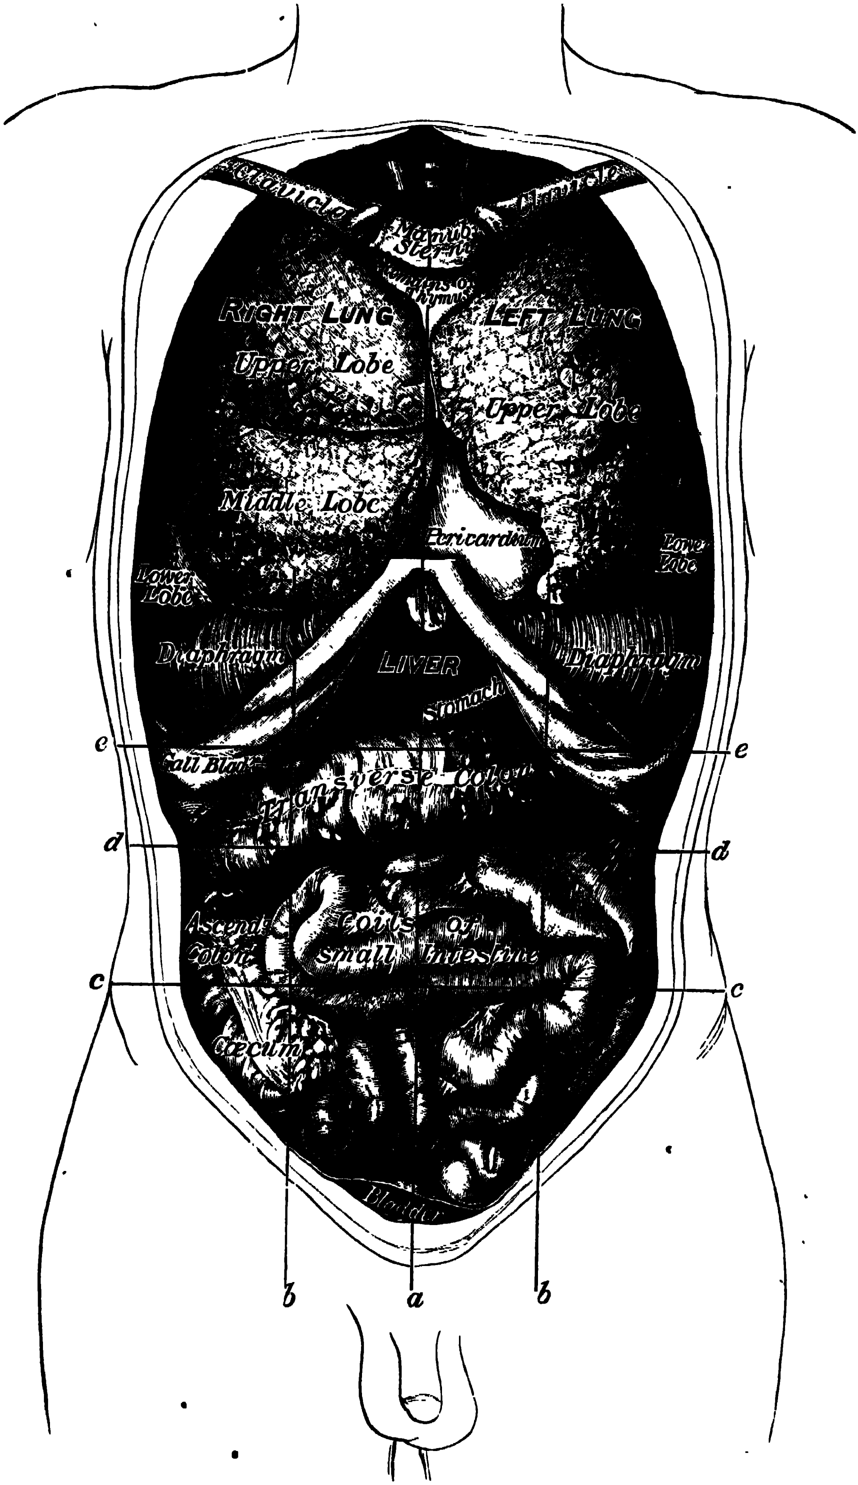
The middle region of the upper zone is called the *epigastric*; and the two lateral regions, the *right* and *left hypochondriac*. The central region of the

* *Journal of Anatomy and Physiology*, vol. xxvii.

† Anatomists are far from agreed as to the best method of subdividing the abdominal cavity, but that given above is the one which is generally adopted in this country. Addison,[1] in a careful analysis of the abdominal viscera in a large number of subjects, adopts the following lines: (1) a median, from the symphysis pubis to the ensiform cartilage; (2) two lateral lines each drawn vertically through a point midway between the anterior superior iliac spine and the symphysis pubis; (3) an upper transverse line halfway between the symphysis pubis and the suprasternal notch; and (4) a lower transverse line midway between the last and the upper border of the symphysis pubis. The upper transverse line corresponds with what he has termed the *transpyloric plane*, from the fact that in most cases this plane cuts through the pylorus.

[1] *Journal of Anatomy and Physiology*, vols. xxxiii., xxxiv., xxxv.

FIG. 922.—Front view of the thoracic and abdominal viscera.



a. Mesial plane. *b b.* Lateral planes. *c c.* Intertubercular plane. *d d.* Infracostal plane. *e e.* Transpyloric plane.

middle zone is the *umbilical*; and the two lateral regions, the *right* and *left lumbar*. The middle region of the lower zone is the *hypogastric* or *pubic region*; and the lateral regions are the *right* and *left iliac* or *inguinal* (fig. 922).

The **pelvis** is that portion of the abdominal cavity which lies below and behind a plane passing through the promontory of the sacrum, the ilio-pectineal lines, and the pubic crests. It is bounded behind by the sacrum, coccyx, Pyriformis muscles, and the sacro-sciatic ligaments; in front and laterally by the pubes and ischia and Obturator internus muscles; above it communicates with the abdomen proper; below it is closed by the Levatores ani and Coccygei muscles and the triangular ligament. The pelvis contains the bladder, the pelvic colon, a few coils of the small intestine, and some of the generative organs.

When the anterior abdominal wall is removed, the viscera are partly exposed as follows: above and to the right side is the liver, situated chiefly under the shelter of the right ribs and their cartilages, but extending across the middle line and reaching for some distance below the level of the ensiform cartilage. To the left of the liver is the stomach, from the lower border of which an apron-like fold of peritoneum, the *great omentum*, descends for a varying distance, and obscures, to a greater or lesser extent, the other viscera. Below it, however, some of the coils of the small intestine can generally be seen, while in the right and left iliac regions respectively the cæcum and the iliac colon are partly exposed. The bladder occupies the anterior part of the pelvis, and, if distended, will project above the symphysis pubis; the rectum lies in the concavity of the sacrum, but is usually obscured by the coils of the small intestine. The pelvic colon lies between the rectum and the bladder.

If the stomach is followed from left to right it will be found to be continuous with the first part of the small intestine, or duodenum, the point of continuity being marked by a thickened ring which indicates the position of the pyloric valve. The duodenum passes towards the under surface of the liver, and then, curving downwards, is lost to sight. If, however, the great omentum be thrown upwards over the chest, the terminal part of the duodenum will be observed passing across the vertebral column towards the left side, where it becomes continuous with the coils of the jejunum and ileum. These measure some twenty feet in length, and if followed downwards will be seen to end in the right iliac fossa by opening into the cæcum or commencement of the large intestine. From the cæcum the large intestine takes an arched course, passing at first upwards on the right side, then across the middle line and downwards on the left side, and forming respectively the ascending, transverse, and descending parts of the colon. In the left iliac region and pelvis it assumes the form of a loop, the ilio-pelvic colon or sigmoid flexure, and terminates in the rectum.

The spleen lies behind the stomach in the left hypochondriac region, and may be in part exposed by pulling the stomach over towards the right side.

The glistening appearance of the deep surface of the abdominal wall and of the exposed viscera is due to the fact that the former is lined, and the latter more or less completely covered, by a serous membrane, the *peritoneum*.

The Peritoneum

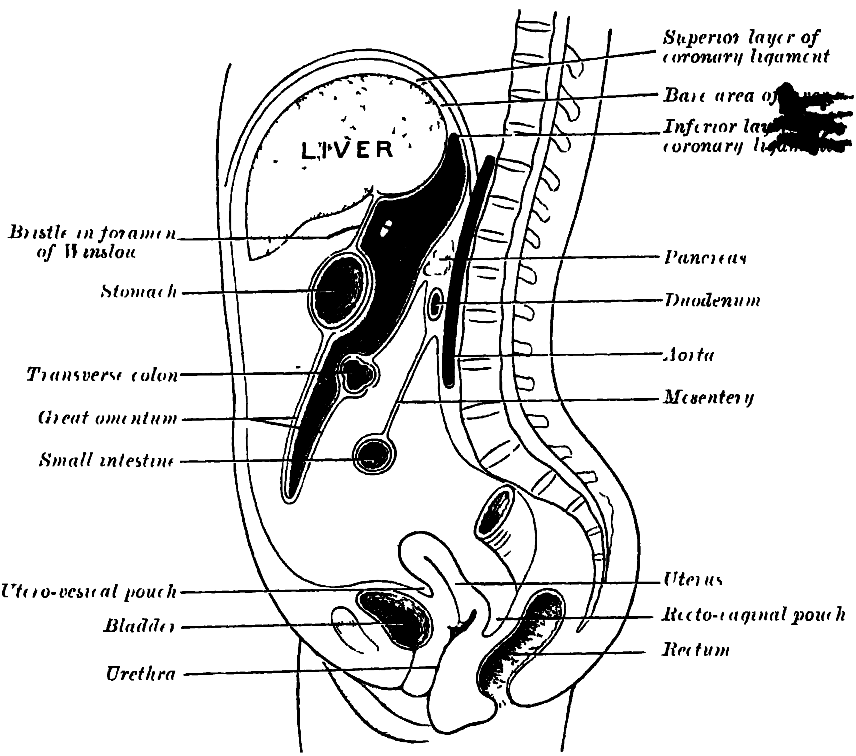
The peritoneum is the largest serous membrane in the body, and consists, in the male, of a closed sac, a part of which is applied against the abdominal parietes, while the remainder is reflected over the contained viscera. In the female the peritoneum is not a closed sac, since the free extremities of the Fallopian tubes open directly into the peritoneal cavity. The part which lines the parietes is named the *parietal* portion of the peritoneum; that which is reflected over the contained viscera constitutes the *visceral* portion of the peritoneum. The *free surface* of the membrane is smooth, covered by a layer of flattened endothelium, and lubricated by a small quantity of serous fluid. Hence the viscera can glide freely against the wall of the cavity or upon one another with the least possible amount of friction. The *attached surface* is rough, being connected to the viscera and inner surface of the parietes by means of areolar tissue, termed the *subserous areolar tissue*.

The parietal portion is loosely connected with the fascial lining of the abdomen and pelvis, but is more closely adherent to the under surface of the Diaphragm and also in the middle line of the abdomen.

The space between the parietal and visceral layers of the peritoneum is named the *peritoneal cavity*; but it must be remembered that under normal conditions this cavity is a potential one, since the parietal and visceral layers are in contact. The peritoneal 'cavity' is subdivided into a *greater* and a *lesser sac*, which communicate through the foramen of Winslow (foramen epiploicum). The greater sac is opened when the abdominal wall is cut through; the lesser is situated behind the stomach and adjoining structures, and may be regarded as a diverticulum from the greater sac.

The peritoneum differs from the other serous membranes of the body in presenting a much more complex arrangement, and one which can only be clearly understood by following the changes which take place in the alimentary

FIG. 923.—Vertical disposition of the peritoneum.



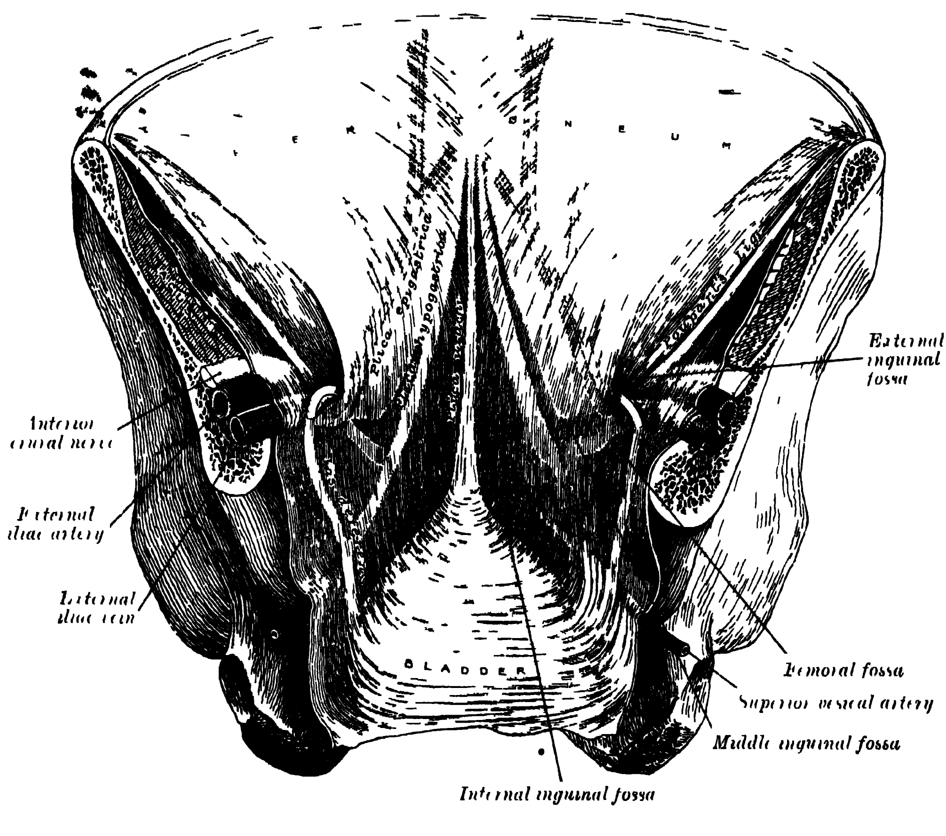
canal during its development; the student therefore is advised to preface his study of the peritoneum by reviewing the chapter dealing with this subject in the section on Embryology (page 150).

To trace the membrane from one viscus to another, and from the viscera to the parietes, it is necessary to follow its continuity in the vertical and horizontal directions, and it will be found simpler to describe the two sacs separately.

Vertical disposition of the greater sac (fig. 923).—It is convenient to trace the greater sac from the back of the abdominal wall at the level of the umbilicus. On following the peritoneum upwards from this level it is seen to be reflected around a fibrous cord, the ***ligamentum teres***, or ***obliterated umbilical vein***, which reaches from the umbilicus to the under surface of the liver. This reflection forms a somewhat triangular fold, the *falciform* or *suspensory ligament of the liver*, attaching the upper and anterior surfaces of the liver to the Diaphragm and abdominal wall. With the exception of the line of attachment of this ligament the peritoneum covers the whole of the under

surface of the anterior part of the Diaphragm, and is continued from it on to the upper surface of the right lobe of the liver as the *superior layer of the coronary ligament*, and on to the upper surface of the left lobe as the *superior layer of the left lateral ligament* of the liver. Covering the upper and anterior surfaces of the liver, it is continued round its sharp margin on to the under surface, where it presents the following relations: (*a*) It covers the under surface of the right lobe and is reflected from the back part of this on to the upper extremity of the right kidney, forming in this situation the *inferior layer of the coronary ligament*; from the kidney it is carried downwards to the duodenum and hepatic flexure of the colon and inwards to the inferior vena cava, where it is continuous with the posterior wall of the lesser sac. Between the two layers of the coronary ligament there is a large triangular surface of the liver devoid of peritoneal covering this

FIG. 924.—Posterior view of the anterior abdominal wall in its lower half. The peritoneum is in place, and the various cords are shining through. (After Joessel.)



is named the *bare area* of the liver, and is attached to the Diaphragm by areolar tissue. Towards the right margin of the liver the two layers of the coronary ligament gradually approach each other, and ultimately fuse to form a small triangular fold connecting the right lobe of the liver to the Diaphragm, and named the *right lateral ligament* of the liver. The apex of the triangular bare area corresponds with the point of meeting of the two layers of the coronary ligament, its base with the fossa for the inferior vena cava. (*b*) It covers the lower surface of the quadrate lobe, the under and lateral surfaces of the gall-bladder, and the under surface and posterior border of the left lobe; it is then reflected from the upper surface of the liver to the Diaphragm as the *inferior layer of the left lateral ligament*, and from the transverse fissure and fissure for the ductus venosus to the lesser curvature of the stomach as the anterior layer of the *gastro-hepatic*, or

4 C 2

small, omentum. If this layer of the small omentum be followed to the right it will be found to turn round the hepatic artery, bile-duct, and portal vein, and become continuous with the anterior wall of the lesser sac, forming a free folded edge of peritoneum. Traced downwards, it covers the antero-superior surface of the stomach and the commencement of the duodenum, and is carried down from the greater curvature of the stomach into a large free fold, known as the *gastro-colic* or *great omentum.* Reaching the free margin of this fold, it is reflected upwards to cover the under and posterior surfaces of the transverse colon, and thence to the posterior abdominal wall as the inferior layer of the *transverse mesocolon.* It reaches the abdominal wall at the upper border of the third part of the duodenum, and is then carried down on the superior mesenteric vessels to the small intestine as the anterior layer of the *mesentery.* It encircles the intestine, and subsequently may be traced, as the posterior layer of the mesentery, upwards and backwards to the abdominal wall. From this it sweeps down over the aorta into the pelvis, where it invests the pelvic colon, its reduplication forming the *pelvic mesocolon.* Leaving first the sides and then the front of the rectum, it is reflected on to the base of the bladder and, after covering the upper surface of that viscus is carried along the urachus and obliterated hypogastric arteries (fig. 924) on to the back of the abdominal wall to the level from which a start was made.

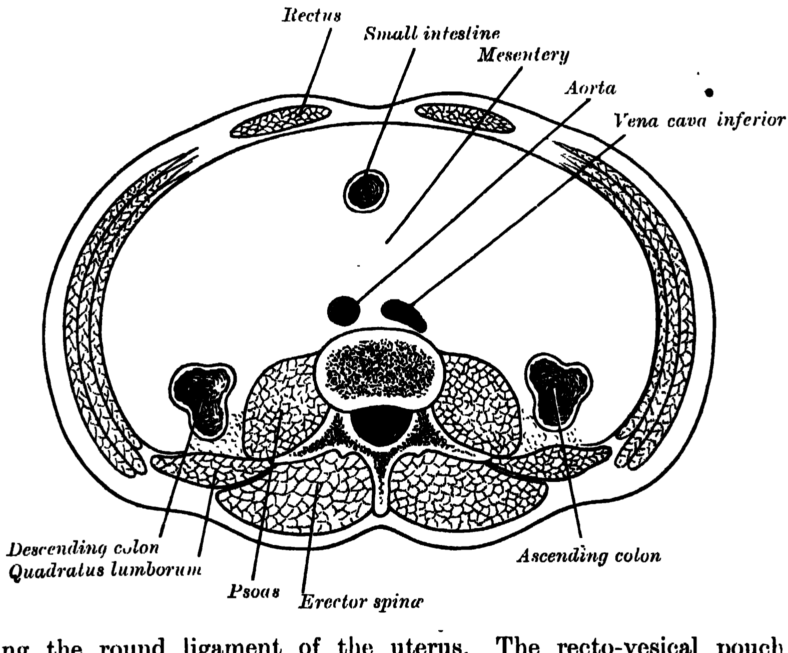
Between the rectum and the bladder it forms, in the male, a pouch, the *recto-vesical pouch*, the bottom of which is about the level of the middle of the vesiculæ seminales—i.e. about three inches from the orifice of the anus. When the bladder is distended, the peritoneum is carried up with the expanded viscus so that a considerable part of the anterior surface of the latter lies directly against the abdominal wall without the intervention of peritoneal membrane. In the female the peritoneum is reflected from the rectum on to the upper part of the posterior vaginal wall, forming the *recto-vaginal pouch* or *pouch of Douglas.* It is continued over the posterior surface and fundus of the uterus on to its anterior surface, which it covers as far as the junction of the body and cervix uteri, and then to the bladder, forming here a second, but shallower, pouch, the *utero-vesical pouch.* It is also reflected from the sides of the uterus to the lateral walls of the pelvis as two expanded folds, the *broad ligaments of the uterus*, in the free margin of each of which is the Fallopian tube.

Vertical disposition of the lesser sac (fig. 923).—A start may be made in this case on the posterior abdominal wall above the pancreas. From this region the peritoneum may be followed upwards on to the inferior surface of the Diaphragm, and thence on to the Spigelian and caudate lobes of the liver to the fissure for the ductus venosus and the transverse fissure. Traced laterally, it is continuous over the inferior vena cava with the posterior wall of the greater sac. From the liver it is carried downwards to the lesser curvature of the stomach as the posterior layer of the gastro-hepatic omentum, and is continuous on the right, round the hepatic artery, bile-duct, and portal vein, with the greater sac. The posterior layer of the gastro-hepatic omentum is carried down to the greater curvature of the stomach as a covering for the postero-inferior surface of this viscus, and from the greater curvature is continued downwards as the deep layer of the gastro-colic or great omentum. From the free margin of this fold it is reflected upwards on itself to the anterior and superior surfaces of the transverse colon, and thence as the superior layer of the transverse meso-colon to the upper border of the third part of the duodenum, from which it may be followed over the front of the pancreas to the level from which a start was made. It will be seen that the loop formed by the wall of the lesser sac below the transverse colon follows, and is closely applied to, the deep surface of that formed by the greater sac, and that the great omentum or large fold of peritoneum which hangs in front of the small intestine therefore consists of four layers, two anterior and two posterior, separated by the potential cavity of the lesser sac.

Horizontal disposition of the peritoneum.—Below the transverse colon the arrangement is simple, as it includes only the greater sac; above the level of the transverse colon it is more complicated on account of the existence of the two sacs. Below the transverse colon it may be considered in the two regions, viz. in the pelvis and in the abdomen proper.

(1) *In the pelvis.*—The peritoneum here follows closely the surfaces of the pelvic viscera and the inequalities of the pelvic walls, and presents important differences in the two sexes. (*a*) *In the male* it encircles the pelvic colon, from which it is reflected to the posterior wall of the pelvis as a fold, the *pelvic mesocolon.* It then leaves the sides and, finally, the front of the rectum, and is continued on to the bladder; on either side of the rectum it forms a fossa, the *pararectal fossa,* which varies in size with the distension of the rectum. In front of the rectum the peritoneum forms the recto-vesical pouch, which is limited laterally by peritoneal folds extending from the sides of the bladder to the rectum and sacrum. These folds are known from their position as the *recto-vesical* or *sacro-genital folds.* The peritoneum of the anterior pelvic wall covers the superior surface of the bladder, and on either side of this viscus forms a depression, termed the *paravesical fossa,* and limited externally by the fold of peritoneum covering the vas deferens. The size of this fossa is dependent on the state of distension of the bladder; when the bladder is empty, a variable fold of peritoneum, the *plica vesicalis transversa,* divides the fossa into two portions. On the peritoneum between the paravesical and pararectal fossæ the only elevations are those produced by the ureters and the internal iliac vessels. (*b*) *In the female,* pararectal and paravesical fossæ similar to those in the male are present: the outer limit of the paravesical fossa is the peritoneum

FIG. 925.—Horizontal disposition of the peritoneum in the lower part of the abdomen.



investing the round ligament of the uterus. The recto-vesical pouch is, however, divided by the uterus and vagina into a small anterior utero-vesical and a large, deep, posterior recto-vaginal pouch. The sacro-genital folds form the margins of the latter, and are continued on to the back of the uterus to form a transverse fold, the *torus uterinus.* The *broad ligaments* extend from the sides of the uterus to the lateral walls of the pelvis; they contain in their free margins the Fallopian tubes, and in their posterior layers the ovaries. Below, the broad ligaments are continuous with the peritoneum on the lateral walls of the pelvis. On the lateral pelvic wall behind the attachment of the broad ligament, in the angle between the elevations produced by the diverging internal and external iliac vessels, is a slight fossa, the *ovarian fossa,* in which the ovary normally lies.

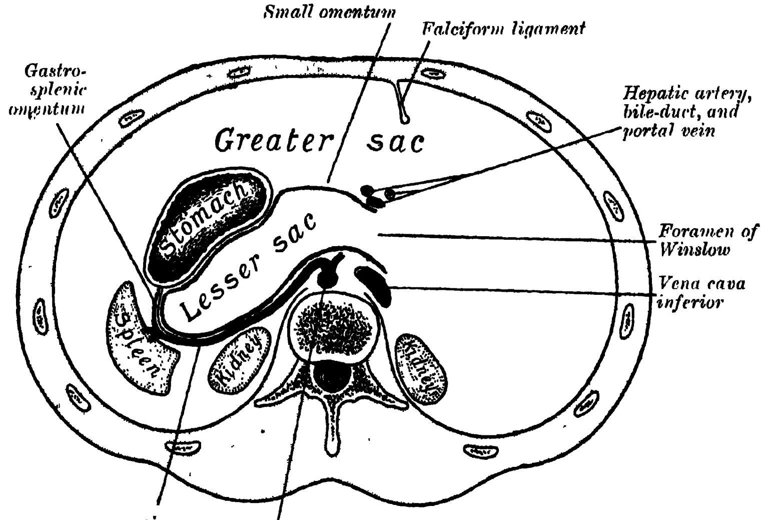
(2) *In the lower abdomen* (fig. 925).—Starting from the linea alba, below the level of the transverse colon, and tracing the continuity of the peritoneum in a horizontal direction to the right, the membrane covers the inner surface of the abdominal wall almost as far as the outer border of the Quadratus lumborum;

it encloses the cæcum and vermiform appendix, and is reflected over the sides and front of the ascending colon; it may then be traced over the Psoas muscle and inferior vena cava towards the middle line, whence it passes along the mesenteric vessels to invest the small intestine, and back again to the large vessels in front of the vertebral column, forming the *mesentery*, between the layers of which are contained the mesenteric blood-vessels, lacteals, and glands. It is then continued over the left Psoas muscle; it covers the sides and front of the descending colon, and, reaching the abdominal wall, is carried on it to the middle line.

(3) *In the upper abdomen* (fig. 926).—Above the transverse colon the peritoneum can be traced, forming the greater and lesser sacs, and the communication of the two sacs with one another through the foramen of Winslow can be demonstrated.

(*a*) *Greater sac.*—Commencing on the posterior abdominal wall at the inferior vena cava, the membrane may be followed to the right over the front of the upper part of the right kidney on to the antero-lateral abdominal wall. From the middle of the anterior wall a backwardly directed fold encircles the obliterated umbilical vein and forms the falciform ligament of the liver.

FIG. 926.—Horizontal disposition of the peritoneum in the upper part of the abdomen.



Continuing to the left, the peritoneum lines the lateral abdominal wall and covers the outer part of the front of the left kidney, and is reflected to the posterior border of the hilus of the spleen as the posterior layer of the *lieno-renal ligament*. It can then be traced over the surface of the spleen to the front of the hilus, and thence to the cardiac extremity of the stomach as the anterior layer of the *gastro-splenic omentum*. It covers the antero-superior surfaces of the stomach and first part of the duodenum, and extends up from the lesser curvature of the stomach to the liver, the latter portion forming the anterior layer of the gastro-hepatic omentum.

(*b*) *Lesser sac.*—On the posterior abdominal wall the peritoneum of the greater sac is continuous with that of the lesser sac in front of the inferior vena cava. Starting from here, the lesser sac may be traced across the aorta and over the inner part of the front of the left kidney to the hilus of the spleen as the anterior layer of the lieno-renal ligament. From the spleen it is reflected to the stomach as the posterior layer of the gastro-splenic omentum. It covers the postero-inferior surfaces of the stomach and commencement of the duodenum, and from the lesser curvature of the stomach extends upwards to the liver as the posterior layer of the gastro-hepatic omentum; the right

margin of this layer is continuous round the hepatic artery, bile-duct, and portal vein, with the wall of the greater sac.

Foramen of Winslow.—The foramen of Winslow is the passage of communication between the greater and lesser sacs. It is bounded *in front* by the free border of the gastro-hepatic omentum, with the common bile-duct, hepatic artery, and portal vein between its two layers; *behind* by the peritoneum covering the inferior vena cava; *above* by the peritoneum on the caudate lobe of the liver, and *below* by the peritoneum covering the commencement of the duodenum and the hepatic artery, the latter passing forwards below the foramen before ascending between the two layers of the gastro-hepatic omentum.

The *boundaries of the lesser sac* will now be evident. It is bounded *in front*, from above downwards, by the Spigelian lobe of the liver, the gastro-hepatic omentum, the stomach, and the anterior two layers of the great omentum. *Behind*, it is limited, from below upwards, by the two posterior layers of the great omentum, the transverse colon, and the ascending layer of the transverse mesocolon, the upper surface of the pancreas, the left suprarenal gland, and the upper end of the left kidney. To the right of the œsophageal opening of the stomach it is formed by that part of the Diaphragm which supports the Spigelian lobe of the liver. Laterally, the lesser sac extends from the foramen of Winslow to the spleen, where it is limited by the lieno-renal ligament and the gastro-splenic omentum.

In the fœtus the lesser sac reaches as low as the free margin of the great omentum, but in the adult its vertical extent is usually more limited owing to adhesions between the layers of the omentum. During a considerable part of fœtal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own, the two posterior layers of the great omentum passing at this stage in front of the colon. This condition occasionally persists throughout life, but as a rule adhesion occurs between the mesentery of the transverse colon and the posterior layer of the great omentum, with the result that the colon appears to receive its peritoneal covering by the splitting of the two posterior layers of the latter fold. In the adult the lesser sac intervenes between the stomach and the structures on which that viscus lies, and performs therefore the functions of a serous bursa for the stomach.

Numerous peritoneal folds extend between the various organs or connect them to the parietes. They serve to hold them in position, and, at the same time, enclose the vessels and nerves proceeding to them. Some of these folds are called *ligaments*, such as the ligaments of the liver and the false ligaments of the bladder. Others, which connect certain parts of the intestine with the abdominal wall, constitute the *mesenteries*; and lastly, those which proceed from the stomach to certain viscera in its neighbourhood are called *omenta*.

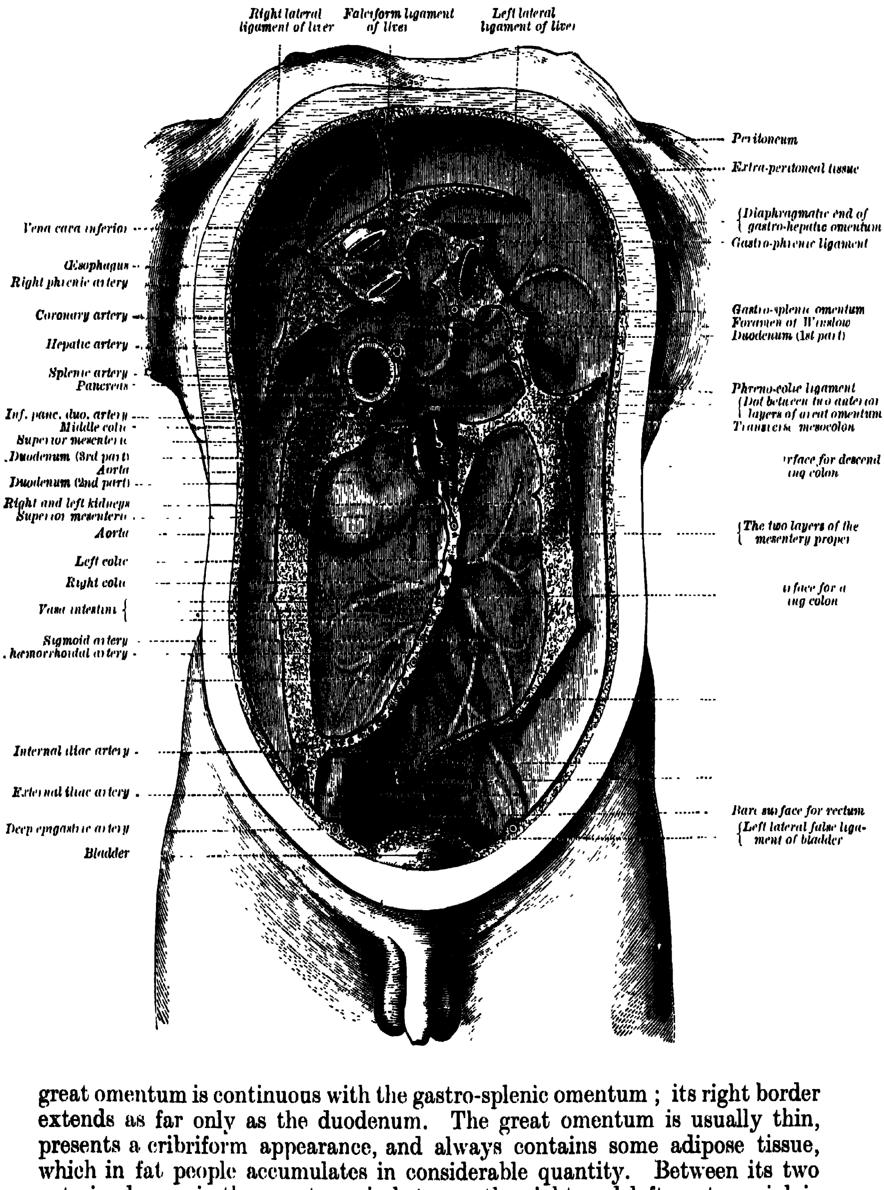
The **ligaments**, formed by folds of the peritoneum, include those of the liver, spleen, bladder, and uterus. They will be found described with their respective organs.

The **omenta** are: the small omentum, the great omentum, and the gastro-splenic omentum.

The *small* or *gastro-hepatic omentum* (omentum minus) is the duplicature which extends between the liver and the lesser curvature of the stomach. It is extremely thin, and is continuous with the two layers of peritoneum which cover respectively the antero-superior and postero-inferior surfaces of the stomach. When these two layers reach the lesser curvature of the stomach, they join together and ascend as a double fold to the transverse fissure of the liver; to the left of this fissure the fold is attached to the bottom of the fissure of the ductus venosus, along which it is carried to the Diaphragm, where the two layers separate to embrace the end of the œsophagus. At the right border the two layers are continuous, and form a free margin which constitutes the anterior boundary of the foramen of Winslow. Between the two layers, close to this free margin, are the hepatic artery, the common bile-duct, the portal vein, lymphatics, and the hepatic plexus of nerves—all these structures being enclosed in loose areolar tissue, called *Glisson's capsule*. Between the layers, where they are attached to the stomach, run the gastric artery and the pyloric branch of the hepatic artery.

The *great* or *gastro-colic omentum* (omentum majus) is the largest peritoneal fold. It consists of a double sheet of peritoneum, folded on itself so that it is made up of four layers. The two layers which descend from the stomach pass in front of the small intestines, sometimes as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These individual layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. The left border of the

FIG. 927.—Diagram devised by Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.



great omentum is continuous with the gastro-splenic omentum ; its right border extends as far only as the duodenum. The great omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat people accumulates in considerable quantity. Between its two anterior layers is the anastomosis between the right and left gastro-epiploic arteries.

The *gastro-splenic omentum* (lig. gastrolienale) is the fold which connects the margins of the hilus of the spleen to the stomach, being continuous by its lower border with the great omentum. It contains the vasa brevia.

The **mesenteries** are: the mesentery proper, the transverse mesocolon, and the pelvic mesocolon. In addition to these there are sometimes present an ascending and a descending mesocolon.

The *mesentery proper* (mesenterium) is the broad, fan-shaped fold of peritoneum which connects the convolutions of the jejunum and ileum with the posterior wall of the abdomen. Its *root*—the part connected with the structures in front of the vertebral column—is narrow, about six inches in length, and is directed obliquely from the duodeno-jejunal flexure at the left side of the second lumbar vertebra to the right iliac fossa (fig. 927). Its intestinal border is about twenty feet in length; and here the two layers separate to enclose the intestine, and form its peritoneal coat. Its breadth, between its vertebral and intestinal borders, is about eight inches. Its *upper border* is continuous with the under surface of the transverse mesocolon: its *lower border*, with the peritoneum covering the cæcum and ascending colon. It serves to retain the small intestines in their position, and contains between its layers the rami intestini tenuis of the superior mesenteric artery, with their accompanying veins and plexuses of nerves, the lacteal vessels, and mesenteric glands.

In most cases the peritoneum covers only the front and sides of the ascending and descending parts of the colon. Sometimes, however, these are surrounded by the serous membrane and attached to the posterior abdominal wall by an ascending and a descending mesocolon respectively. At the place where the transverse colon turns downwards to form the descending colon, a fold of peritoneum is continued to the Diaphragm opposite the tenth and eleventh ribs. This is the *phreno-colic ligament*; it passes below the spleen, and serves to support this organ, and therefore it has received the name of *sustentaculum lienis*.

The *transverse mesocolon* (mesocolon transversum) is a broad fold, which connects the transverse colon to the posterior wall of the abdomen. It is continuous with the two posterior layers of the great omentum, which, after separating to surround the transverse colon, join behind it, and are continued backwards to the spine, where they diverge in front of the anterior border of the pancreas. This fold contains between its layers the vessels which supply the transverse colon.

The *pelvic mesocolon* is the fold of peritoneum which retains the pelvic colon in connection with the pelvic wall. Its line of attachment forms a V-shaped curve, the apex of the curve being placed about the point of division of the left common iliac artery. The curve begins on the inner side of the left Psoas, and runs upwards and backwards to the apex, from which it bends sharply downwards and inwards, and ends in the mesial plane at the level of the third sacral vertebra. Between the two layers of this fold run the sigmoid and superior hæmorrhoidal vessels.

The *appendices epiploicæ* are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

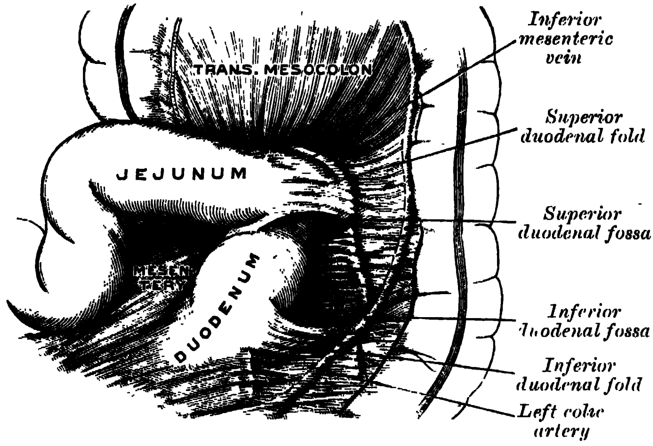
Retro-peritoneal fossæ.—In certain parts of the abdominal cavity there are recesses of peritoneum forming *culs-de-sac* or pouches, which are of surgical interest in connection with the possibility of the occurrence of retro-peritoneal hernia. One of these is the lesser sac of the peritoneum, which may be regarded as a recess of peritoneum through the foramen of Winslow, in which a hernia may take place, but there are several others, of smaller size, which require mention.

These recesses or fossæ may be divided into three groups, viz.: 1, the duodenal fossæ; 2, the circumcæcal fossæ; and 3, the intersigmoid fossa.

1. *Duodenal fossæ* (figs. 928, 929).—Moynihan has described no less than nine fossæ as occurring in the neighbourhood of the duodenum. Three of these are fairly constant, and are the only ones which require mention. (*a*) The *inferior duodenal fossa* is the most constant of all the peritoneal fossæ in this region, being present in from 70 to 75 per cent. of cases. It is situated opposite the third lumbar vertebra on the left side of the ascending portion of the duodenum. Its opening is directed upwards, and is bounded by a thin sharp fold of peritoneum with a concave margin, called the *inferior duodenal fold*. The tip of the index finger introduced into the fossa under the fold passes

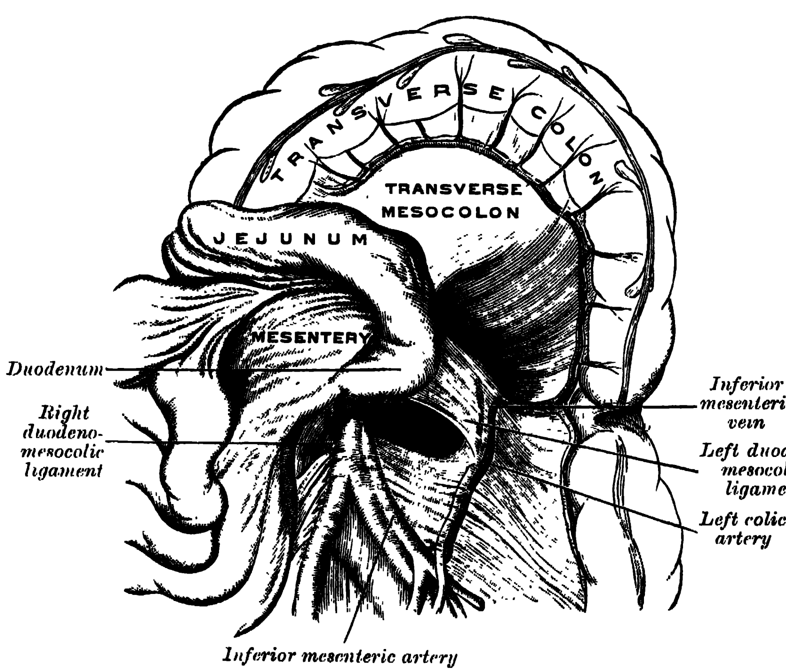
some little distance behind the ascending or fourth portion of the duodenum. (*b*) The *superior duodenal fossa* is the next most constant pouch or recess, being present in from 40 to 50 per cent. of cases. It often coexists with the inferior one, and its orifice looks downwards, in the opposite direction to the

FIG. 928.—Superior and inferior duodenal fossæ. (Poirier and Charpy.)



preceding fossa. It lies to the left of the ascending portion of the duodenum. It is bounded by the free edge of the *superior duodenal fold*, which presents a semilunar margin; to the right it is blended with the peritoneum covering the ascending duodenum, and to the left with the peritoneum covering the

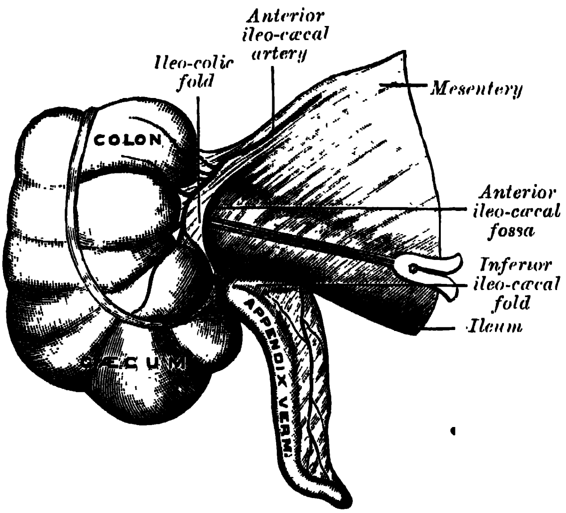
FIG. 929.—Duodeno-jejunal fossa. (Poirier and Charpy.)



peri-nephric tissues. The fossa is bounded in front by the superior duodenal fold; behind by the second lumbar vertebra; to the right by the duodenum. Its depth is two centimetres, and it terminates in the angle formed by the left renal vein crossing the aorta. This fossa is of importance, as it is in

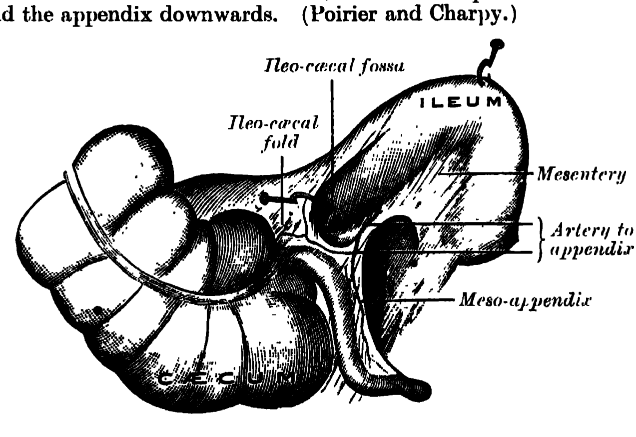
relation with the inferior mesenteric vein: that is to say, the vein almost always corresponds to the line of union of the superior duodenal fold with the posterior parietal peritoneum. (*c*) The *duodeno-jejunal fossa* can be seen by pulling the jejunum downwards and to the right, after the transverse colon has been pulled upwards. It will appear as an almost circular opening, looking downwards and to the right, and bounded by two free borders or folds of peritoneum, the *duodeno-mesocolic ligaments*. The opening admits the little finger into the fossa, to the depth of from two to three centimetres. The fossa is bounded above by the pancreas, to the right by the aorta, and to the left by the kidney; beneath is the left renal vein. The fossa exists in from 15 to 20 per cent. of cases, and has never yet been found in conjunction with any other form of duodenal fossa.

FIG. 930.—Ileo-colic fossa. (Poirier and Charpy.)



2. *Circumcæcal fossæ* (figs. 930, 931, 932).—There are at least three pouches or recesses termed *circumcæcal fossæ* to be found in the neighbourhood of the cæcum. (*a*) The *ileo-colic fossa* (superior ileo-cæcal) is formed by a fold of peritoneum, the ileo-colic fold, arching over the branch of the ileo-colic artery which supplies the ileo-colic junction. The fossa is a narrow chink situated

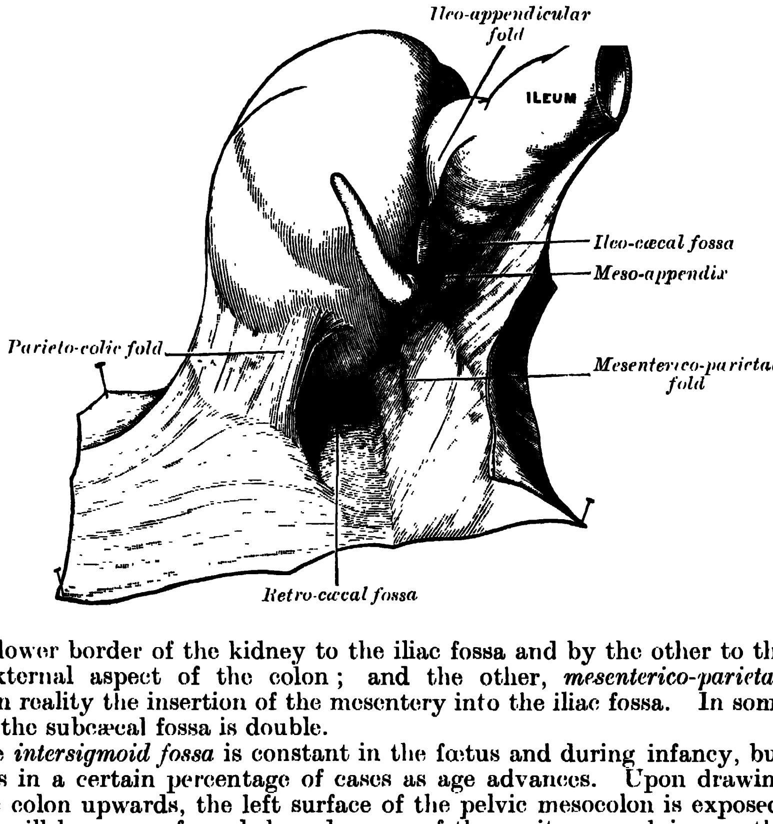
FIG. 931.—Ileo-cæcal fossa. The cæcum and ascending colon have been drawn outwards and downwards, the ileum upwards and backwards, and the appendix downwards. (Poirier and Charpy.)



between the ileo-colic fold in front, and the mesentery of the small intestine, the ileum, and the small portion of the cæcum behind. (*b*) The *ileo-cæcal fossa* (inferior ileo-cæcal) is situated behind the angle of junction of the ileum and cæcum. It is formed by a fold of peritoneum (the ileo-cæcal fold or bloodless fold of Treves), the upper border of which is attached to the ileum, opposite its mesenteric attachment, while the lower border, passing over the ileo-cæcal junction, joins the mesentery of the appendix, and sometimes the appendix itself; hence this fold has been called the ileo-appendicular. Between this fold and the mesentery of the vermiform

appendix is the ileo-cæcal fossa. It is bounded above by the posterior surface of the ileum and the mesentery; in front and below by the ileo-cæcal fold, and behind by the upper part of the mesentery of the appendix. (c) The *subcæcal fossa* (retro-cæcal) is situated immediately behind the cæcum, which has to be raised to bring it into view. It varies much in size and extent. In some cases it is sufficiently large to admit the index finger, and extends upwards behind the ascending colon in the direction of the kidney: in others it is merely a shallow depression. It is bounded and formed by two folds: one, the *parieto-colic*, which is attached by one edge to the abdominal wall

FIG. 932.—The sub-cæcal fossa. The ileum and cæcum are drawn backwards and upwards. (Souligoux.)



from the lower border of the kidney to the iliac fossa and by the other to the postero-external aspect of the colon; and the other, *mesenterico-parietal*, which is in reality the insertion of the mesentery into the iliac fossa. In some instances the subcæcal fossa is double.

3. The *intersigmoid fossa* is constant in the fœtus and during infancy, but disappears in a certain percentage of cases as age advances. Upon drawing the pelvic colon upwards, the left surface of the pelvic mesocolon is exposed, and on it will be seen a funnel-shaped recess of the peritoneum, lying on the external iliac vessels, in the interspace between the Psoas and Iliacus muscles. This is the orifice leading to the fossa intersigmoidea, which lies behind the pelvic mesocolon, and in front of the parietal peritoneum. The fossa varies in size; in some instances it is a mere dimple, whereas in others it will admit the whole of the index finger.

Applied Anatomy.—Any of these fossæ may be the site of a retro-peritoneal hernia. The circumcæcal fossæ are of especial interest, because hernia of the vermiform appendix frequently takes place into one of them, and it may there become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the appendix, where it travels upwards behind the ascending colon as far as the Diaphragm.*

THE STOMACH

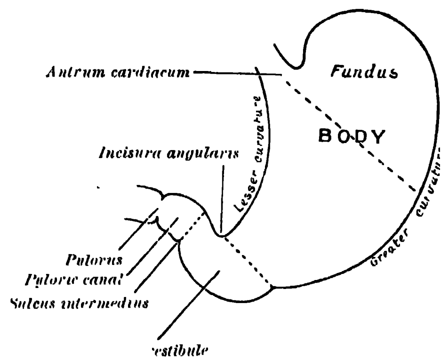
The **stomach** is the most dilated part of the alimentary canal, and is situated between the end of the œsophagus and the beginning of the small

* On the anatomy of these fossæ, see the *Arris and Gale Lectures* by Moynihan, 1899.

intestine. It lies more or less horizontally in the epigastric, umbilical, and left hypochondriac regions of the abdomen, and occupies a recess bounded by the upper abdominal viscera, and completed in front and on the left side by the anterior abdominal wall and the Diaphragm.

The *shape and position* of the stomach are so greatly modified by changes within itself and in the surrounding viscera that no one form can be described as typical. The chief modifications are determined by (1) the amount of the stomach contents, (2) the stage which the digestive process has reached, (3) the degree of development of the gastric musculature, and (4) the condition of the adjacent intestines. It is, however, possible by comparing a series of stomachs to determine certain markings more or less common to all.

FIG. 933.—Outline of stomach showing its anatomical landmarks.

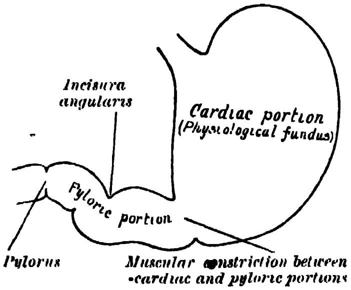


The stomach presents two openings, two borders or curvatures, and two surfaces.

Openings. — The opening by which the œsophagus communicates with the stomach is known as the *cardiac orifice*, and is situated on the left of the middle line at the level of the tenth thoracic vertebra. The short intra-abdominal portion of the œsophagus (*antrum cardiacum*) is conical in shape and curved sharply to the left, the base of the cone being continuous with the cardiac orifice of the stomach. The right margin of the œsophagus is continuous with the lesser curvature of the stomach, while the left margin joins the greater curvature at an acute angle, termed the *incisura cardiaca*.

The *pyloric orifice* communicates with the duodenum, and its position is usually indicated on the surface of the stomach by a circular groove, the *duodeno-pyloric constriction*. This orifice lies to the right of the middle line at the level of the upper border of the first lumbar vertebra.

FIG. 934. — Outline of stomach at an early stage of gastric digestion.



Curvatures. — The *lesser curvature*, extending between the cardiac and pyloric orifices, forms the right or posterior border of the stomach. It descends as a continuation of the right margin of the œsophagus in front of the left crus of the Diaphragm, and then, turning to the right, it crosses the first lumbar vertebra and ends at the pylorus. Nearer its pyloric than its cardiac end is a well-marked notch, the *incisura angularis*, which varies somewhat in position with the state of distension of the viscus; it serves to separate the stomach into a right and a left portion. The lesser curvature gives attachment to the two layers of the gastro-hepatic omentum, and between these two layers are the gastric branch of the coronary artery and the pyloric branch of the hepatic artery.

The *greater curvature* is directed mainly forwards, and is four or five times as long as the lesser curvature. Starting from the cardiac orifice at the incisura cardiaca, it forms an arch backwards, upwards, and to the left; the highest point of the convexity is on a level with the sixth left costal cartilage. From this level it may be followed downwards and forwards, with a slight convexity to the left as low as the cartilage of the ninth rib; it then turns to the right, to end at the pylorus. Directly opposite the incisura angularis of the lesser curvature the greater curvature presents a dilatation, the *pyloric vestibule*, which is limited on the right by a slight groove, the *sulcus intermedius*; this sulcus is about an inch from the duodeno-pyloric constriction.

The portion between the sulcus intermedius and the duodeno-pyloric constriction is termed the *pyloric canal*. At its commencement the greater curvature is covered by peritoneum continuous with that covering the front of the organ. The left part of the curvature gives attachment to the gastro-splenic omentum, while to its anterior portion are attached the two layers of the great omentum, separated from each other by the gastro-epiploic vessels.

Surfaces.—When the stomach is in the contracted condition, its surfaces are directed upwards and downwards respectively, but when the viscus is distended they are directed forwards and backwards. They may therefore be described as antero-superior and postero-inferior.

Antero-superior surface.—The left half of this surface is in contact with the Diaphragm, which separates it from the base of the left lung, the pericardium, and the seventh, eighth, and ninth ribs and intercostal spaces of the left side. The right half is in relation with the left and quadrate lobes of the liver and with the anterior abdominal wall. When the stomach is empty, the transverse colon may lie on the front part of this surface. The whole surface is covered by peritoneum.

The *postero-inferior surface* is in relation with the Diaphragm, the spleen, the left suprarenal gland, the upper part of the front of the left kidney, the anterior surface of the pancreas, the splenic flexure of the colon, and the upper layer of the transverse mesocolon. These structures form a shallow bed, the *stomach bed*, on which the viscus rests. The transverse mesocolon separates the stomach from the duodeno-jejunal flexure and small intestine. The postero-inferior surface is covered by peritoneum, except over a small area close to the cardiac orifice; this area is limited by the lines of attachment of the *gastro-phrenic ligament*, and lies in apposition with the Diaphragm, and frequently the upper portion of the left suprarenal gland.

Component parts of the stomach.—The stomach is capable of subdivision into distinctive parts, and the divisions may be made on either anatomical or physiological grounds.

Anatomical subdivisions.—A plane passing through the incisura angularis on the lesser curvature and the left limit of the opposed dilatation (pyloric vestibule) on the greater curvature divides the stomach into a left portion or *body* and a right or *pyloric* portion. The left portion of the body is known as the *fundus*, and is marked off from the remainder of the body by a plane passing through the cardiac orifice and a point on the greater curvature directly opposite. The pyloric portion is divided into a right part, the *pyloric canal*, and a left, the *pyloric vestibule*, by a plane through the sulcus intermedius at right angles to the long axis of this portion (fig. 933).

Physiological subdivisions.—If the stomach be examined during the process of digestion it will be found divided by a muscular constriction into a large dilated left portion, and a narrow contracted tubular right portion. The constriction is in the body of the stomach, and does not follow any of the anatomical landmarks; indeed it shifts gradually towards the left as digestion progresses, i.e. more of the body is gradually absorbed into the tubular part. These two portions are known as the *fundus* and *pyloric* portions. It will be seen therefore that the physiological fundus includes the anatomical fundus and the proximal part of the body, while the physiological pyloric portion comprises the distal part of the body, the pyloric vestibule and the pyloric canal (fig. 934).

Position of the stomach.—The position of the stomach varies with the amount of the stomach contents and with the condition of the intestines on which it rests. Variation in the amount of its contents affects only the physiological fundus, the pyloric portion remaining in a more or less contracted condition during the process of digestion. As the stomach fills it tends to expand forwards and downwards in the direction of least resistance, but when this is interfered with by a distended condition of the colon or intestines the fundus presses upwards on the liver and Diaphragm and gives rise to the feelings of oppression and palpitation complained of in such cases. His * and Cunningham † have shown by hardening the viscera *in situ* that the contracted stomach has a sickle shape, the fundus looking directly backwards. The surfaces are directed upwards and downwards, the upper surface having, however, a gradual downward slope to the right. The greater curvature is in front and at a slightly higher level than the lesser.

The position of the full stomach depends, as already indicated, on the state of the intestines; when these are empty the fundus expands vertically and also forwards, the pylorus is displaced towards the right, and the whole organ assumes an oblique position, so that

* *Archiv für Anatomie und Physiologie, anat. Abth.*, 1903.

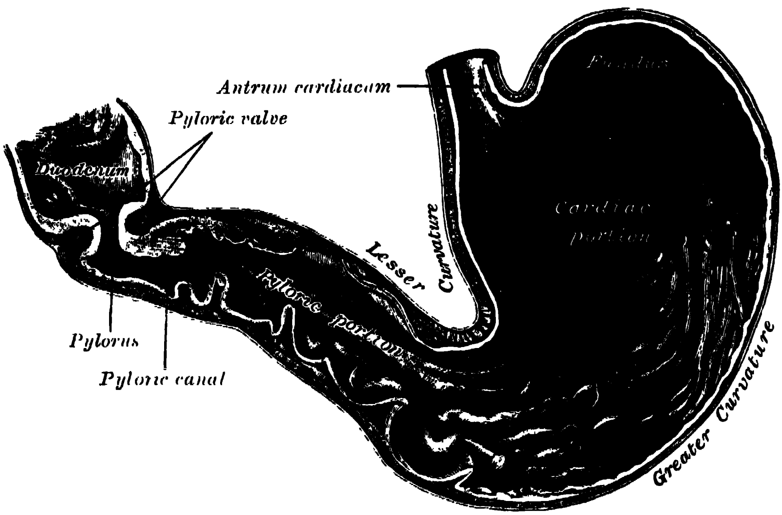
† *Transactions of the Royal Society of Edinburgh*, vol. xlv. part i.

its surfaces are directed more forwards and backwards. The lowest part of the stomach is at the pyloric vestibule, which reaches to the region of the umbilicus. Where the intestines interfere with the downward expansion of the fundus the stomach retains the horizontal position which is characteristic of the contracted viscus.

Examination of the stomach during life by x-rays has confirmed these findings, and has demonstrated that, in the erect posture, the full stomach usually presents a hook-like appearance, the long axis of the physiological fundus being directed downwards, inwards, and forwards towards the umbilicus, while the pyloric portion curves upwards to the duodeno-pyloric junction.

Interior of the stomach.—When examined after death, the stomach is usually fixed at some temporary stage of the digestive process. A common form is that shown in fig. 935. If the viscus be laid open by a section through the plane of its two curvatures, it is seen to

FIG. 935.—Interior of the stomach.



consist of two segments: (*a*) a large globular portion on the left and (*b*) a narrow tubular part on the right. These correspond to the physiological subdivisions of fundus and pyloric portions already described, and are separated by a constriction which indents the body and greater curvature, but does not involve the lesser curvature. To the left of the cardiac orifice is the incisura cardiaca: the projection of this notch into the cavity of the stomach increases as the organ distends, and has been supposed to act as a valve preventing regurgitation into the œsophagus. In the pyloric portion are seen: (*a*) the elevation corresponding to the incisura angularis, and (*b*) the circular projection from the duodeno-pyloric constriction which forms the pyloric valve. The separation of the pyloric vestibule from the pyloric canal is scarcely indicated, but the manner in which the pylorus is invaginated into the duodenum is evident.

The *pyloric valve* is formed by a reduplication of the mucous membrane of the stomach, containing numerous circular muscular fibres, which are aggregated into a thick ring. Some of the deeper longitudinal fibres turn in and interlace with the circular fibres of the valve.

Structure.—The wall of the stomach consists of four coats: serous, muscular, areolar, and mucous, together with vessels and nerves.

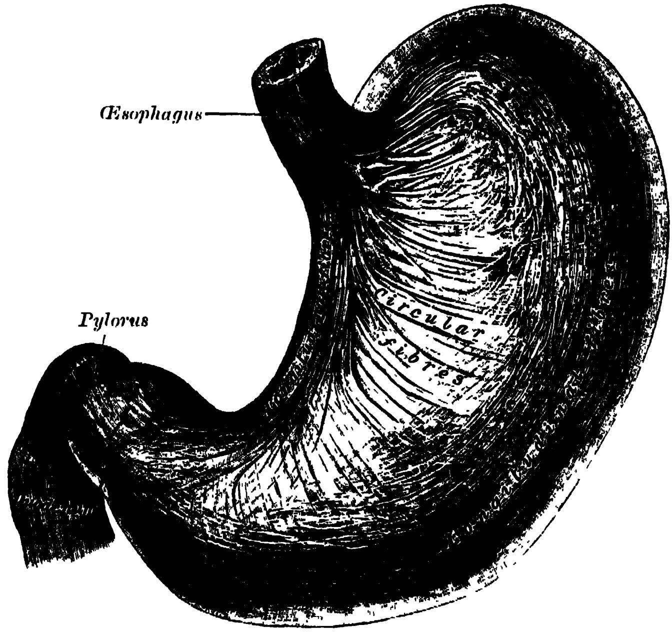
The *serous coat* is derived from the peritoneum, and covers the entire surface of the organ, excepting along the greater and lesser curvatures, at the points of attachment of the greater and lesser omenta; here the two layers of peritoneum leave a small triangular space, along which the nutrient vessels and nerves pass. On the posterior surface of the stomach, close to the cardiac orifice, there is also a small area uncovered by peritoneum, where the organ is in contact with the under surface of the Diaphragm.

The *muscular coat* (figs. 936, 937) is situated immediately beneath the serous covering, to which it is closely connected. It consists of three sets of fibres: longitudinal, circular, and oblique.

The *longitudinal fibres* are the most superficial, and are arranged in two sets. The first set consists of fibres continuous with the longitudinal fibres of the œsophagus; they radiate in a stellate manner from the cardiac orifice and are practically all lost before the pyloric

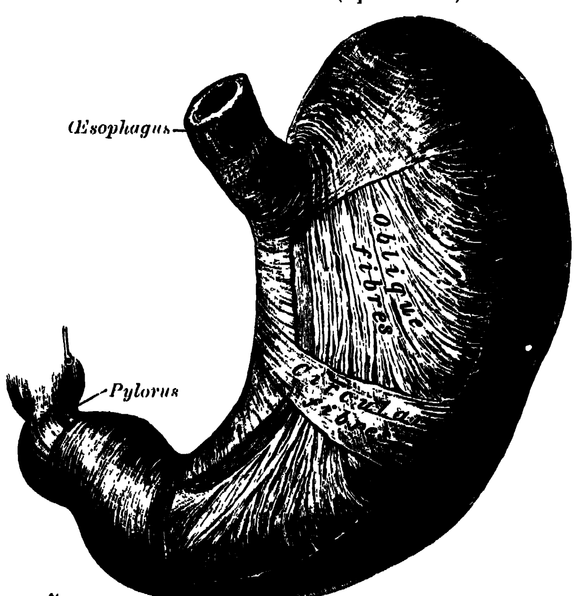
portion is reached. The second set commences on the body of the stomach and passes to the right, its fibres becoming more thickly distributed as they approach the pylorus.

Fig. 936.—The longitudinal and circular muscular fibres of the stomach, viewed from above and in front. (Spalteholz.)



Some of the more superficial fibres of this set pass on to the duodenum, but the deeper fibres dip inwards and interlace with the circular fibres of the pyloric valve.

Fig. 937.—The oblique muscular fibres of the stomach, viewed from above and in front. (Spalteholz.)



The *circular fibres* form a uniform layer over the whole extent of the stomach beneath the longitudinal fibres. At the pylorus they are most abundant, and are aggregated into a circular ring, which projects into the lumen, and forms, with the fold of mucous membrane

covering its surface, the *pyloric valve.* They are continuous with the circular fibres of the œsophagus, but are sharply marked off from the circular fibres of the duodenum.

The *oblique fibres* are limited chiefly to the cardiac end of the stomach, where they are disposed as a thick uniform layer, covering both surfaces, some passing obliquely from left to right, others from right to left, round the cardiac end.

The *areolar* or *submucous coat* consists of a loose, areolar tissue, connecting the mucous and muscular layers.

The *mucous membrane* is thick and its surface is smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown colour over the rest of its surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker towards the pylorus. During the contracted state of the organ it is thrown into numerous plaits or rugæ, which, for the most part, have a longitudinal direction, and are most marked towards the lesser end of the stomach, and along the greater curvature (fig. 935). These folds are entirely obliterated when the organ becomes distended.

Structure of the Mucous Membrane.—When examined with a lens, the inner surface of the mucous membrane presents a peculiar honeycomb appearance from being covered

FIG. 938.—Pyloric gland.

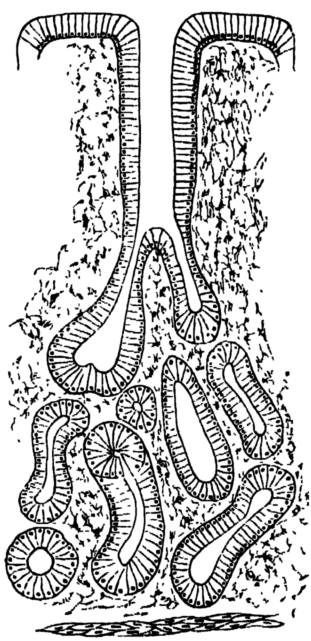


FIG. 939.—Cardiac gland.

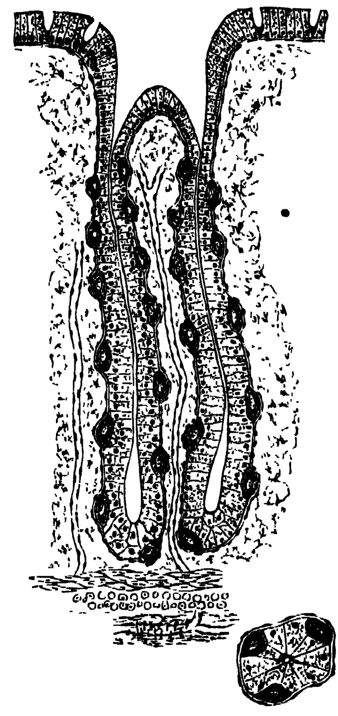


with small shallow depressions or alveoli, of a polygonal or hexagonal form, which vary from $\frac{1}{100}$ to $\frac{1}{250}$ of an inch in diameter, and are separated by slightly elevated ridges. In the bottom of the alveoli are seen the orifices of minute tubes, the *gastric glands,* which are situated perpendicularly side by side throughout the entire substance of the mucous membrane. The surface of the mucous membrane of the stomach is covered by a single layer of columnar epithelium ; it lines the alveoli, and also for a certain distance the mouths of the gastric glands. This epithelium commences very abruptly at the cardiac orifice, where the cells suddenly change in character from the stratified epithelium of the œsophagus.

The gastric glands are of two kinds, (*a*) *pyloric* and (*b*) *cardiac* or *oxyntic glands.* They are both tubular in character, and are formed of a delicate basement-membrane, lined by epithelium; the basement-membrane consists of flattened transparent endothelial cells. The *pyloric glands* (fig. 938) are most numerous at the pyloric end of the stomach, and from this fact have received their name. They consist of two or three short closed tubes opening into a common duct or mouth, the external orifice of which is situated at the bottom of an alveolus. These tubes are wavy, and are about equal in length to the duct. The tubes and duct are lined throughout with epithelium, the duct being lined by columnar cells, continuous with the epithelium lining the surface of the mucous

membrane of the stomach, the tubes with shorter and more cubical cells which are finely granular. The *cardiac glands* (fig. 939) are found all over the surface of the stomach, but occur most numerously at the cardiac end. Like the pyloric glands they consist of a duct, into which open two or more closed tubes. The duct, however, in these glands is shorter than in the other variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the duct, and which is termed the neck, the epithelium alters, and consists of short columnar or polyhedral, granular cells, which almost fill the tube, so that the lumen becomes suddenly constricted, and is continued down as a very fine channel. They are known as the *chief* or *central* cells of the glands. Between these cells and the basement-membrane, larger oval cells, which stain deeply with eosin, are found; these cells are studded throughout the tube at intervals, giving it a beaded or varicose appearance. These are known as the *parietal* or *oxyntic* cells. Between the glands the mucous membrane consists of a connective-tissue framework, with lymphoid tissue. In places, this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary glands of the intestine, and are termed the *lenticular* glands of the stomach. They are not, however, so distinctly circumscribed as the solitary glands. Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscular fibre (*muscularis mucosæ*), which in some parts consists only of a single longitudinal layer; in others of two layers, an inner circular, and an outer longitudinal.

Vessels and Nerves.—The arteries supplying the stomach are: the gastric, the pyloric and right gastro-epiploic branches of the hepatic, the left gastro-epiploic and vasa brevia from the splenic. They supply the muscular coat, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upwards between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes, and also form hexagonal meshes around the alveoli. From these the *veins* arise, and pursue a straight course downwards, between the tubules, to the submucous tissue; they terminate either in the splenic and superior mesenteric veins, or directly in the portal vein. The *lymphatics* are numerous: they consist of a superficial and a deep set, and pass to the lymphatic glands found along the two curvatures of the organ. The *nerves* are the terminal branches of the right and left pneumogastric, the former being distributed upon the back, and the latter upon the front part of the organ. A great number of branches from the solar plexus of the sympathetic are also distributed to it.

Surface Form.—The stomach lies for the most part in the left hypochondriac region, but also slightly in the epigastric region, and is partly in contact with the abdominal wall, partly under cover of the lower ribs on the left side, and partly under the left lobe of the liver. Its cardiac orifice corresponds to the seventh left costal cartilage, about an inch from the sternum. The pyloric orifice would be pierced by a needle passed through the abdominal wall, five centimetres (two inches) below the junction of the right seventh costal cartilage with the sternum, to the disc between the last thoracic and the first lumbar vertebra (Macalister). The fundus of the stomach reaches as high as the level of the sixth costal cartilage of the left side, being a little below and behind the apex of the heart. The portion of the stomach which is in contact with the abdominal wall, and is therefore accessible for opening in the operations of gastrotomy and gastrostomy, is represented by a triangular space, the base of which is formed by a line drawn from the tip of the tenth costal cartilage on the left side to the tip of the ninth costal cartilage on the right, and the sides by two lines drawn from the extremity of the eighth costal cartilage on the left side to the ends of the base line.

Applied Anatomy.—Operations on the stomach are frequently performed. By 'gastrotomy' is meant an incision into the stomach for the removal of a foreign body, the opening being immediately afterwards closed—in contradistinction to 'gastrostomy' the making of a more or less permanent fistulous opening. *Gastrotomy* is probably best performed by an incision in the linea alba, especially if the foreign body be large, by a cut from the ensiform cartilage to the umbilicus; but may be performed by an incision over the foreign body itself, where this can be felt, or by one of the incisions for gastrostomy mentioned below. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound, and sponges are carefully packed round it. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert's sutures, i.e. by sutures passed through the peritoneal and muscular coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition. In *gastrostomy* the incision is commenced opposite the eighth left intercostal space, two inches from the median line, and carried downwards for three inches. By this incision the fibres of the Rectus muscle are exposed, and these are separated in the same line. The posterior layer of the sheath, the Transversalis muscle and fascia, and the peritoneum are then divided, and the peritoneal cavity opened. The anterior wall of the stomach is now seized and drawn out of the wound, and a silk suture passed through its muscular and serous coats at the point selected for opening the viscus. This is held by an assistant so that a

long conical diverticulum of the stomach protrudes from the external wound, and the parietal peritoneum and the posterior layer of the sheath of the Rectus are sutured to it. A second incision is made through the skin, over the margin of the costal cartilage, above and a little to the outer side of the first incision. A track is made under the skin through the subcutaneous tissue from the one opening to the other, and the diverticulum of the stomach is drawn along this track by means of the suture inserted into it, so that its apex appears at the second opening. A small perforation is now made into the stomach through this protruding apex, and its margins are carefully and accurately sutured to the edge of the external wound. The remainder of this incision and the whole of the first incision are then closed in the ordinary way and the wound dressed.

In cases of gastric ulcer perforation sometimes takes place, and this was formerly regarded as an almost fatal complication. In the present day, by opening the abdomen and closing the perforation, which is generally situated on the anterior surface of the stomach, a considerable number of cases are cured, provided the operation is done not longer than twelve or fifteen hours after the perforation has taken place. The opening is best closed by bringing the peritoneal surfaces on either side into apposition by means of Lembert's sutures.

Excision of the pylorus has occasionally been performed, but the results of this operation are by no means favourable, and, in cases of cancer of the pylorus, before operative proceedings are undertaken, the tumour has become so fixed and has so far implicated surrounding parts that removal of the pylorus is impossible and gastro-enterostomy has to be substituted. The object of this operation is to make a fistulous communication between the stomach, on the cardiac side of the disease, and the small intestine, as high up as is possible. In cases of cancer of the stomach involving other parts than the pylorus, the question of removing the whole or greater part of the stomach has to be considered. This operation has been performed by Schlatter and others with success.

Hypertrophy and spasm of the circumferential muscular coat of the pylorus coming on during the first few weeks or months of life, and somewhat erroneously described as *congenital hypertrophic stenosis of the pylorus*, is a rare but serious disorder of infancy. It is characterised by abdominal pains and obstinate vomiting coming on after food has been given, and gastric peristalsis can be observed by inspection of the child's epigastrium after it has been fed and before vomiting has occurred. Progressive wasting for want of nourishment, and death from exhaustion, tend to ensue. Treatment should be by washing out the stomach, and the administration at frequent intervals of small quantities of easily digested food, so as to minimise irritation of the gastric mucous membrane. Surgical interference — pyloroplasty or pylorectomy — entailing a severe operation, gives less favourable results.

The stomach is seldom ruptured from external violence, on account of its protected position. If it occurs, it is when the organ is distended with food. The stomach is sometimes injured in gunshot wounds. There is intense shock and severe pain, localised at first at the seat of the injury, but soon radiating over the whole abdomen. The treatment consists in opening the peritoneal cavity, clearing away all the extruded contents of the stomach, and repairing the rent.

The Small Intestine (Intestinum tenue)

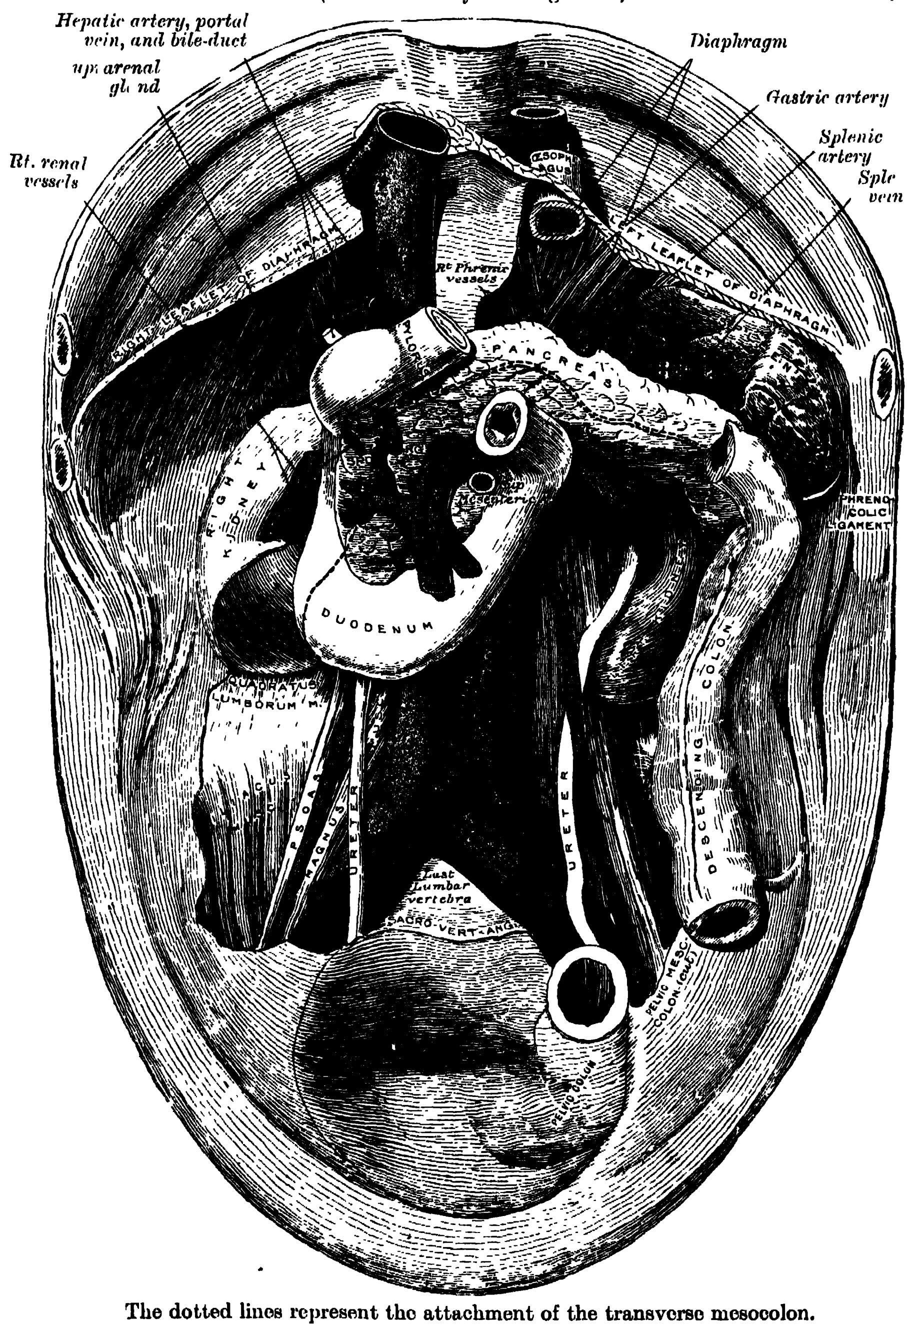
The **small intestine** is a convoluted tube, extending from the pylorus to the ileo-cæcal valve, where it terminates in the large intestine. It is about twenty feet in length,* and gradually diminishes in size from its commencement to its termination. It is contained in the central and lower parts of the abdominal cavity, and is surrounded above and at the sides by the large intestine; a portion of it extends below the brim of the pelvis and lies in front of the rectum. It is in relation, in front, with the great omentum and abdominal parietes, and is connected to the vertebral column by a fold of peritoneum, the mesentery. The small intestine is divisible into three portions: the duodenum, the jejunum, and ileum.

The **duodenum** (figs. 940, 970) has received its name from being about equal in length to the breadth of twelve fingers (ten inches). It is the shortest, the widest, and the most fixed part of the small intestine, and has no mesentery, being only partially covered by peritoneum. Its course presents a remarkable curve, somewhat of the shape of an imperfect circle, so that its termination is not far removed from its starting-point.

* Treves states that, in one hundred cases, the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches; but that it varies very much, the extremes in the male being 31 feet 10 inches in one case, and 15 feet 6 inches in another, a difference of over 15 feet. He states that he has convinced himself that the length of the bowel is independent, in the adult, of age, height, and weight.

In the adult the course of the duodenum is as follows: commencing at the pylorus it passes backwards, upwards, and to the right, beneath the quadrate lobe of the liver to the neck of the gall-bladder, varying slightly in direction

FIG. 940.—Relations of duodenum, pancreas, and spleen. (From a cast by Birmingham.*)



The dotted lines represent the attachment of the transverse mesocolon.

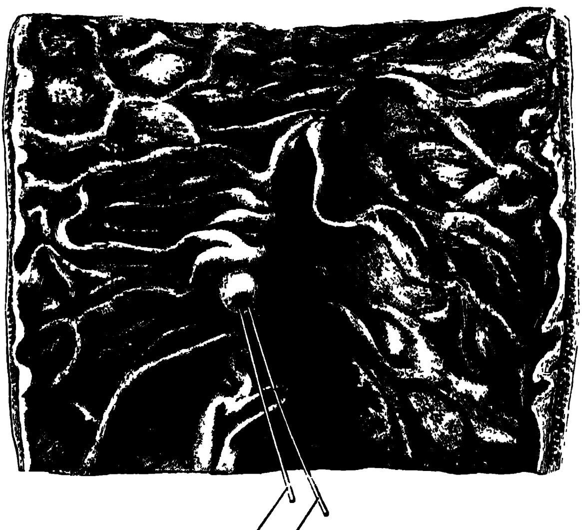
according to the degree of distension of the stomach: it then takes a sharp curve and descends along the right margin of the head of the pancreas, for a variable distance, generally to the level of the upper border of the body of the

* In the subject from which the cast was taken the left kidney was lower than normal.

fourth lumbar vertebra. It now takes a second bend, and passes from right to left across the vertebral column, having a slight inclination upwards; and on the left side of the vertebral column it ascends for about an inch, and then terminates opposite the second lumbar vertebra in the jejunum. As it unites with the jejunum it turns abruptly forwards, forming the *duodeno-jejunal flexure*. From the above description it will be seen that the duodenum may be divided into four portions: superior, descending, transverse, and ascending.

Relations.—The first or *superior portion* is about two inches in length. Beginning at the pylorus, it ends at the neck of the gall-bladder. It is the most movable of the four portions. It is almost completely covered by peritoneum derived from the two layers of the lesser omentum, but a small part of its posterior surface near the neck of the gall-bladder and the inferior vena cava is uncovered. It is in such close relation with the gall-bladder that it is usually found to be stained by bile after death, especially on its anterior surface. It is in relation above and in front with the quadrate lobe of the liver and the gall-bladder; behind with the gastro-duodenal artery, the

FIG. 941.—Interior of a portion of the duodenum, showing bile papilla.



common bile-duct, and the portal vein; and below with the head and neck of the pancreas.

The second or *descending portion* is between three and four inches in length, and extends from the neck of the gall-bladder on a level with the first lumbar vertebra along the right side of the vertebral column as low as the upper border of the body of the fourth lumbar vertebra. It is crossed in its middle third by the transverse colon, the posterior surface of which is uncovered by peritoneum and is connected to the duodenum by a small quantity of connective tissue. The portions of the descending part of the duodenum above and below this interspace are named the supra- and infra-colic portions, and are covered in front by peritoneum; the infra-colic part is covered by the right leaf of the mesentery. Posteriorly the descending portion of the duodenum is not covered by peritoneum. It is in relation, in front, with the transverse colon, and above this with the liver; behind, with the inner part of the right kidney to which it is connected by loose areolar tissue, the renal vessels, the vena cava inferior, and the Psoas magnus below; at its inner side is the head of the pancreas, and the common bile-duct; to its outer side is the hepatic flexure of the colon. The common bile-duct and the pancreatic duct perforate the inner side of this portion of the intestine obliquely, some three or four inches below the pylorus (fig. 941). The relations of the second part of the duodenum to the right kidney present considerable variations.

The third or *transverse portion* (pre-aortic portion) is from two to three inches in length. It commences at the right side of the upper border of the fourth lumbar vertebra and passes from right to left, with a slight inclination upwards, in front of the great vessels and crura of the Diaphragm, and ends in the fourth portion in front of the abdominal aorta. It is crossed by the superior mesenteric vessels and the mesentery. Its front surface is covered by peritoneum, except near the middle line, where it is crossed by the superior mesenteric vessels. Its posterior surface is uncovered by peritoneum, except towards its left extremity, where the posterior layer of the mesentery may sometimes be found covering it to a variable extent. This surface rests upon the right crus of the Diaphragm, the vena cava inferior, and the aorta. The upper surface is in relation with the head of the pancreas.

The fourth or *ascending portion* of the duodenum is about an inch in length. It ascends on the left side of the aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly forwards to become the jejunum, forming the *duodeno-jejunal flexure*. It lies in front of the left Psoas muscle and left renal vessels, and is covered in front, and partly at the sides, by peritoneum continuous with the left portion of the mesentery.

The first part of the duodenum, as stated above, is somewhat movable, but the rest is practically fixed, and is bound down to neighbouring viscera and the posterior abdominal wall by the peritoneum. In addition to this, the fourth part of the duodenum and the duodeno-jejunal flexure are fixed by a structure to which the name of *musculus suspensorius duodeni* has been given. This structure commences in the connective tissue around the cœliac axis and left crus of the Diaphragm, and passes downwards to be inserted into the superior border of the duodeno-jejunal curve and a part of the ascending duodenum, and from this it is continued into the mesentery. It possesses, according to Treitz, plain muscular fibres mixed with the fibrous tissue of which it is principally made up. It is of little importance as a muscle, but acts as a suspensory ligament.

Vessels and Nerves.—The *arteries* supplying the duodenum are the pyloric and superior pancreatico-duodenal branches of the hepatic, and the inferior pancreatico-duodenal branch of the superior mesenteric. The *veins* terminate in the splenic and superior mesenteric. The *nerves* are derived from the solar plexus.

Jejunum and ileum.—The remainder of the small intestine from the termination of the duodenum is named *jejunum* and *ileum*; the former term being given to the upper two-fifths and the latter to the lower three-fifths. There is no morphological line of distinction between the two, and the division is arbitrary; but at the same time it must be noted that the character of the intestine gradually undergoes a change from the commencement of the jejunum to the termination of the ileum, so that a portion of the bowel taken from these two situations would present characteristic and marked differences. These are briefly as follows.

The *jejunum* (intestinum jejunum) is wider, its diameter being about an inch and a half, and is thicker, more vascular, and of a deeper colour than the ileum, so that a given length weighs more. Its valvulæ conniventes are large and thickly set, and its villi are larger than in the ileum. The glands of Peyer are almost absent in the upper part of the jejunum, and in the lower part are less frequently found than in the ileum, and are smaller and tend to assume a circular form. By grasping the jejunum between the finger and thumb the valvulæ conniventes can be felt through the walls of the gut; these being absent in the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

The *ileum* (intestinum ileum) is narrow, its diameter being an inch and a quarter, and its coats thinner and less vascular than those of the jejunum. It possesses but few valvulæ conniventes, and they are small and disappear entirely towards its lower end, but Peyer's patches are larger and more numerous. The jejunum for the most part occupies the umbilical and left iliac regions, while the ileum occupies chiefly the umbilical, hypogastric, right iliac, and pelvic regions. Its terminal part usually lies in the pelvis, from which it ascends over the right iliac vessels and Psoas muscle; it ends in the right iliac fossa by opening into the inner side of the commencement of the

large intestine. The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, the *mesentery*, which allows the freest motion, so that each coil can accommodate itself to changes in form and position. The mesentery is fan-shaped; its posterior border or root, about six inches in length, is attached to the posterior abdominal wall from the left side of the body of the second lumbar vertebra to the right iliac fossa, crossing successively the third part of the duodenum, the aorta, the inferior vena cava, the ureter, and right Psoas muscle (fig. 927). Its breadth between its vertebral and intestinal borders is about eight inches, and is greater in the middle than at its upper and lower extremities. According to Lockwood it tends to increase in breadth as age advances. Between the two layers of which it is composed are contained blood-vessels, nerves, lacteals, and lymphatic glands, together with a variable amount of fat.

Meckel's diverticulum.—This consists of a pouch which projects from the lower part of the ileum in about 2 per cent. of subjects. Its average position is about three feet above the ileo-cæcal valve, and its average length about two inches. Its calibre is generally similar to that of the ileum, and its blind extremity may be free or may be connected with the abdominal wall or with some other portion of the intestine by a fibrous band. It represents the remains of the proximal part of the vitelline or omphalo-mesenteric duct, the duct of communication between the yolk sac and the alimentary canal in early fœtal life.

Structure.—The wall of the small intestine is composed of four coats: serous, muscular, areolar, and mucous.

The *serous coat* is derived from the peritoneum. The first or ascending portion of the duodenum is almost completely surrounded by this membrane near its pyloric end, but is only covered in front at the other extremity; the second or descending portion is covered by it in front, except where it is carried off by the transverse colon; and the third or transverse portion lies behind the peritoneum, which passes over it, without being closely incorporated with the other coats of this part of the intestine, and is separated from it in and near the middle line by the superior mesenteric vessels. The remaining portion of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to pass to the gut.

The *muscular coat* consists of two layers of fibres, an external, longitudinal, and an internal, circular layer. The *longitudinal fibres* are thinly scattered over the surface of the intestine, and are more distinct along its free border. The *circular fibres* form a thick, uniform layer, and are composed of plain muscle-cells of considerable length. The muscular coat is thicker at the upper than at the lower part of the small intestine.

The *areolar* or *submucous coat* connects together the mucous and muscular layers. It consists of loose, filamentous areolar tissue containing blood-vessels, lymphatics, and nerves.

The *mucous membrane* is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is a layer of longitudinal unstriped muscular fibres, the *muscularis mucosæ*; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph-corpuscles, and in which the blood-vessels and nerves ramify; lastly, a basement-membrane, supporting a single layer of epithelial cells, which throughout the intestines are columnar in character. The cells are granular in appearance, and each possesses a clear oval nucleus. At their superficial or unattached ends they present a distinct layer of highly refracting material, marked by vertical striæ (the *striated border*).

The mucous membrane presents for examination the following structures, contained within it or belonging to it:

Valvulæ conniventes.		Duodenal glands.
Villi.	Glands	Solitary glands.
Simple follicles.		Peyer's or agminated glands.

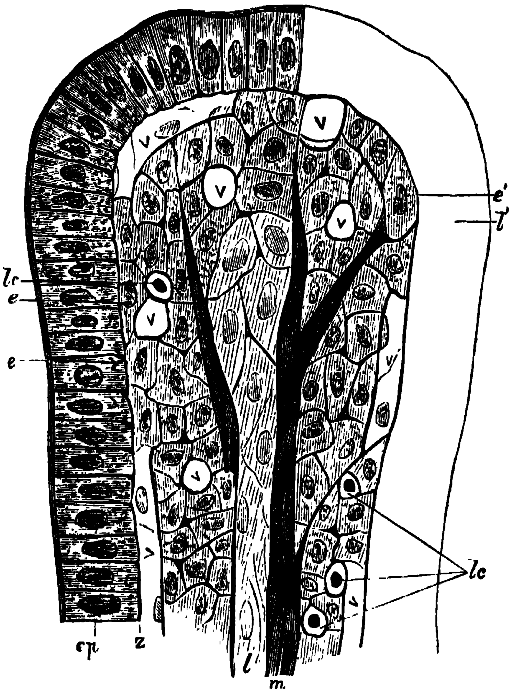
The **valvulæ conniventes** or valves of Kerkring (plicæ circulares) are large folds or valvular flaps projecting into the lumen of the bowel. They are composed of reduplications or folds of the mucous membrane, the two layers of the fold being bound together by submucous tissue; unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. The majority extend transversely across the cylinder of the intestine for about one-half or two-thirds of its circumference, but some form complete circles, and others have a spiral direction; the latter usually extend a little more than once round the bowel, but occasionally two or three times. The larger folds are about one-third of an inch in depth at their broadest part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. They are not found at the commencement of the duodenum, but begin to appear about one or two inches beyond the pylorus. In the lower part of the descending portion, below the point where the bile and pancreatic

ducts enter the intestine, they are very large and closely approximated. In the transverse portion of the duodenum and upper half of the jejunum they are large and numerous, but from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine, as compared with the duodenum and jejunum. The valvulæ conniventes retard the passage of the food along the intestines, and afford an increased surface for absorption.

The **villi** (villi intestinales) are highly vascular processes, projecting from the mucous membrane of the small intestine throughout its whole extent, and giving to its surface a velvety appearance. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum.

Structure of the villi (figs. 942, 943).—The essential parts of a villus are: the lacteal vessel, the blood-vessels, the epithelium, the basement-membrane, and muscular tissue of the mucosa, all being supported and held together by retiform lymphoid tissue.

Fig. 942.—Diagrammatic section of a villus. (Watney.)



ep. Epithelium only partially shaded in. *l.* Central chyle-vessel: the cells forming the vessel have been less shaded to distinguish them from the cells of the parenchyma of the villus. *m.* Muscle-fibres running up by the side of the chyle-vessel. It will be noticed that each muscle-fibre is surrounded by the reticulum, and by this reticulum the muscles are attached to the cells forming the membrana propria, as at *e'*, or to the reticulum of the villus. *lc.* Lymph-corpuscles, marked by a spherical nucleus and a clear zone of protoplasm. *l'.* Upper limit of the chyle-vessel. *e*, *e*, *e'*. Cells forming the membrana propria. It will be seen that there is hardly any difference between the cells of the parenchyma, the endothelium of the *upper* part of the chyle-vessel, and the cells of the membrana propria. V. Blood-vessels. *z.* Dark line at the base of the epithelium formed by the reticulum. It will be seen that the reticulum penetrates between all the other elements of the villus. The reticulum contains thickenings or 'nodal points.' The diagram shows that the cells of the upper part of the villus are larger and contain a larger zone of protoplasm than those of the lower part. The cells of the upper part of the chyle-vessel differ somewhat from those of the lower part, in that they more nearly resemble the cells of the parenchyma.

These structures are arranged in the following manner. Situated in the centre of the villus is the lacteal, terminating near the summit in a blind extremity; running along this vessel are unstriped muscular fibres; surrounding it is a plexus of capillary vessels, the whole being enclosed by a basement-membrane, and covered by columnar epithelium. Those structures which are contained within the basement-membrane—namely, the lacteal, the muscular tissue, and the blood-vessels—are surrounded and enclosed by a delicate reticulum which forms the matrix of the villus, and in the meshes of which are found large flattened cells, each with an oval nucleus, and, in smaller numbers, lymph-corpuscles. Nerve-fibres are contained within the villi; they form ramifications throughout the reticulum.

The *lacteals* are in some cases double, and in some animals multiple. Situated in the axis of the villi, they commence by dilated cæcal extremities near to, but not quite at, the

summit of the villus. The walls are composed of a single layer of endothelial cells, the interstitial substance between the cells being continuous with the reticulum of the matrix.

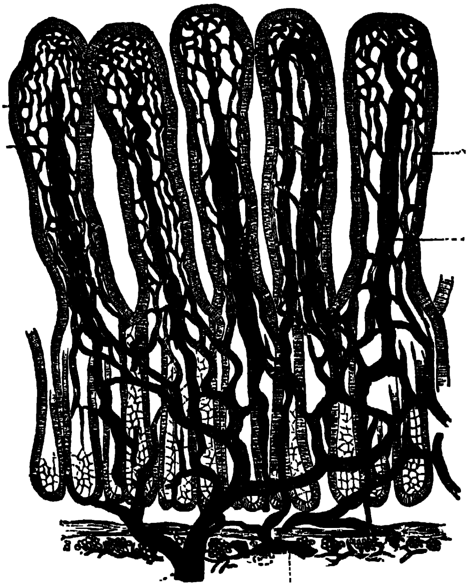


Fig. 943.—Villi of small intestine. (Cadiat.)

Fig. 944.—Longitudinal section of crypts of Lieberkühn. Goblet-cells seen among the columnar epithelial cells. (Klein and Noble Smith.)

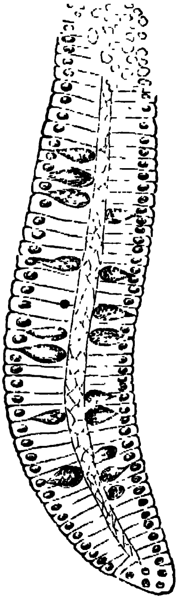

Fig. 945.—Transverse section of crypts of Lieberkühn. (Klein and Noble Smith.)

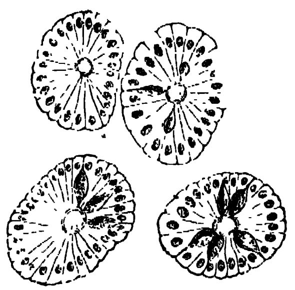


The *muscular fibres* are derived from the muscularis mucosæ, and are arranged in longitudinal bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off, laterally, individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement-membrane.

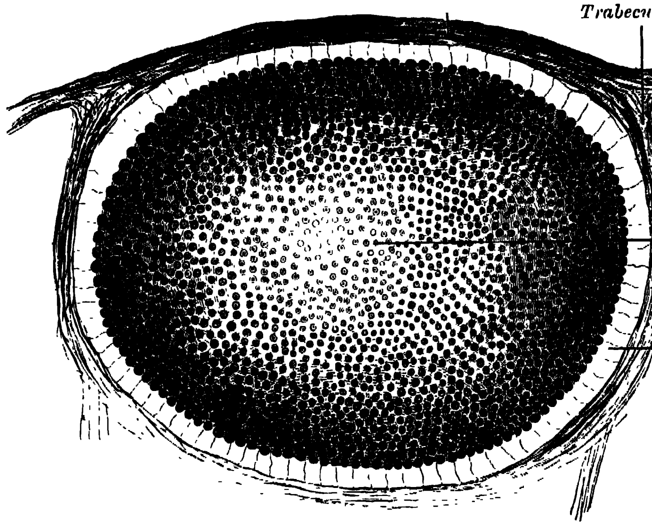
The *blood-vessels* form a plexus between the lacteal and the basement-membrane, and are enclosed in the reticular tissue. In the interstices of the capillary plexus are contained the cells of the villus.

These structures are surrounded by the basement-membrane, which is made up of a stratum of endothelial cells, and upon this is placed a layer of columnar epithelium. The reticulum of the matrix is continuous through the basement-membrane (that is, through the interstitial substance between the individual endothelial cells) with the interstitial cement-substance of the columnar cells on the surface of the villus. Thus we are enabled to trace a direct continuity between the interior of the lacteal and the surface of

the villus by means of the reticular tissue, and it is along this path that the chyle passes in the process of absorption by the villi. That is to say, it passes first of all into the columnar epithelial cells, and, escaping from them, is carried into the reticulum of the villus, and thence into the central lacteal.

The **simple follicles**, or *crypts of Lieberkühn* (gl. intestinales) (figs. 944, 945), are found in considerable numbers over every part of the mucous membrane of the small intestine.

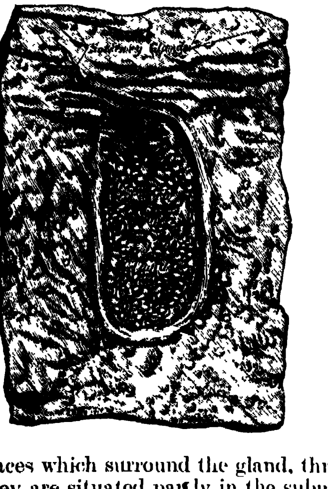
FIG. 946.—Lymphoid nodule.



They consist of minute tubular depressions of the mucous membrane, arranged perpendicularly to the surface, upon which they open by small circular apertures. They may be seen with the aid of a lens, their orifices appearing as minute dots scattered between the villi. Their walls are thin, consisting of a basement-membrane lined by columnar epithelium, and covered on their exterior by capillary vessels.

The **duodenal** or **Brunner's glands** (gl. duodenales) are limited to the duodenum, and are found in the submucous areolar tissue. They are largest and most numerous near the pylorus, forming an almost complete layer in the first and upper half of the second portions of the duodenum. They then begin to diminish in number, and practically disappear at the junction of the duodenum and jejunum. They are small compound acino-tubular glands, consisting of a number of alveoli lined by short columnar epithelium and opening by a single duct on the inner surface of the intestine.

FIG. 947.—Patch of Peyer's glands. From the lower part of the ileum.

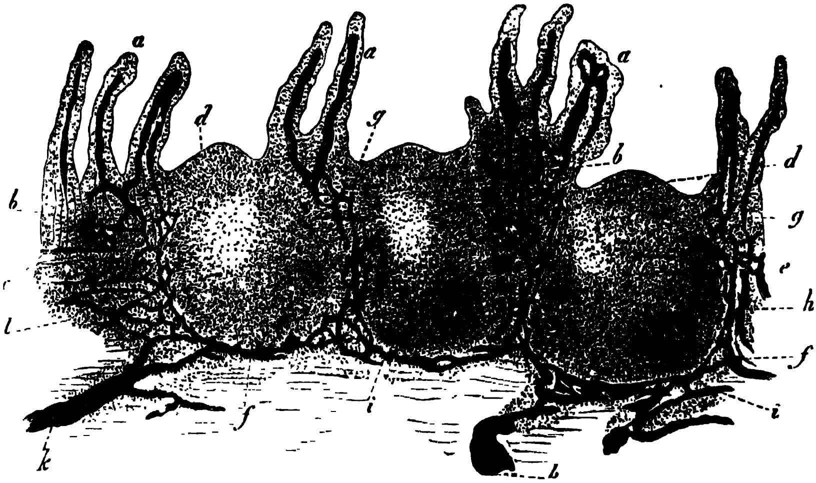


The **solitary glands** (noduli lymphatici solitarii) (fig. 946) are found scattered throughout the mucous membrane of the small intestine, but are most numerous in the lower part of the ileum. They are small, round, lymphoid nodules; their free surfaces are covered with rudimentary villi, except at the summit, and each gland is surrounded by the openings of the follicles of Lieberkühn. Each consists of a dense interlacing retiform tissue closely packed with lymph-corpuscles, and permeated with an abundant capillary network. The interspaces of the retiform tissue are continuous with larger lymph-spaces which surround the gland, through which they communicate with the lacteal system. They are situated partly in the submucous tissue, partly in the mucous membrane, where they form slight projections of its epithelial layer, after having penetrated the muscularis mucosæ.

Peyer's glands (noduli lymphatici aggregati) (figs. 947 to 949) may be regarded as aggregations of solitary glands forming circular or oval patches, from twenty to thirty in number, and varying in length from half an inch to four inches. They are largest and

most numerous in the ileum. In the lower part of the jejunum they are small, circular, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are situated in the portion of the tube most distant from

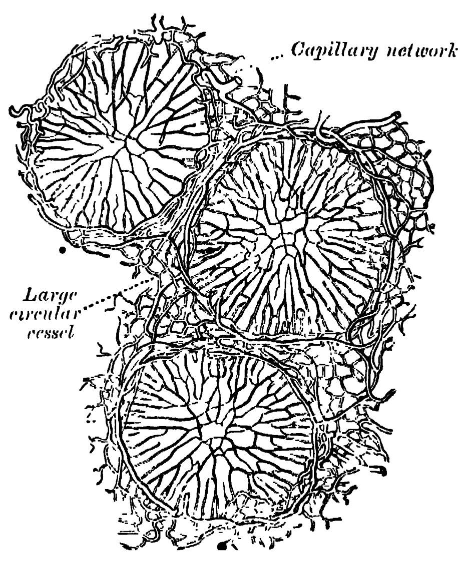
FIG. 948.—Vertical section of one of Peyer's patches from man, injected through its lymphatic canals.



a. Villi with their chyle-passages. *b.* Follicles of Lieberkuhn. *c.* Muscularis mucosæ. *d.* Cupula or apex of solitary glands. *e.* Mesial zone of glands. *f.* Base of glands. *g.* Points of exit of the chyle-passages from the villi, and entrance into the true mucous membrane. *h.* Retiform arrangement of the lymphatics in the mesial zone. *i.* Course of the latter at the base of the glands. *k.* Confluence of the lymphatics opening into the vessels of the submucous tissue. *l.* Follicular tissue of the latter.

the attachment of the mesentery. Each patch is formed of a group of solitary glands covered with mucous membrane, but the patches do not, as a rule, possess villi on their free surfaces. They are best marked in the young subject, become indistinct in middle age, and sometimes disappear altogether in advanced life. They are freely supplied with blood-vessels, which form an abundant plexus around each follicle and give off fine branches which permeate the lymphoid tissue in the interior of the follicle. The lymphatic plexuses are especially abundant around these patches (fig. 948).

FIG. 949.—Transverse section through the equatorial plane of three of Peyer's follicles from the rabbit.

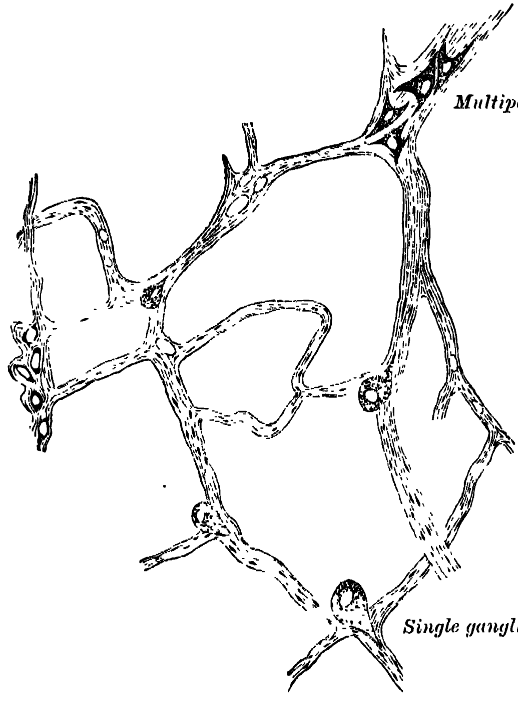


Vessels and Nerves.—The jejunum and ileum are supplied by the superior mesenteric artery, the branches of which, having reached the attached border of the bowel, run between the serous and muscular coats, with frequent inosculations to the free border, where they also anastomose with other branches running round the opposite surface of the gut. From these vessels numerous branches are given off, which pierce the muscular coat, supplying it and forming an intricate plexus in the submucous tissue. From this plexus minute vessels pass to the glands and villi of the mucous membrane. The veins have a similar course and arrangement to the arteries. The *lymphatics* of the small intestine (lacteals) are arranged in two sets, those of the mucous membrane and those of the muscular coat. The lymphatics of the villi commence in these structures in the manner described above, and form an intricate plexus in the mucous and submucous tissue, being joined by the lymphatics from the lymph-spaces at the bases of the solitary glands, and from this pass to larger vessels at the mesenteric border of the gut. The lymphatics of the muscular coat are situated to a great extent between the two layers of muscular fibres, where they form a

close plexus, and throughout their course communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner into the origins of the lacteal vessels at the attached border of the gut.

The *nerves of the small intestines* are derived from the plexuses of sympathetic nerves around the superior mesenteric artery. From this source they run to a plexus of nerves and ganglia situated between the circular and longitudinal muscular fibres (*Auerbach's plexus*), from which the nervous branches are distributed to the muscular coats of the intestine. From this plexus a secondary plexus (*Meissner's plexus*) is derived, and is formed

FIG. 950.—Meissner's plexus. (Klein and Noble Smith.)



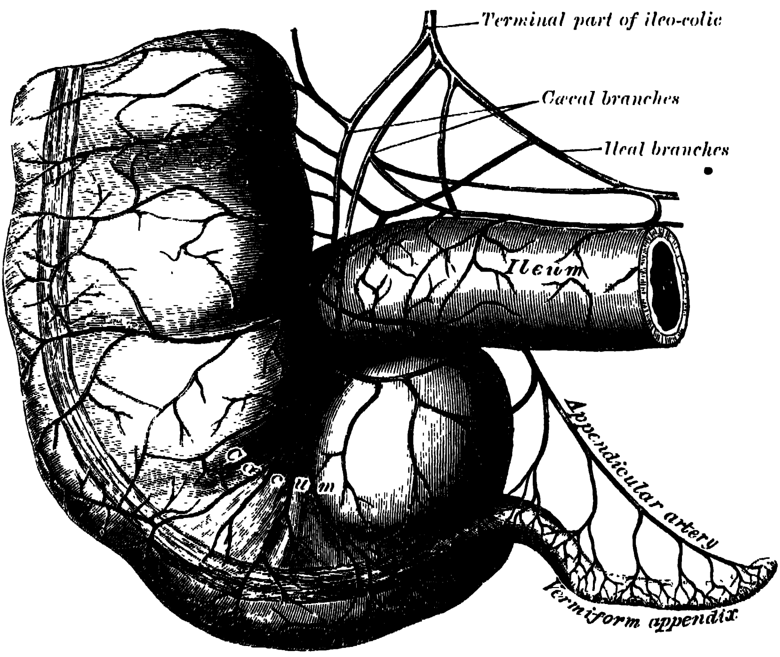
by branches which have perforated the circular muscular fibres (fig. 950). This plexus lies between the muscular and mucous coats of the intestine; it also contains ganglia from which nerve-fibres pass to the muscularis mucosæ and to the mucous membrane.

THE LARGE INTESTINE (INTESTINUM CRASSUM)

The large intestine extends from the termination of the ileum to the anus. It is about five feet in length, being one-fifth of the whole extent of the intestinal canal. It is largest at its commencement at the cæcum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anal canal. It differs from the small intestine in its greater calibre, its more fixed position, its sacculated form, and in possessing certain appendages to its external coat, the *appendices epiploicæ*. Further, its longitudinal muscular fibres do not form a continuous layer around the gut, but are arranged in three longitudinal bands or *tæniæ*. The large intestine, in its course, describes an arch which surrounds the convolutions of the small intestine. It commences in the right iliac region, in a dilated part, the *cæcum*. It ascends through the right lumbar and hypochondriac regions to the under surface of the liver; it here takes a bend (the *hepatic flexure*) to the left, and passes transversely across the abdomen on the confines of the epigastric and umbilical regions, to the left hypochondriac region; it then bends again (the *splenic flexure*), and descends through the left lumbar region to the left iliac fossa, where it becomes convoluted, and forms the *sigmoid flexure*; finally it enters the pelvis, and descends along its posterior wall to the anus. The large intestine is divided into the cæcum, colon, rectum, and anal canal.

The **cæcum** (intestinum cæcum), the commencement of the large intestine, is the large blind pouch situated below the ileo-cæcal valve (fig. 951). Its blind end is directed downwards, and its open end upwards, communicating directly with the colon, of which this blind pouch appears to be the beginning or head, and hence the old name of *caput cæcum coli* was applied to it. Its size is variously estimated by different authors, but on an average it may be said to be two and a half inches in length and three in breadth. It is situated in the right iliac fossa, above the outer half of Poupart's ligament: it rests on the Ilio-psoas muscle and lies immediately behind the anterior abdominal wall. As a rule, it is entirely enveloped by peritoneum, but in a certain number of cases (5 per cent., Berry) the peritoneal covering is not complete, so that the upper part of the posterior surface is uncovered and connected to the iliac fascia by connective tissue. The cæcum lies quite free in the abdominal cavity and enjoys a considerable amount of movement, so that it may become herniated down the right inguinal canal, and has occasionally been found in an inguinal hernia on the left side. The cæcum varies in shape, but, according to Treves, in man it may be classified under one of four types. In early

FIG. 951.—The cæcum and appendix, with their arteries.



fœtal life it is short, conical, and broad at the base, with its apex turned upwards and inwards towards the ileo-cæcal junction. It then resembles the cæcum of some monkeys, e.g. mangabey monkey. As the fœtus grows the cæcum increases in length more than in breadth, so that it forms a longer tube than in the primitive form and without the broad base, but with the same inclination inwards of the apex towards the ileo-cæcal junction. This form is seen in other monkeys: e.g. the spider monkey. As development goes on, the lower part of the tube ceases to grow and the upper part becomes greatly increased, so that at birth there is a narrow tube, the vermiform appendix, hanging from a conical projection, the cæcum. This is the infantile form, and as it persists throughout life in about 2 per cent. of cases, it is regarded by Treves as the *first* of his four types of human cæca. The cæcum is conical and the appendix rises from its apex. The three longitudinal bands start from the appendix and are equidistant from each other. In the *second* type, the conical cæcum has become quadrate by the growing out of a saccule on either side of the anterior longitudinal band. These saccules are of equal size, and the appendix arises from between them,

instead of from the apex of a cone. This type is found in about 3 per cent. of cases. The *third* type is the normal type of man. Here the two saccules, which in the second type were uniform, have grown at unequal rates: the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the growing downwards of the right saccule, and the original apex, with the appendix attached, is pushed over to the left towards the ileo-cæcal junction. The three longitudinal bands still start from the base of the appendix, but they are now no longer equidistant from each other, because the right saccule has grown between the anterior and postero-external bands, pushing them over to the left. This type occurs in about 90 per cent. of cases. The *fourth* type is merely an exaggerated condition of the third; the right saccule is still larger, and at the same time the left saccule has become atrophied, so that the original apex of the cæcum, with the appendix, is close to the ileo-cæcal junction, and the anterior band courses inwards to the same situation. This type is present in about 4 per cent. of cases.

The **vermiform appendix** (processus vermiformis) is a long, narrow, worm-shaped tube, which starts from what was originally the apex of the cæcum, and may pass in several directions: upwards behind the cæcum; to the left behind the ileum and mesentery; or downwards into the true pelvis. It varies from one to nine inches in length, its average being a little over three inches (8·3 cm.). It is retained in position by a fold of peritoneum, the *meso-appendix*, derived from the left leaf of the mesentery. This fold, in the majority of cases, is more or less triangular in shape, and as a rule extends along the entire length of the tube. Between its two layers lies a considerable branch of the ileo-colic artery, the appendicular artery (fig. 951). The canal of the appendix is small, extends throughout the whole length of the tube, and communicates with the cæcum by an orifice which is placed below and behind the ileo-cæcal opening. It is sometimes guarded by a semilunar valve formed by a fold of mucous membrane, but this is by no means constant. Its coats are the same as those of the intestine: serous, muscular, submucous, and mucous.

Structure.—The *serous* coat forms a complete investment for the tube, except along the narrow line of attachment of its mesentery in its proximal two-thirds. The *longitudinal muscular fibres* do not form three bands as in the greater part of the large intestine, but invest the whole organ, except at one or two points where both the longitudinal and circular fibres are deficient so that the peritoneal and submucous coats are contiguous over small areas. The circular muscle fibres form a much thicker layer than the longitudinal fibres, and are separated from them by a small amount of connective tissue. The *submucous coat* is well marked, and contains a large number of masses of lymphoid tissue which cause the mucous membrane to bulge into the lumen and so render the latter of small size and irregular shape. The *mucous membrane* is lined by columnar epithelium and resembles that of the rest of the large intestine, but the simple follicles are fewer in number.

The **ileo-cæcal valve** (valvula coli) (fig. 952).—The lower end of the ileum terminates by opening into the inner and back part of the large intestine, at the point of junction of the cæcum with the colon. The opening is guarded by a valve, consisting of two segments, an upper or colic and lower or cæcal, which project into the lumen of the large intestine. If the intestine has been inflated and dried, the segments are of a semilunar shape. The upper one, nearly horizontal in direction, is attached by its convex border to the line of junction of the ileum with the colon; the lower segment, which is longer and more concave, is attached to the line of junction of the ileum with the cæcum. At the ends of the aperture the two segments of the valve coalesce, and are continued as narrow membranous ridges around the canal for a short distance, forming the *frenula* or *retinacula* of the valve. The left or anterior end of the aperture is rounded; the right or posterior is narrow and pointed. In the fresh condition, or in specimens which have been hardened *in situ*, the segments project as thick cushion-like folds into the lumen of the large gut, while the opening between them may present the appearance of a slit or may be somewhat oval in shape.

Each segment of the valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly across from one portion of the intestine to the other. When these are divided or removed, the ileum

may be drawn outwards, and all traces of the valve will be lost, the ileum appearing to open into the large intestine by a funnel-shaped orifice of large size.

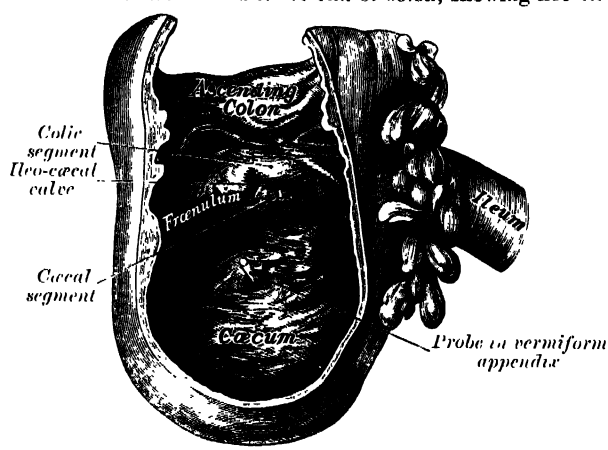
The surface of each segment of the valve directed towards the ileum is covered with villi, and presents the characteristic structure of the mucous membrane of the small intestine; while that turned towards the large intestine is destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. These differences in structure continue as far as the free margin of the valve.

When the cæcum is distended, the margins of the opening are approximated so as to prevent any reflux into the ileum. This is believed to be due to tension or stretching of the retinacula of the valve.

The **colon** is divided into five parts: the ascending, transverse, descending, iliac, and pelvic.

The **ascending colon** (colon ascendens) is smaller in calibre than the cæcum, with which it is continuous. It passes upwards, from its commencement at the cæcum, opposite the ileo-cæcal valve, to the under surface of the right lobe of the liver, on the right of the gall bladder, where it is lodged in a shallow

FIG. 952.—Interior of the cæcum and lower end of colon, showing ileo-cæcal valve.



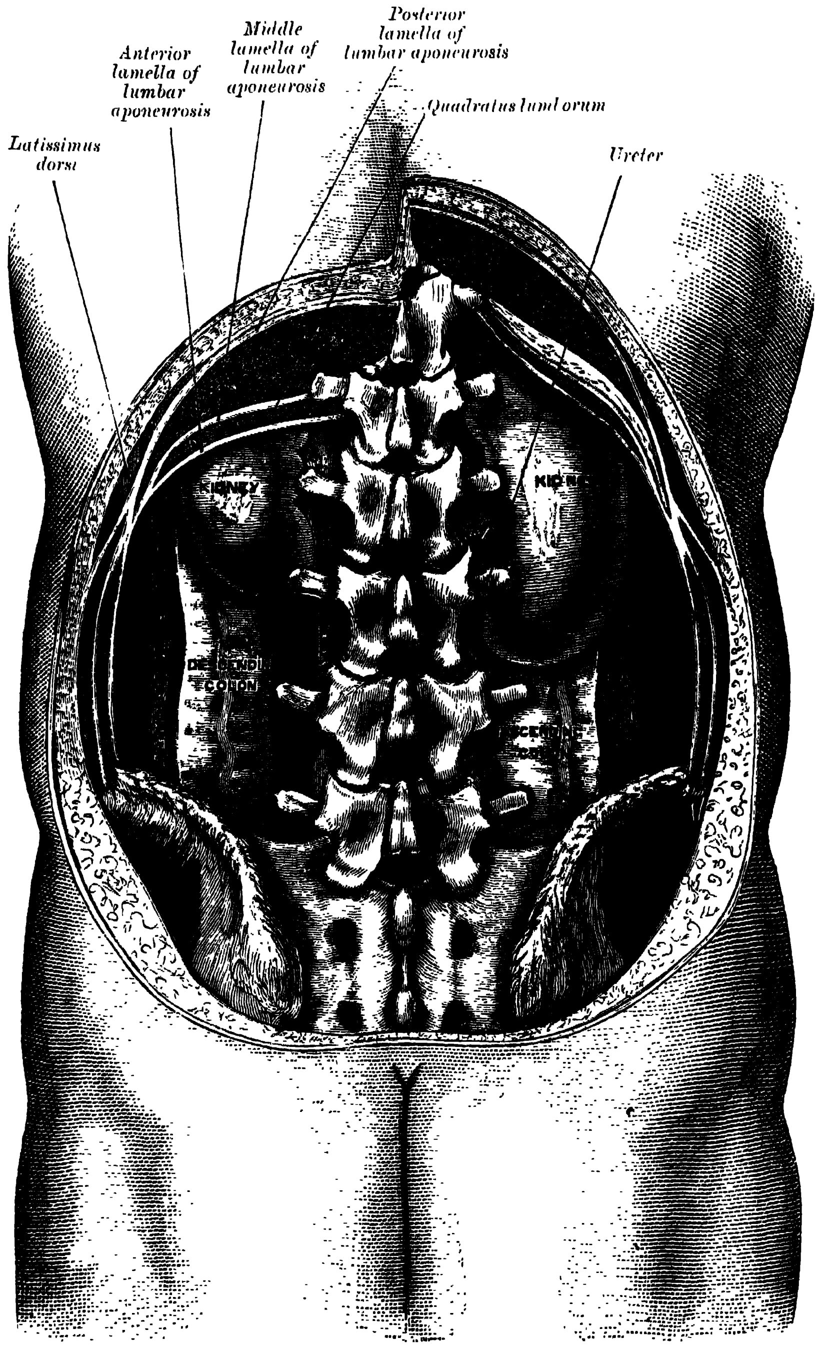
depression, the impressio colica; here it bends abruptly forwards and to the left, forming the *hepatic flexure* (flexura coli dextra). It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the Quadratus lumborum muscle, and with the front of the lower and outer part of the right kidney (fig. 953). Sometimes the peritoneum completely invests it, and forms a distinct but narrow mesocolon.* It is in relation, in front, with the convolutions of the ileum and the abdominal parietes.

The **transverse colon** (colon transversum), the longest and most movable part of the colon, passes transversely from the right hypochondriac region across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves downwards beneath the lower end of the spleen, forming the *splenic flexure* (flexura coli sinistra). In its course it describes an arch, the concavity of which is directed backwards and a little upwards. It is almost completely invested by peritoneum, and is connected to the posterior abdominal wall by a large and wide duplicature

* Treves states that, after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending mesocolon. In twenty-two there was a descending mesocolon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a mesocolon to both the ascending and the descending segments of the bowel; while in the remaining twelve there was an ascending mesocolon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colotomy a mesocolon may be expected upon the left side in 36 per cent. of all cases, and on the right in 26 per cent.—*The Anatomy of the Intestinal Canal and Peritoneum in Man*, 1885, p. 55.

of that membrane, the *transverse mesocolon.* It is in relation, by its upper surface, with the liver and gall-bladder, the great curvature of the stomach, and the lower end of the spleen; by its under surface, with the small intestines;

FIG. 953.—Diagram of the relations of the large intestine and kidneys, from behind.

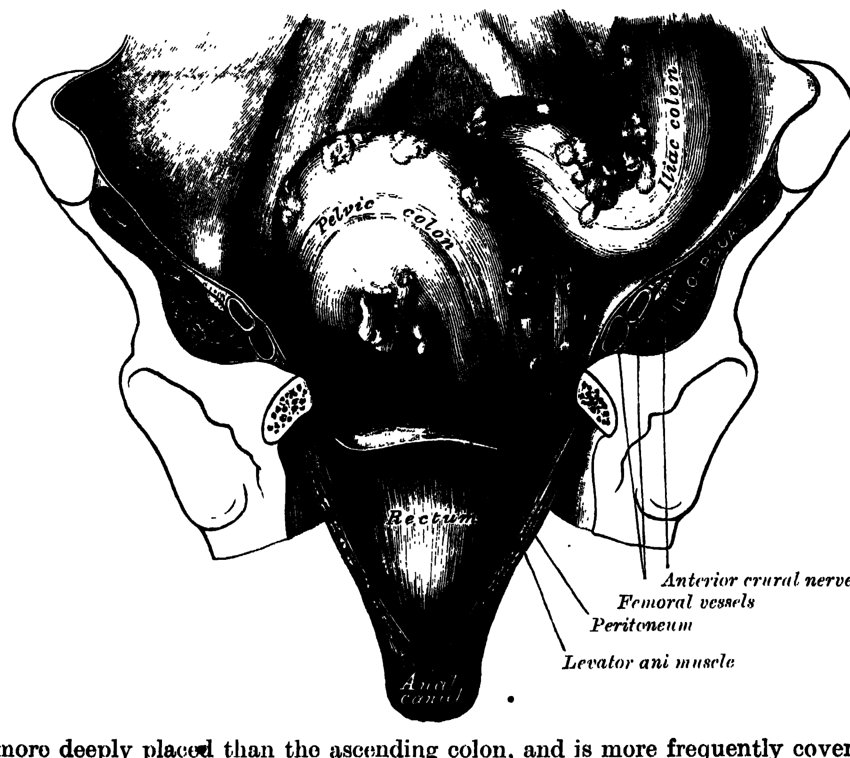


by its anterior surface, with the anterior layers of the great omentum and the abdominal parietes; its posterior surface is in relation from right to left with the second portion of the duodenum, the head of the pancreas, and some of the convolutions of the jejunum and ileum.

The *splenic flexure* (flexura coli sinistra) is situated at the junction of the transverse and descending parts of the colon, and is in relation with the lower end of the spleen and the tail of the pancreas. It lies at a higher level than, and on a plane posterior to, the hepatic flexure, and is attached to the Diaphragm, opposite the tenth and eleventh ribs, by a peritoneal fold, named the *phrenocolic* or *costocolic ligament*, which assists in supporting the lower end of the spleen (see page 1129).

The **descending colon** (colon descendens) passes downwards through the left hypochondriac and lumbar regions along the outer border of the left kidney. At the lower end of the kidney it turns inwards towards the outer border of the Psoas muscle, along which it descends to the crest of the ilium, where it terminates in the iliac colon. It is retained in position by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by areolar tissue with the outer border of the left kidney, and with the Quadratus lumborum muscle (fig. 953). It is smaller in calibre and

FIG. 954.—Ilio-pelvic colon and rectum seen from the front, after removal of pubic bones and bladder.



more deeply placed than the ascending colon, and is more frequently covered with peritoneum on its posterior surface than the ascending colon (Treves).

The **iliac colon** (fig. 954) is situated in the left iliac fossa, and measures about five or six inches in length. It begins at the level of the iliac crest, where it is continuous with the descending colon, and ends in the pelvic colon at the brim of the pelvis. It curves downwards and inwards in front of the Iliacus and Psoas, and, as a rule, is covered by peritoneum on its sides and anterior surface only.

The **pelvic colon** (fig. 954) forms a loop which averages about sixteen inches in length, and normally lies within the pelvis, but on account of its freedom of movement it is liable to be displaced into the abdominal cavity. It begins at the brim of the pelvis, where it is continuous with the pelvic colon, and passes transversely across the front of the sacrum to the right side of the pelvis; it then curves on itself and turns towards the left to reach the middle line at the level of the third piece of the sacrum, where it bends downwards and ends

in the rectum. It is completely surrounded by peritoneum, which forms a mesentery (pelvic mesocolon): the mesentery diminishes in length from the centre towards the ends of the loop, where it disappears, so that the loop is fixed at its junctions with the iliac colon and rectum, but enjoys a considerable range of movement in its central portion.

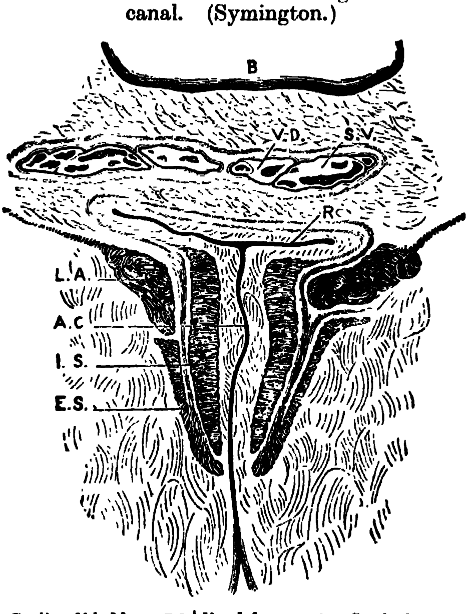
Relations of the pelvic colon.—*Behind* the pelvic colon are the external iliac vessels, the left Pyriformis muscle, and left sacral plexus of nerves; in *front*, it is separated from the bladder in the male, and the uterus in the female, by some coils of the small intestine.

The **rectum** is continuous above with the pelvic colon, whilst below it ends in the anal canal. From its origin at the level of the third sacral vertebra it passes downwards, lying in the sacro-coccygeal curve, and extends for about an inch in front of, and a little below, the tip of the coccyx, as far as the apex of the prostate gland. It then bends sharply backwards into the anal canal. It therefore presents two antero-posterior curves: an upper, with its convexity backwards, and a lower, with its convexity forwards. Two lateral curves are also described, one to the right opposite the junction of the third and fourth sacral vertebræ, and the other to the left, opposite the left sacro-coccygeal articulation; they are, however, of little importance. The rectum measures about five inches in length, and at its commencement its calibre is similar to that of the pelvic colon, but near its termination it is dilated to form the *rectal ampulla*. The rectum has no sacculations comparable to those of the colon, but a sacculated condition, due to the presence in its interior of valves (shortly to be described) is sometimes seen.

The peritoneum is related to the upper two-thirds of the rectum, covering at first its front and sides, but lower down its front only; from the latter it is reflected on to the seminal vesicles in the male and the posterior vaginal wall in the female.

The level at which the peritoneum leaves the anterior wall of the rectum to be reflected on to the viscus in front of it is of considerable importance from a surgical point of view, in connection with removal of the lower part of the rectum. It is higher in the male than in the female. In the former the height of the recto-vesical pouch is about three inches: that is to say, the height to which an ordinary index finger can reach from the anus. In the female the height of the recto-vaginal pouch is about two and a quarter inches from the anal orifice. The rectum is surrounded by a dense tube of fascia derived from the fascia endopelvina, but fused behind with the fascia covering the sacrum and coccyx. The fascial tube is loosely attached to the rectal wall by areolar tissue in order to allow of distension of the viscus.

Fig. 955.—Coronal section through the anal canal. (Symington.)



B. Cavity of bladder. V.D. Vas deferens. S.V. Seminal vesicle. R. Second part of rectum. A.C. Anal canal. L.A. Levator ani. I.S. Internal sphincter. E.S. External sphincter.

Relations of the rectum.—The upper part of the rectum is in relation, *behind*, with the superior hæmorrhoidal vessels, the left Pyriformis muscle, and left sacral plexus of nerves, which separate it from the anterior surfaces of the sacral vertebræ; in its lower part it lies directly on the sacrum, coccyx, and Levatores ani, a dense fascia alone intervening; *in front*, it is separated above, in the male, from the posterior surface of the bladder; in the female, from the posterior surface of the uterus and its appendages, by some

convolutions of the small intestine, and frequently by the pelvic colon; *below*, in the male, it is in relation with the triangular portion of the base of the bladder, the vesiculæ seminales, and vasa deferentia, and more anteriorly with the posterior surface of the prostate; in the female, with the posterior wall of the vagina.

The **anal canal** (fig. 955) or terminal portion of the large intestine begins at the level of the apex of the prostate, is directed downwards and backwards, and ends at the anus. It forms an angle with the lower part of the rectum, and measures from an inch to an inch and a half in length. It has no peritoneal covering, but is invested by the Sphincter ani internus, supported by the Levatores ani, and surrounded at its termination by the Sphincter ani externus. In the empty condition it presents the appearance of an antero-posterior longitudinal slit. Behind it, is a mass of muscular and fibrous tissue, the *ano-coccygeal body* (Symington); in front of it, in the male, are the membranous portion and bulb of the urethra, and the base of the triangular ligament; and in the female it is separated from the lower end of the vagina by a mass of muscular and fibrous tissue, named the *perineal body*.

Structure of the colon.—The large intestine has four coats: serous, muscular, areolar, and mucous.

The *serous coat* is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The cæcum is completely covered by the serous membrane, except in about 5 per cent. of cases where the upper part of the posterior surface is uncovered. The ascending, descending, and iliac parts of the colon are usually covered only in front and at the sides; a variable amount of the posterior surface is uncovered.* The transverse colon is almost completely invested, the parts corresponding to the attachment of the great omentum and transverse mesocolon being alone excepted. The pelvic colon is entirely surrounded. The rectum is covered above on its anterior surface and sides; below, on its anterior aspect only; the anal canal is entirely devoid of any serous covering. In the course of the colon the peritoneal coat is thrown into a number of small pouches filled with fat, called *appendices epiploicæ*. They are most numerous on the transverse colon.

The *muscular coat* consists of an external longitudinal, and an internal circular, layer of non-striped muscular fibres.

The *longitudinal fibres* do not form a continuous layer over the whole surface of the large intestine. In the cæcum and colon they are especially collected into three flat longitudinal bands (*tæniæ coli*), each of about half an inch in width. The vermiform appendix is surrounded by a uniform layer of longitudinal muscular fibres, and these bands commence at the attachment of the appendix to the cæcum; one, the posterior, is placed along the attached border of the intestine; the anterior, the largest, corresponds along the arch of the colon to the attachment of the great omentum, but is in front in the ascending, descending and iliac parts of the colon, and in the pelvic colon; the third, or lateral band, is found on the inner side of the ascending and descending parts of the colon, and on the under aspect of the transverse colon. These bands are shorter than the other coats of the intestine, and serve to produce the sacculi which are characteristic of the cæcum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. In the pelvic colon the longitudinal fibres become more scattered; and round the rectum they spread out and form a layer, which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, where it forms two bands, than on the lateral surfaces. In addition, two bands of plain muscular tissue arise from the second and third coccygeal vertebræ, and pass downwards and forwards to blend with the longitudinal muscular fibres on the posterior wall of the anal canal. These are known as the *recto-coccygeal* muscles.

The *circular fibres* form a thin layer over the cæcum and colon, being especially accumulated in the intervals between the sacculi; in the rectum they form a thick layer, and in the anal canal they become numerous, and constitute the Internal sphincter.

The *areolar coat* connects the muscular and mucous layers closely together.

The *mucous membrane*, in the cæcum and colon, is pale, smooth, destitute of villi, and raised into numerous crescentic folds which correspond to the intervals between the sacculi. In the rectum it is thicker, of a darker colour, more vascular, and connected loosely to the muscular coat, as in the œsophagus. When the lower part of the rectum is contracted, its mucous membrane is thrown into a number of folds, which are longitudinal in direction and are effaced by the distension of the gut. Besides these there are certain permanent horizontal folds, of a semilunar shape, known as Houston's valves (fig. 956).† They are usually three in number; sometimes a fourth is found, and occasionally only two are present. One is situated near the commencement of the rectum, on the right side; a second extends

* See footnote, p. 1151.

† *Dublin Hosp. Reports*, vol. v. p. 163.

inwards from the left side of the tube, opposite the middle of the sacrum; a third, the largest and most constant, projects backwards from the fore part of the rectum, opposite the base of the bladder. When a fourth is present, it is situated nearly an inch above the anus on the left and posterior wall of the tube. These folds are about half an inch in width, and contain some of the circular fibres of the gut. In the empty state of the intestines they overlap each other, as Houston remarks, so effectually as to require considerable manœuvring to conduct a bougie or the finger along to the canal of the intestine. Their use seems to be, 'to support the weight of fæcal matter, and prevent its urging towards the anus, where its presence always excites a sensation demanding its discharge.' *

The lumen of the anal canal presents, in its upper half, a number of vertical folds, produced by an infolding of the mucous membrane and some of the muscular tissue. They are known as the *columns of Morgagni* (fig. 956), and are separated from one another by furrows, which terminate below in small valve-like folds, termed *anal valves*, which join together the lower ends of the columns of Morgagni.

As in the small intestine, the mucous membrane consists of: a muscular layer, the muscularis mucosæ; a quantity of retiform tissue in which the vessels ramify; a

FIG. 956.—Coronal section of rectum and anal canal.

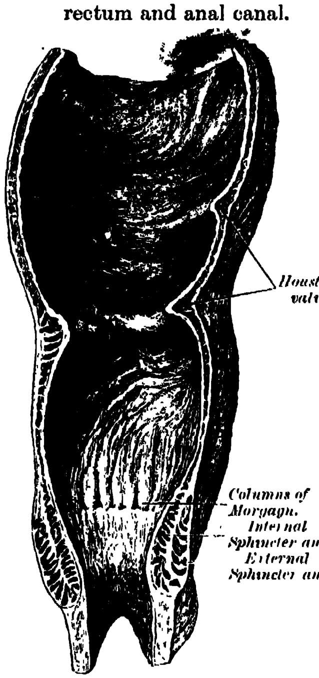


FIG. 957.—Transverse section of large intestine.

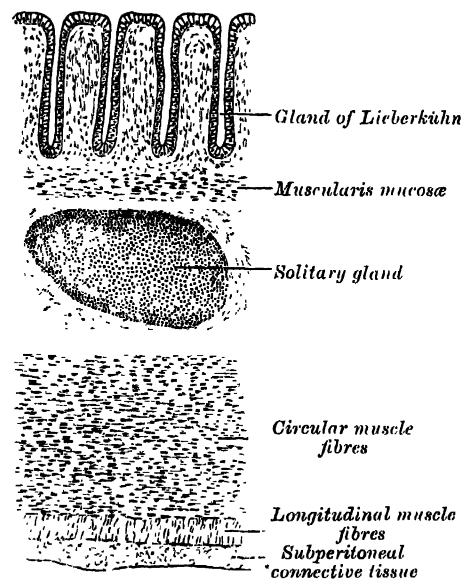

basement-membrane and epithelium which is of the columnar variety, and exactly resembles the epithelium found in the small intestine. The mucous membrane of the large intestine presents for examination simple follicles and solitary glands.

The *simple follicles* (glands of Lieberkühn) are minute tubular prolongations of the mucous membrane arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and placed in much closer apposition than those of the small intestine; and they open by minute rounded orifices upon the surface, giving it a cribriform appearance. Each gland is lined by short columnar epithelium and contains numerous goblet cells.

The *solitary glands* (fig. 957) of the large intestine are most abundant in the cæcum and vermiform appendix, but are irregularly scattered also over the rest of the intestine. They are similar to those of the small intestine.

Vessels and Nerves.—The *arteries* supplying the colon are derived from the colic and sigmoid branches of the mesenteric arteries. They give off large branches, which ramify between and supply the muscular coats, and after dividing into small vessels in the submucous tissue, pass to the mucous membrane. The rectum is supplied by the superior

* Paterson (The form of the rectum, *Journal of Anatomy and Physiology*, vol. xliii.) utilises the third fold for the purpose of dividing the rectum into an upper and a lower portion; he considers the latter 'to be just as much a duct as the narrower anal canal below,' and maintains that, under normal conditions, it does not contain fæces except during the act of defæcation.

hæmorrhoidal branch of the inferior mesenteric, and the anal canal by the middle hæmorrhoidal from the internal iliac, and the inferior hæmorrhoidal from the pudic artery. The superior hæmorrhoidal, the continuation of the superior mesenteric, divides into two branches, which run down either side of the rectum to within about five inches of the anus; they here split up into about six branches, which pierce the muscular coat and descend between it and the mucous membrane in a longitudinal direction, parallel with each other as far as the Internal sphincter, where they anastomose with the other hæmorrhoidal arteries and form a series of loops around the anus. The *veins* of the rectum commence in a plexus of vessels which surrounds the anal canal. In the vessels forming this plexus are small saccular dilatations just within the margin of the anus; from the plexus about six vessels of considerable size are given off. These ascend between the muscular and mucous coats for about five inches, running parallel to each other; they then pierce the muscular coat, and, by their union, form a single trunk, the superior hæmorrhoidal vein. This arrangement is termed the *hæmorrhoidal plexus*; it communicates with the tributaries of the middle and inferior hæmorrhoidal veins, at its commencement, and thus a communication is established between the systemic and portal circulations. The *nerves* are derived from the sympathetic plexuses around the branches of the superior and inferior mesenteric arteries. They are distributed in a similar way to those found in the small intestine.

The *lymphatics* of the large intestine are described on page 78[illegible]

Surface Relations.—The coils of the small intestine occupy the [illegible] of the abdomen, below the transverse colon, and are covered more or less completely by the great omentum. For the most part the coils of the jejunum occupy the left side of the abdominal cavity, i.e. the left lumbar and iliac regions and the left half of the umbilical region; while the coils of the ilium are situated to the right, in the right lumbar and iliac regions, in the right half of the umbilical region, and also in the hypogastric region. The cæcum is situated in the right iliac region. Its position varies slightly, but the mid-point of a line drawn from the anterior superior spinous process of the ilium to the symphysis pubis will about mark the middle of its lower border. It is comparatively superficial. From it the ascending colon passes upwards through the right lumbar and hypochondriac regions, and becomes more deeply situated as it ascends to the hepatic flexure, which is deeply placed under cover of the liver. The transverse colon crosses the belly transversely on the confines of the umbilical and epigastric regions; its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach.* The splenic flexure of the colon is situated behind the stomach in the left hypochondrium, and is on a higher level than the hepatic flexure. The descending colon is deeply seated, passing down through the left hypochondriac and lumbar regions to the sigmoid flexure, which is situated in the left iliac region and can be felt in thin persons, with relaxed abdominal walls, rolling under the fingers when empty, and when distended forming a distinct tumour. The position of the base of the vermiform appendix is indicated by a point an inch and a half from the right anterior superior spinous process of the ilium, in a line drawn from this process to the umbilicus. This is known as *McBurney's spot.* Another mode of defining the position of the base of the appendix is to draw a line between the anterior superior iliac spines, marking the point where this line intersects the right semilunar line.

Peristalsis of the coils of the small intestine can be observed in some persons with extremely thin abdominal walls, when some degree of constipation exists; it is, however, of great importance as a diagnostic sign of chronic intestinal obstruction, and when such is suspected, should be always looked for. Owing to the resistance offered to the passage of the bowel contents for some period, hypertrophy of the muscular coats of the intestine takes place, and the peristaltic movements of the distended gut may become distinctly visible through the normal thickness of abdominal wall.

In cases of obstruction near the ileo-cæcal junction the distension of the small intestine gives rise to a marked prominence of the central portion of the abdomen, whereas if the obstruction be low down in the large gut, the whole course of the colon may be seen mapped out, thus giving rise to distension in the flanks and transversely about the level of the umbilicus. Thus valuable information as to the seat of the obstruction may often be obtained from simple inspection of the abdomen. Great distension of the intestines also occurs in peritonitis and in typhoid fever.

Upon introducing the finger into the male rectum, the membranous portion of the urethra can be felt exactly in the middle line if an instrument has been introduced into the bladder; above this the prostate gland can be recognised by its shape and hardness and any enlargement detected; behind the prostate the fluctuating wall of the bladder when full can be felt, and if thought desirable, can be tapped in this situation; on either side of and behind the prostate the vesicula seminalis can be readily felt, especially if enlarged by tuberculous disease. Behind, the coccyx is to be felt; and on the mucous membrane one or two of Houston's folds. The ischio-rectal fossa can be explored on either side, with a view to

* The transverse colon frequently sags downwards, especially in those affected with chronic constipation; when the abdomen is opened it is not unusual to find the upper border of the colon distinctly below the umbilicus, and in some cases the convexity of this portion of the large intestine reaches the pelvic brim.

ascertaining the presence of deep-seated collections of pus. Finally, it will be noted that the finger is firmly gripped by the Sphincter for about an inch up the bowel.

Applied Anatomy.—The small intestines are much exposed to injury, but, in consequence of their elasticity and the ease with which one coil glides over another, they are not so frequently ruptured as would otherwise be the case. Any part of the small intestine may be ruptured, but probably the most common situation is the transverse duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebræ, so that if this portion of the intestine is struck by a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and so lacerated. Wounds of the intestine sometimes occur. If the wound is a small puncture, under, it is said, three lines in length, no extravasation of the contents of the bowel takes place; the mucous membrane becomes everted and plugs the little opening. The small intestine, and most frequently the ileum, may become strangulated by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from previous attacks of peritonitis; or an adherent omentum from the same cause; or the band may be formed by Meckel's diverticulum, which has contracted adhesions at its distal extremity; or it may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicæ, or an adherent vermiform appendix or Fallopian tube. Intussusception, most commonly an invagination of the small intestine into the large, may take place; it may attain great size, and it is not uncommon in these cases to find the ileo-cæcal valve projecting from the anus. Stricture, the impaction of foreign bodies, and twisting of the gut (*volvulus*) may also lead to intestinal obstruction.

Resection of a portion of the intestine may be required in cases of gangrene; for the removal of new growth in the bowel; in dealing with artificial anus; and in cases of rupture. The operation is termed *enterectomy*, and is performed as follows: the abdomen having been opened and the amount of bowel requiring removal having been determined upon, the intestine must be clamped on either side of this portion in order to prevent the escape of any of its contents during the operation. The portion of the bowel is then separated above and below by means of scissors. If the portion resected is small, it may be simply removed from the mesentery at its attachment, and the bleeding vessels tied; but if it be large it will be necessary to take away a triangular piece of the mesentery, and, having secured the vessels, suture the cut edges of this structure together. In doing this, care must be taken not to leave any intestine projecting beyond the line of the section of mesentery, as gangrene is very likely to occur in the projecting part if this is done. The surgeon then proceeds to unite the cut ends of the bowel together by what is termed end-to-end anastomosis. There are many ways of doing this, which may be divided into two classes, one where the anastomosis is made by means of some mechanical appliance, such as Murphy's button, or one of the forms of decalcified bone bobbin; and the other, where the operation is performed by suturing the ends of the bowel in such a manner that the peritoneum covering the two divided ends is brought into contact, so that speedy union may ensue.

The vermiform appendix is very liable to become inflamed, because it contains a relatively large amount of lymphoid tissue which is prone to bacterial infection. In many cases the inflammation is set up by the impaction in it of a solid mass of fæces or a foreign body, or by the inspissation of its mucous secretion in catarrhal conditions. The inflammation may result in ulceration and perforation, or if very acute in gangrene of the appendix. These conditions generally require immediate operative interference, and in chronic cases with recurring attacks of inflammation it is generally advisable to remove this diverticulum of the bowel. In incising the abdominal wall for this operation, the muscles should be split in the direction of their fibres rather than cut across in order to prevent subsequent weakening of the abdominal parietes and the occurrence of a ventral hernia. After the appendix has been removed it is better to suture the planes of the abdominal wall separately.

In external hernia the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved it is usually the cæcum, and this may occur even on the left side. In some few cases the vermiform appendix has been the part implicated in strangulated hernia.

Chronic ulcer of the duodenum is sometimes met with, probably produced by the same causes as chronic ulcer of the stomach. It may perforate and set up a rapidly fatal peritonitis, or it may open into one of the large duodenal vessels and cause death from hæmorrhage. An acute ulcer sometimes, but rarely, follows extensive burns of the skin.

The calibre of the large intestine gradually diminishes from the cæcum, which has the greatest diameter of any part of the bowel, to the point of junction of the pelvic colon with the rectum. At or a little below this point stricture most commonly occurs, and diminishes in frequency as one proceeds upwards to the cæcum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the hepatic and splenic flexures, which are more deeply placed; the distension is most obvious in the flanks and on the front of the abdomen just above the umbilicus. The cæcum, however, is the portion of the bowel

which becomes most distended. It may assume enormous dimensions, and has been known to give way from the distension, causing fatal peritonitis. The hepatic flexure and the right extremity of the transverse colon are in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The gall-bladder may become adherent to the colon, and gall-stones may find their way through into it and may become impacted or may be discharged per anum. The mobility of the pelvic colon renders it more liable to become the seat of a volvulus or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the mesocolon is elongated. The gut at this part, being loaded with fæces, falls over the part below, and so gives rise to the twist.

Hernia.—The two chief sites at which external hernia may take place are the inguinal region and the crural canal. The description of the inguinal canal and its relations will be found on page 1205 and that of the crural canal on pages 708 and 709. Some points in regard to the disposition of the peritoneum in these regions may, however, be recapitulated here.

Between the upper margin of the front of the pelvis and the umbilicus, the peritoneum, when viewed from behind, will be seen to be raised into five folds, with intervening depressions, by more or less prominent bands which converge to the umbilicus (fig. 924). The urachus, situated in the middle line, is covered by a fold of peritoneum known as the *plica urachi.* On either side of this a fold of peritoneum round the obliterated hypogastric artery forms the *plica hypogastrica.* To either side of these three cords is the deep epigastric artery covered by the *plica epigastrica.* Between these raised folds are depressions constituting the so-called fossæ. The most internal, between the plica urachi and plica hypogastrica, is known as the *internal inguinal fossa* (fovea supravesicalis). The middle one is situated between the plica hypogastrica and plica epigastrica, and is termed the *middle inguinal fossa* (fovea inguinalis mesialis). The external one is external to the plica epigastrica, and is known as the *external inguinal fossa* (fovea inguinalis lateralis). Occasionally the deep epigastric artery corresponds in position to the obliterated hypogastric artery, and then there is but one fold on each side of the middle line. In the usual position of the parts, the floor of the external inguinal fossa corresponds to the internal abdominal ring, and into this fossa an oblique inguinal hernia descends. To the inner side of the plica epigastrica are the two internal fossæ, and through either of these a direct hernia may descend. The whole of the space between the deep epigastric artery, the margin of the Rectus, and Poupart's ligament, is known as Hesselbach's triangle. Below the level of Poupart's ligament is a small depression corresponding to the position of the crural ring. It is known as the *femoral fossa,* and into it a femoral hernia descends.

Inguinal hernia.—Inguinal hernia is that form of protrusion which makes its way through the abdomen in the inguinal region. There are two principal varieties of it: external or oblique, and internal or direct.

In *oblique inguinal hernia* the intestine escapes from the abdominal cavity at the internal ring, pushing before it a pouch of peritoneum which forms the hernial sac. As it enters the inguinal canal it receives an investment from the extra-peritoneal tissue and is enclosed in the infundibuliform fascia. In passing along the inguinal canal it displaces upwards the arched fibres of the Transversalis and Internal oblique, and receives a covering of Cremaster muscle and cremasteric fascia. It then passes along the front of the spermatic cord and escapes from the inguinal canal at the external ring, becoming invested by intercolumnar fascia. Lastly it descends into the scrotum, receiving coverings from the superficial fascia and the integument.

The seat of stricture in oblique inguinal hernia is at either the external or internal abdominal ring; most frequently in the latter situation. If it is situated at the external ring, the division of a few fibres at one point of the circumference is all that is necessary for the replacement of the hernia. If at the internal ring, it is necessary to divide the aponeurosis of the External oblique so as to lay open the inguinal canal; in dividing the aponeurosis the incision should be directed parallel to Poupart's ligament, and the constriction at the internal ring should then be divided directly upwards.

When the intestine passes along the inguinal canal and escapes from the external ring into the scrotum, it is called *complete* oblique inguinal or *scrotal* hernia. If the intestine does not escape from the external ring, but is retained in the inguinal canal, it is called *incomplete* inguinal hernia or *bubonocele.* In each of these cases the coverings which invest it will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia (fig. 958) depending upon congenital defects in the processus vaginalis, the pouch of peritoneum which precedes the descent of the testis. Normally this pouch is closed before birth, closure commencing at two points, viz. at the internal abdominal ring and at the top of the epididymis, and gradually extending until the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process, variations in the relation of the hernial protrusion to the testis and tunica vaginalis are produced; these constitute distinct varieties of inguinal hernia, viz. congenital, infantile, encysted, and hernia of the funicular process.

Where the processus vaginalis remains patent throughout, the cavity of the tunica vaginalis communicates directly with that of the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis which constitutes the sac of the

Fig. 958.—Varieties of oblique inguinal hernia.

D. Encysted hernia.

E. Hernia into the funicular process.

hernia, and the gut lies in contact with the testis. Though this form of hernia is termed *congenital*, the term does not imply that the hernia existed at birth, but merely that a condition is present which may allow of the descent of the hernia at any moment. As a matter of fact, congenital herniæ frequently do not appear till adult life.

Where the processus vaginalis is occluded at the internal ring only and remains patent throughout the rest of its extent two varieties of oblique inguinal hernia may be produced, viz. infantile and encysted herniæ. In the *infantile* form (fig. 958, C) the bowel presses upon the peritoneum in the immediate neighbourhood of the septum and causes it to yield and form a sac which descends behind the tunica vaginalis; so that in front of the bowel there are three layers of peritoneum, the two layers of the tunica vaginalis and its own sac. In the *encysted* form (fig. 958, D) pressure at the occluded spot causes the septum to yield and form a sac which projects into the tunica vaginalis, forming thus a sac within a sac, so that in front of the bowel there are two layers of peritoneum, one from the tunica vaginalis, and one from its own sac.

Where the processus vaginalis is occluded at the lower point only, i.e. just above the testis, the intestine descends into the pouch of peritoneum as far as the testis, but is prevented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch. This is known as *hernia into the funicular process*; it resembles the congenital form except that instead of enveloping the testis it lies above it.

In *direct inguinal hernia* the protrusion makes its way through some part of Hesselbach's triangle, either through (*a*) the outer part, where only extra-peritoneal tissue and transversalis fascia intervene between the peritoneum and the aponeurosis of the External oblique; or through (*b*) the conjoined tendon which stretches across the inner two-thirds of the triangle between the artery and the middle line. In the former the hernial protrusion escapes from the abdomen on the outer side of the conjoined tendon, pushes before it the peritoneum, extra-peritoneal tissue and transversalis fascia, and enters the inguinal canal. It passes along nearly the whole length of the canal and finally emerges from the external ring, receiving an investment from the intercolumnar fascia. The coverings of this form of hernia are similar to those of the oblique form, except that a portion derived from the general layer of transversalis fascia replaces the infundibuliform fascia.

In the second form, which is the more frequent, the hernia is either forced through the fibres of the conjoined tendon, or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the external ring, lying on the inner side of the cord, and receives additional coverings from the intercolumnar fascia, the superficial fascia and the integument. The coverings of this form therefore differ from those of the oblique form in that the conjoined tendon is substituted for the cremaster, and the infundibuliform fascia is replaced by a portion of the general layer of the transversalis fascia.

The seat of stricture in both varieties of direct hernia is usually found either at the neck of the sac or at the external ring. In that form which perforates the conjoined tendon it not infrequently occurs at the edges of the fissure through which the gut passes. In all cases of inguinal hernia, whether direct or oblique, it is proper to divide the stricture directly upwards; by cutting in this direction the incision is made parallel to the deep epigastric artery—external to it in the oblique variety, internal to it in the direct form of hernia; all chance of wounding the vessel is thus avoided. Direct inguinal hernia is of much less frequent occurrence than oblique, and is found more often in men than in women. The main differences in position between it and the oblique form are: (*a*) it is placed over the pubis and not in the course of the inguinal canal; (*b*) the deep epigastric artery runs on the outer or iliac side of the neck of the sac; and (*c*) the spermatic cord lies along its external and posterior sides, not directly behind it as in oblique inguinal hernia.

Femoral hernia.—In femoral hernia the protrusion of the intestine takes place through the crural ring. As already described (page 708), this ring is closed by the septum crurale, a partition of modified extra-peritoneal tissue; it is therefore a weak spot in the abdominal wall, and especially in the female, where the ring is larger and where profound changes are produced in the tissues of the abdomen by pregnancy. Femoral hernia is therefore more common in women than in men.

When a portion of intestine is forced through the crural ring, it carries before it a pouch of peritoneum, which forms the hernial sac. It receives an investment from the extra-peritoneal tissue or septum crurale, and descends along the crural canal, or inner compartment of the sheath of the femoral vessels, as far as the saphenous opening; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the latter, and its close contact with the vessels, and also the close attachment of the superficial fascia and femoral sheath to the lower part of the circumference of the saphenous opening. The tumour is consequently directed forwards, pushing before it the cribriform fascia, and then curves upwards over Poupart's ligament and the lower part of the External oblique, being covered by the superficial fascia and integument. While the hernia is contained in the crural canal it is usually of small size, owing to the resisting nature of the surrounding parts, but when it escapes from the saphenous opening into the loose areolar tissue of the groin it becomes considerably enlarged. The direction taken by a femoral hernia in its descent is at first downwards, then forwards and upwards; in the application of taxis for the reduction of a femoral hernia therefore, pressure should be directed in the reverse order.

The coverings of a femoral hernia from within outwards are: peritoneum, septum crurale, femoral sheath, cribriform fascia, superficial fascia, and integument. Sir Astley

Cooper has described an investment for femoral hernia under the name of *fascia propria*, lying immediately external to the peritoneal sac but frequently separated from it by some adipose tissue. Surgically it is important to remember the frequent existence of this layer on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained fat for omentum, as there is often a great excess of subperitoneal fatty tissue enclosed in the 'fascia propria.' In many cases it resembles a fatty tumour, but on further dissection the true hernial sac will be found in the centre of the mass of fat. The fascia propria is merely modified extra-peritoneal tissue which has been thickened to form a membranous sheet by the pressure of the hernia.

When the intestine descends along the femoral canal only as far as the saphenous opening the condition is known as *incomplete* femoral hernia. The small size of the protrusion in this form of hernia, on account of the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety of the disease, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia would be from without inwards: integument, superficial fascia, superior falciform process of fascia lata, femoral sheath, septum crurale and peritoneum.

The seat of stricture of a femoral hernia varies: it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it is at the point of junction of the superior falciform process with the free edge of Gimbernat's ligament; or it may be at the margin of the saphenous opening. The stricture should in every case be divided in a direction upwards and inwards for a distance of about one-sixth to one-quarter of an inch. All vessels or other structures of importance in relation to the neck of the sac will thus be avoided.

The spine of the pubis forms an important landmark in serving to differentiate the inguinal from the femoral variety of hernia. The inguinal protrusion is above and to the inner side of the spine, while the femoral is below and to its outer side.

There are several details of practical interest in connection with the mesentery which merit notice. 1. The depth of the mesentery—that is to say, the distance from its parietal to its intestinal attachment—is normally less than eight inches, generally nearer six or seven; but under certain abnormal conditions it may become elongated, and this would appear to favour the occurrence of hernia of the intestine. 2. Not only may the depth of the mesentery be increased, but its point of attachment to the posterior abdominal wall may yield, and descend over the lumbar vertebræ. This condition, which is known under the name of *enteroptosis*, usually occurs in women who have borne many children, and is attended with general relaxation of the abdominal parietes. It produces a characteristic appearance, the abdomen being prominent and pendulous below, while above, it is flattened and constricted. 3. Holes are sometimes present in the mesentery, and these may be congenital, or may be the result of injury. They are of practical importance, since a knuckle of intestine may become herniated into one of them, causing acute strangulation. 4. The lymphatic glands contained between the two layers of the mesentery are frequently the seat of tuberculous deposit, especially in children.

The surgical anatomy of the rectum is of considerable importance. There may be congenital malformations due to arrest of, or imperfection in, development. Thus, there may be no proctodæal invagination (see page 161), and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the ectodermal invagination may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fœtal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath, and thus favours prolapse, especially in children. The vessels of the rectum are arranged, as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues, and this favours varicosity. Moreover, the veins, after running upwards in a longitudinal direction for about five inches in the submucous tissue, pierce the muscular coats, and are liable to become constricted at this spot by the contraction of the muscular wall of the gut. In addition to this there are no valves in the superior hæmorrhoidal veins, and the vessels of the rectum are placed in a dependent position, and are liable to be pressed upon and obstructed by hardened fæces. The anatomical arrangement, therefore, of the hæmorrhoidal vessels explains the great tendency to the occurrence of piles. The presence of the Sphincter ani externus is of surgical importance, since it is the constant contraction of this muscle which prevents an ischio-rectal abscess from healing, and causes it to become a fistula. Also the reflex contraction of this muscle is the cause of the severe pain complained of in fissure of the anus. The relations of the peritoneum to the bowel are of importance in connection with the operation of removal of the rectum for malignant disease. This membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface, to become reflected, in the male on to the posterior wall of the bladder, forming the recto-vesical pouch, and in the female on to the posterior wall of the vagina, forming Douglas's pouch. The recto-vesical pouch of peritoneum extends to within three inches from the anus. Within recent years much more extensive operations

have been done for the removal of cancer of the rectum, and in these the peritoneal cavity has necessarily been opened. If, in these cases, the opening is plugged with antiseptic gauze until the operation is completed and then the edges of the wound in the peritoneum are accurately brought together with sutures, no evil result appears to follow. For cases of cancer of the rectum which are too low to be reached by abdominal section, and too high to be removed by the perinæum, Kraske has devised an operation which goes by his name. The patient is placed on his right side and an incision is made from the last piece of the sacrum to the anus. The soft parts are now separated from the back of the sides of the sacrum and coccyx, and the greater and lesser sacro-sciatic ligaments are separated. The coccyx is removed, and if necessary a small piece of the sacrum, and the edges of the wound being now forcibly drawn outwards, a considerable length of the rectum is brought into view, and the diseased portion can be removed, leaving the anal portion of the gut, if healthy. The two divided ends of the gut can sometimes be approximated and sutured together, the posterior part being left open for drainage.

The colon frequently requires opening in cases of intestinal obstruction, and by some surgeons this operation is performed in cases of cancer of the rectum as soon as the disease is recognised, in the hope that the symptoms may be relieved by removing the irritation produced by the passage of fæcal matter over the diseased surface. The operation of colostomy may be performed either in the inguinal or lumbar region; but inguinal colostomy has in the present day entirely superseded the lumbar operation. The main reason for preferring this operation is that a spur-shaped process of the mesocolon can be formed, which prevents any fæcal matter finding its way past the artificial anus, and the greater ease in maintaining cleanliness. The pelvic colon being entirely surrounded by peritoneum, a coil can be drawn out of the wound and opened, leaving the attachment of the mesocolon to form a spur, much as it does in an artificial anus caused by sloughing of the intestine after a strangulated hernia, and this prevents any fæcal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision two or three inches in length from a point one inch internal to the anterior superior spinous process of the ilium, parallel to Poupart's ligament. The various muscular layers are cut through, and the peritoneum opened; the pelvic colon is now sought for, pulled out of the wound, and fixed by passing a needle threaded with carbolised silk first through the mesocolon close to the gut, and then through the abdominal wall. The wound is dressed, and about the second day the protruding coil of intestine is opened.

The loose connective tissue round the rectum is occasionally the site of an abscess, the active focus of which, however, may be located elsewhere. This form of abscess may be described as the *superior pelvic-rectal*; it is placed above the pelvic diaphragm but beneath the peritoneum. The acute variety is generally due to ulceration or perforation of the bowel (possibly produced by a foreign body) above the level of attachment of the Levator ani. The abscess may also occur above a stricture (simple or malignant) of the rectum; occasionally it arises from suppuration around the prostate, and more rarely follows abscess of the vesiculæ seminales. Chronic abscesses also appear in the same region either from caries of the anterior surface of the sacrum or from caseation of the presacral lymphatic glands, whilst in other cases an abscess finds its way down into the pelvis from disease of the anterior surfaces of the bodies of the lumbar vertebræ.

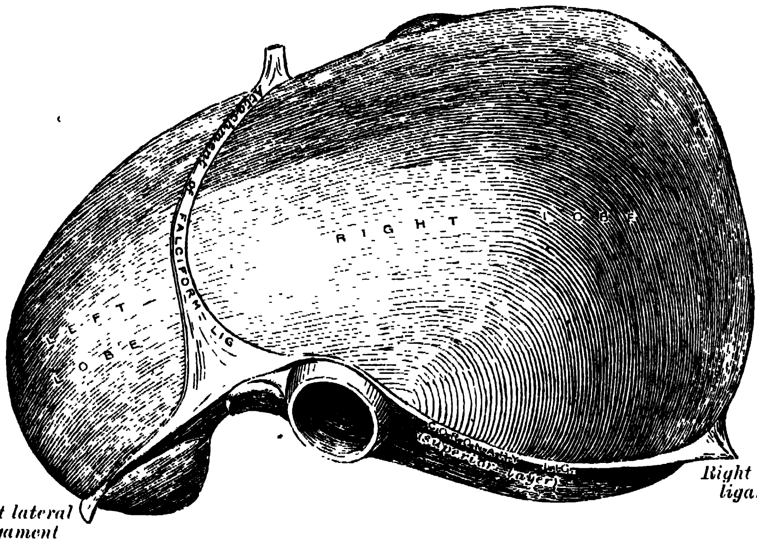
The Liver

The **liver** (hepar) is the largest gland in the body, and is situated in the upper and right parts of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and not uncommonly extending into the left hypochondrium as far as the mammary line. In the male it weighs from fifty to sixty ounces, in the female from forty to fifty. It is relatively much larger in the fœtus than in the adult, constituting, in the former, about one-eighteenth, and in the latter, about one thirty-sixth of the entire body weight. Its greatest transverse measurement is from eight to nine inches. Vertically, near its lateral or right surface, it measures about six or seven inches, while its greatest antero-posterior diameter is on a level with the upper end of the right kidney, and is from four to five inches. Opposite the vertebral column its measurement from before backwards is reduced to about three inches. Its consistence is that of a soft solid; it is, however, friable and easily lacerated; its colour is a dark reddish-brown, and its specific gravity is 1·05.

To obtain a correct idea of its shape it must be hardened *in situ*, and it will then be seen to present the appearance of a wedge, the base of which is directed to the right and the thin edge towards the left. Symington describes its shape as that 'of a right-angled triangular prism with the right angle rounded off.'

Surfaces.—The liver possesses five surfaces, viz. superior, inferior, anterior, posterior, and lateral. A sharp, well-defined margin divides the inferior from the anterior and lateral surfaces, but the other surfaces are separated from one another by thick, rounded borders. The superior and anterior surfaces are attached to the Diaphragm and anterior abdominal wall by a triangular or falciform fold of peritoneum, the *suspensory* or *falciform ligament*, in the free margin of which is a rounded cord, the *ligamentum teres* or obliterated umbilical vein. The line of attachment of the falciform ligament divides the liver into two parts, termed the right and left lobes, the right being much the larger. The inferior and posterior surfaces are divided into five lobes by five fissures, which are arranged in the form of the letter H. The left limb of the H marks on these surfaces the division of the liver into right and left lobes; it is known as the *longitudinal fissure*, and consists of two parts, viz. the *umbilical fissure* in front and the *fissure for the ductus venosus* behind. The right limb of the H is formed in front by the *fissure or fossa for the gall-bladder*, and behind by the *fissure for the inferior vena cava*; these two fissures are separated from one another by a band of liver-substance, termed the *caudate lobe*. The bar connecting the two limbs

Fig. 959.—The liver. Superior and anterior surfaces. (Slightly modified from His' model.)



of the H is the *transverse* or *portal fissure*; in front of it is the *quadrate lobe*, behind it the *Spigelian lobe*.

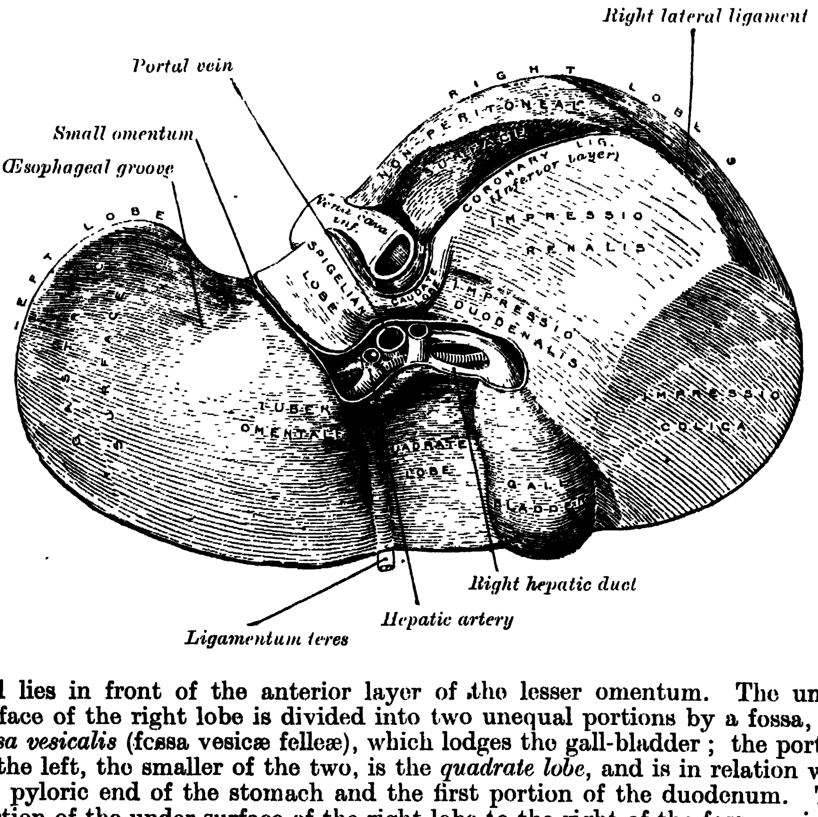
The *superior surface* (fig. 959) comprises a part of both lobes, and, as a whole, is convex, and fits under the vault of the Diaphragm; its central part, however, presents a shallow depression, which corresponds with the position of the pericardium on the upper surface of the Diaphragm. It is separated from the anterior, posterior, and lateral surfaces by thick, rounded borders. Its left extremity is separated from the under surface by a prominent sharp margin. Except along the lines of attachment of the falciform ligament it is completely covered by peritoneum.

The *anterior surface* is large, triangular in shape, and comprises also a part of both lobes. It is directed forwards, and the greater part of it is in contact with the Diaphragm, which separates it on the right from the sixth to the tenth ribs and their cartilages, and on the left from the seventh and eighth costal cartilages. In the middle line it lies behind the ensiform cartilage, and in the angle between the diverging rib cartilages of opposite sides is in contact with the abdominal wall. It is separated from the inferior surface by a sharp margin, and from the superior and lateral surfaces by thick rounded borders. It is completely covered by peritoneum except along the line of attachment of the falciform ligament.

The *lateral* or *right surface* is covered by peritoneum, and is convex from before backwards and slightly so from above downwards. It is directed towards the right side, forming the base of the wedge, and lies against the lateral portion of the Diaphragm, which separates it from the lower part of the pleura and lung, outside which are the right costal arches from the seventh to the eleventh inclusive.

The *inferior* or *visceral surface* (figs. 960, 961) is uneven, concave, directed downwards, backwards, and to the left, and is in relation with the stomach and duodenum, the hepatic flexure of the colon, and the right kidney and suprarenal gland. The surface is almost completely invested by peritoneum; the only parts where this covering is absent are where the gall-bladder is attached to the liver, and at the transverse fissure where the two layers of the lesser omentum are separated from each other by the blood-vessels and ducts of the viscus. The inferior surface of the left lobe presents behind and to the left an impression (impressio cardiaca) where it is moulded over the cardiac part of the stomach, and to the right of this a rounded eminence, the *tuber omentale*, which fits into the concavity of the lesser curvature of the stomach

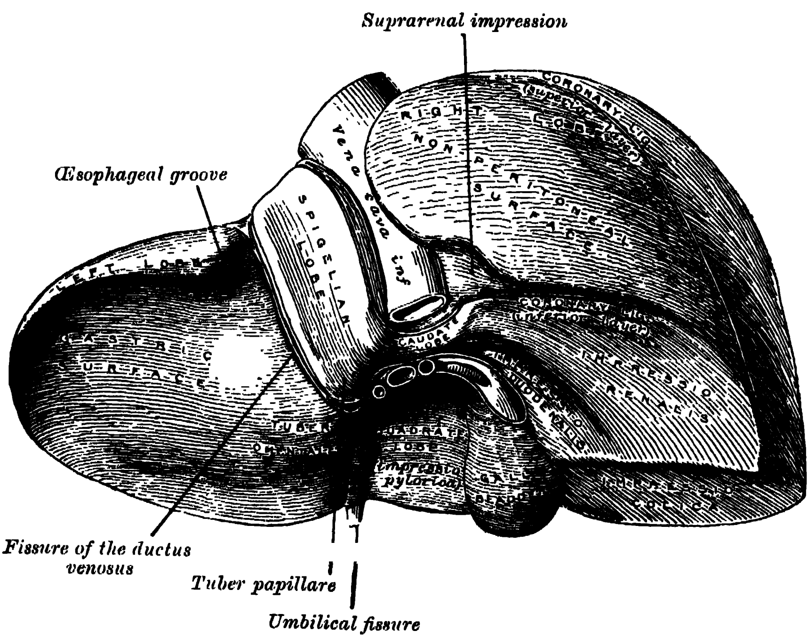
Fig. 960.—The liver. Inferior surface. (Drawn from His' model.)



and lies in front of the anterior layer of the lesser omentum. The under surface of the right lobe is divided into two unequal portions by a fossa, the *fossa vesicalis* (fossa vesicæ felleæ), which lodges the gall-bladder; the portion to the left, the smaller of the two, is the *quadrate lobe*, and is in relation with the pyloric end of the stomach and the first portion of the duodenum. The portion of the under surface of the right lobe to the right of the fossa vesicalis presents two shallow impressions, one situated behind the other, the two being separated by a ridge. The anterior of these two impressions, the *impressio colica*, is produced by the hepatic flexure of the colon; the posterior, the *impressio renalis*, is occupied by the upper part of the right kidney and lower part of the right suprarenal gland. To the inner side of the renal impression is a third and slightly marked impression, lying between it and the neck of the gall-bladder. This is caused by the second portion of the duodenum, and is known as the *impressio duodenalis*. Just in front of the inferior vena cava is a narrow strip of liver tissue, the *caudate lobe*, which connects the right inferior angle of the Spigelian lobe to the under surface of the right lobe. It forms the upper boundary of the foramen of Winslow.

The *posterior surface* (fig. 961) is rounded and broad behind the right lobe, but narrow on the left. Over a large part of its extent it is not covered by peritoneum; this uncovered portion is about three inches broad at its widest part, and is in direct contact with the Diaphragm. It is marked off from the upper surface by the line of reflection of the upper or anterior layer of the coronary ligament, and from the under surface by the line of reflection of the lower layer of the coronary ligament. The central part of the posterior surface presents a deep concavity which is moulded on the vertebral column and crura of the Diaphragm. To the right of this the inferior vena cava is lodged in an indentation in the liver substance, lying between the uncovered area and the Spigelian lobe. Close to the right of this indentation and immediately above the renal impression is a small triangular depressed area (*impressio suprarenalis*), the greater part of which is devoid of peritoneum; it lodges the right suprarenal gland. To the left of the inferior vena cava is the *Spigelian lobe*, which lies between the fissure for the vena cava and the fissure for the ductus venosus. Its lower end projects and forms part of the posterior boundary of the transverse fissure; on the right, it is connected with the

FIG. 961.—The liver. Posterior surface. (Drawn from His' model.)



under surface of the right lobe of the liver by the caudate lobe, and on the left it presents a tubercle, the *tuber papillare*. Its posterior surface rests upon the Diaphragm, being separated from it merely by the upper part of the lesser sac of the peritoneum. To the left of the fissure for the ductus venosus is a groove in which lies the antrum cardiacum of the œsophagus.

The *inferior border* is thin and sharp, and marked opposite the attachment of the falciform ligament by a deep notch, the *umbilical notch*, and opposite the cartilage of the ninth rib by a second notch for the fundus of the gall-bladder. In adult males this border generally corresponds with the lower margin of the thorax in the right nipple line; but in women and children it usually projects below the ribs.

The *left extremity of the liver* is thin and flattened from above downwards.

Fissures (fig. 961).—As already described, five fissures are seen upon the under and posterior surfaces of the liver. They are, the umbilical fissure and the fissure for the ductus venosus, forming together the longitudinal fissure; the transverse fissure; the fissure for the gall-bladder; and the fissure for the inferior vena cava.

The *longitudinal fissure* (fossa sagittalis sinistra) is a deep groove, which extends from the notch on the anterior margin of the liver to the upper border of the posterior surface of the organ; it separates the right and left lobes. The transverse fissure joins it, at right angles, and divides it into two parts. The anterior part, or *umbilical fissure* (fossa venæ umbilicalis), lodges the umbilical vein in the fœtus, and its remains (the ligamentum teres) in the adult; it lies between the quadrate lobe and the left lobe of the liver, and is often partially bridged over by a prolongation of the hepatic substance, the *pons hepatis*. The posterior part, or *fissure for the ductus venosus* (fossa ductus venosi), lies between the left lobe and the lobe of Spigelius; it lodges in the fœtus the ductus venosus, and in the adult a slender fibrous cord (lig. venosum), the obliterated remains of that vessel.

The *transverse* or *portal fissure* (porta hepatis) is a short but deep fissure, about two inches in length, extending transversely across the under surface of the left portion of the right lobe, nearer its posterior surface than its anterior border. It joins nearly at right angles with the longitudinal fissure, and separates the quadrate lobe in front from the caudate and Spigelian lobes behind. It transmits the portal vein, the hepatic artery and nerves, and the hepatic duct and lymphatics. The hepatic duct lies in front and to the right, the hepatic artery to the left, and the portal vein behind and between the duct and artery.

The *fissure for the gall-bladder* (fossa vesicæ felleæ) is a shallow, oblong fossa, placed on the under surface of the right lobe, parallel with the longitudinal fissure. It extends from the anterior free margin of the liver, which is notched by it, to the right extremity of the transverse fissure.

The *fissure for the inferior vena cava* (fossa venæ cavæ) is a short deep fissure, occasionally a complete canal, in consequence of the substance of the liver surrounding the vena cava. It extends obliquely upwards on the posterior surface from the lobus caudatus which separates it from the transverse fissure, and is situated between the Spigelian lobe and the bare area of the liver. On slitting open the inferior vena cava the orifices of the hepatic veins will be seen opening into this vessel at its upper part, after perforating the floor of this fissure.

Lobes.—The lobes of the liver, like the ligaments and fissures, are five in number—the right lobe, the left lobe, the lobus quadratus, the lobus Spigelii, and the lobus caudatus, the last three being merely parts of the right lobe.

The *right lobe* is much larger than the left; the proportion between them being as six to one. It occupies the right hypochondrium, and is separated from the left lobe on its upper and anterior surfaces by the falciform ligament: on its under and posterior surfaces by the longitudinal fissure; and in front by the umbilical notch. It is of a somewhat quadrilateral form, its under and posterior surfaces being marked by three fissures: the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava, which separate its left part into three smaller lobes: the lobus Spigelii, lobus quadratus, and lobus caudatus. The impressions on the right lobe have already been described.

The *lobus quadratus* is situated on the under surface of the right lobe, bounded in front by the inferior margin of the liver; behind by the transverse fissure; on the right, by the fossa for the gall-bladder; and on the left, by the umbilical fissure. It is oblong in shape, its antero-posterior diameter being greater than its transverse.

The *lobus Spigelii* is situated upon the posterior surface of the right lobe of the liver, opposite the tenth and eleventh thoracic vertebræ. It is bounded, below, by the transverse fissure; on the right, by the fissure for the inferior vena cava; and, on the left, by the fissure for the ductus venosus. It looks backwards, being nearly vertical in position; it is longer from above downwards than from side to side, and is somewhat concave in the transverse direction.

The *lobus caudatus*, or tailed lobe, is a small elevation of the hepatic substance extending obliquely outwards, from the lower extremity of the lobus Spigelii to the under surface of the right lobe. It is situated behind the transverse fissure, and separates the fissure for the gall-bladder from the commencement of the fissure for the inferior vena cava.

The *left lobe* is smaller and more flattened than the right. It is situated in the epigastric and left hypochondriac regions. Its upper surface is slightly

convex and is moulded on to the Diaphragm; its under surface presents the *gastric impression* and *omental tuberosity*, already referred to.

Ligaments.—The liver is connected to the under surface of the Diaphragm and to the anterior wall of the abdomen by five ligaments, four of which are peritoneal folds; the fifth is a round, fibrous cord, resulting from the obliteration of the umbilical vein. These ligaments are the falciform, coronary, two lateral, and round. It is also attached to the lesser curvature of the stomach by the gastro-hepatic or small omentum (see page 1123).

The *falciform ligament* (lig. falciforme hepatis) is a broad and thin antero-posterior peritoneal fold, falciform in shape, its base being directed downwards and backwards, its apex upwards and backwards. It is attached by one margin to the under surface of the Diaphragm, and the posterior surface of the sheath of the right Rectus muscle as low down as the umbilicus; by its hepatic margin it extends from the notch on the anterior margin of the liver, as far back as the posterior surface. It is composed of two layers of peritoneum closely united together. Its base or free edge contains the round ligament between its layers.

The *coronary ligament* (lig. coronarium hepatis) consists of an upper and a lower layer. The *upper layer* is formed by the reflection of the peritoneum from the upper margin of the bare area of the liver to the under surface of the Diaphragm, and is continuous with the right layer of the falciform ligament. The *lower layer* is reflected from the lower margin of the bare area on to the right kidney and suprarenal gland.

The *lateral ligaments*, two in number, right and left, are triangular in shape. The *right lateral ligament* (lig. triangulare dextrum) is situated at the right extremity of the bare area, and is a small fold which passes to the Diaphragm, being formed by the apposition of the upper and lower layers of the coronary ligament. The *left lateral ligament* (lig. triangulare sinistrum) is a fold of some considerable size, which connects the posterior part of the upper surface of the left lobe to the Diaphragm; its anterior layer is continuous with the left layer of the falciform ligament.

The *round ligament* (lig. teres hepatis) is a fibrous cord resulting from the obliteration of the umbilical vein. It ascends from the umbilicus, in the free margin of the falciform ligament, to the notch in the anterior border of the liver, from which it may be traced along the longitudinal fissure on the inferior surface of the liver; on the posterior surface it is continued upwards as the obliterated ductus venosus (lig. venosum) as far as the inferior vena cava.

Vessels and Nerves.—The vessels connected with the liver are, the hepatic artery, the portal vein, and the hepatic veins.

The *hepatic artery* and *portal vein*, accompanied by numerous nerves, ascend to the transverse fissure, between the layers of the gastro-hepatic omentum. The *bile-duct* and lymphatic vessels descend from the transverse fissure between the layers of the same omentum. The relative positions of the three structures are as follows: the bile-duct lies to the right, the hepatic artery to the left, and the portal vein behind and between the other two. They are enveloped in a loose areolar tissue, the *capsule of Glisson*, which accompanies the vessels in their course through the portal canals, in the interior of the organ.

The *hepatic veins* convey the blood from the liver, and are described on page 760. They have very little cellular investment, and what there is binds their parietes closely to the walls of the canals through which they run; so that, on section of the organ, they remain widely open and are solitary, and may be easily distinguished from the branches of the portal vein, which are more or less collapsed, and always accompanied by an artery and duct.

The *lymphatics* of the liver are described on page 786.

The *nerves* of the liver, derived from the left pneumogastric and sympathetic, enter at the transverse fissure and accompany the vessels and ducts to the interlobular spaces. Here, according to Korolkow, the medullated fibres are distributed almost exclusively to the coats of the blood-vessels; while the non-medullated enter the lobules and ramify between the cells.

Structure of the Liver.—The substance of the liver is composed of lobules, held together by an extremely fine areolar tissue, in which ramify the portal vein, hepatic ducts, hepatic artery, hepatic veins, lymphatics, and nerves; the whole being invested by a serous and a fibrous coat.

The *serous coat* is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

The *fibrous coat* lies beneath the serous investment, and covers the entire surface of the organ. It is difficult of demonstration, excepting where the serous coat is deficient. At the transverse fissure it is continuous with the capsule of Glisson, and, on the surface of the organ, with the areolar tissue separating the lobules.

The *lobules* (figs. 962, 963) form the chief mass of the hepatic substance; they may be seen either on the surface of the organ, or by making a section through the gland, as small

Fig. 962.—Longitudinal section of an hepatic vein. (After Kiernan.)

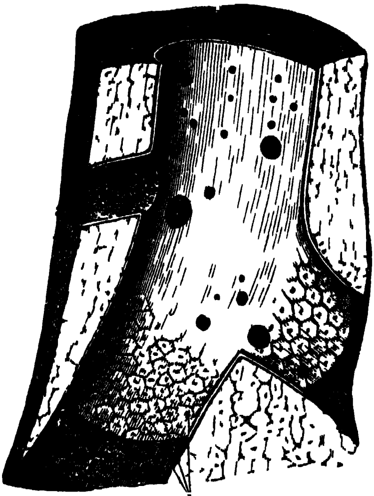


Fig. 963.—Longitudinal section of a small portal vein and canal. (After Kiernan.)

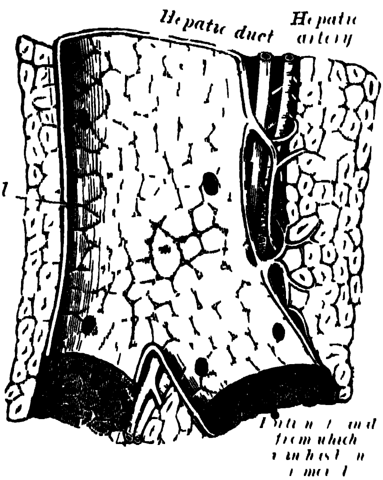
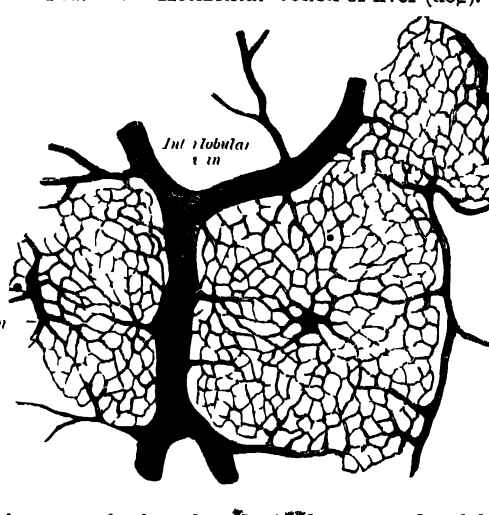


granular bodies about the size of a millet seed, measuring from one twentieth to one tenth of an inch in diameter. In the human subject their outlines are very irregular; but in some of the lower animals (for example, the pig) they are well defined, and, when divided transversely, have polygonal outlines. The bases of the lobules are clustered round the smallest radicles (*sublobular*) of the hepatic veins, to which each is connected by means of a small branch which issues from the centre of the lobule (*intralobular*). The remaining part of the

Fig. 964.—Horizontal section of liver (dog).



surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of areolar tissue, in which is contained a plexus of vessels (the *interlobular plexus*) and ducts. In some animals, as the pig, the lobules are completely isolated from one another by the interlobular areolar tissue.

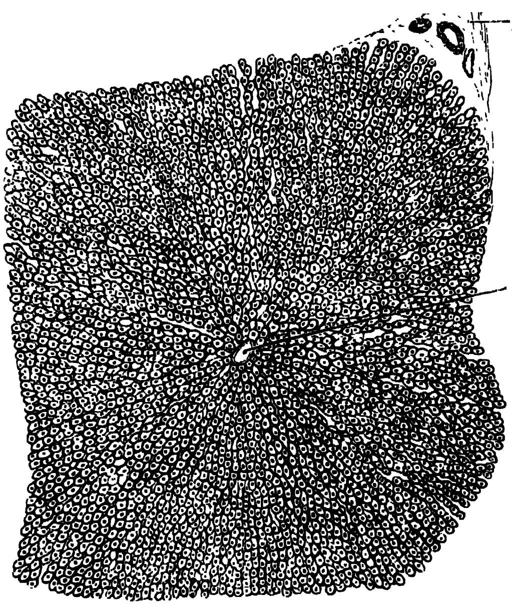
If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in a form resembling a tesselated

pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intralobular vein (fig. 962).

Microscopic appearance (fig. 965).—Each lobule consists of a mass of cells (*hepatic cells*), surrounded by a dense capillary plexus, composed of vessels which penetrate from the circumference to the centre of the lobule, and terminate in the *intralobular vein,* which runs through its centre, to open at its base into one of the *sublobular veins.* Between the cells are also the minute bile capillaries. Therefore, in the lobule there are all the essentials of a secreting gland; that is to say: (1) *cells,* by which the secretion is formed; (2) *blood-vessels,* in close relation with the cells, containing the blood from which the secretion is derived; (3) *ducts,* by which the secretion, when formed, is carried away.

(1) The *hepatic cells* are more or less spheroidal in form; but may be rounded, flattened, or many-sided from mutual compression. They vary in size from $\frac{1}{1000}$ to $\frac{1}{2000}$ of an inch in diameter. They consist of a honeycomb network, and contain one or sometimes two distinct nuclei. The nucleus contains an intranuclear network and one or two refractile nucleoli. Imbedded in the honeycomb network are numerous yellow particles, the colouring-matter of the bile, and fat globules. The cells adhere together by their surfaces so as to form rows, which radiate from the centre to the circumference of the lobules.*

Fig. 965.—A single liver lobule.



(2) *The blood-vessels.*—The blood in the capillary plexus around the liver-cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery.

The *hepatic artery,* entering the liver at the transverse fissure with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off *vaginal branches,* which ramify in the capsule of Glisson, and appear to be destined chiefly for the nutrition of the coats of the vessels and ducts. It also gives off *capsular branches,* which reach the surface of the organ, terminating in its fibrous coat in stellate plexuses. Finally it gives off *interlobular branches,* which form a plexus on the outer side of each lobule, to supply the walls of the interlobular veins and the accompanying bile-ducts. From this plexus lobular branches enter the lobule and end in the capillary network between the cells.

The *portal vein* also enters at the transverse fissure, and runs through the portal canals, enclosed in Glisson's capsule, dividing in its course into branches, which finally break up into a plexus (the *interlobular plexus*) in the interlobular spaces. These branches receive the vaginal and capsular veins, corresponding to the vaginal and capsular branches of the hepatic artery (fig. 963). Thus it will be seen that all the blood carried to

* Delépine states that there are evidences of the arrangement of these cells in the form of columns, which form tubes with narrow lumina branching from terminal bile-ducts. This branching is evidenced by a divergence of the columns from lines extending between adjacent portal vessels. The columns of cells group round terminal bile-ducts and not round the so-called intralobular veins.—*Lancet,* 1895, vol. i. p. 1254.

the liver by the portal vein and hepatic artery finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which converge from the circumference to the centre of the lobule, and are connected by transverse branches (fig. 964). In the interstices of the network of vessels thus formed are situated the liver-cells; and here it is that, the blood being brought into intimate connection with the liver-cells, the bile is secreted. Arrived at the centre of the lobule, all these minute vessels empty themselves into one vein, of considerable size, which runs down the centre of the lobule from apex to base, and is called the *intralobular vein*. At the base of the lobule this vein opens directly into the *sublobular vein*, with which the lobule is connected. The sublobular veins unite to form larger and larger trunks, and end at last in the hepatic veins, which converge to form three large trunks which open into the inferior vena cava, while that vessel is situated in the fissure appropriated to it at the back of the liver.

(3) *The bile-ducts.*—Several views have prevailed as to the mode of origin of the hepatic ducts; it seems, however, to be generally believed that they commence by little passages

Fig. 966.—Section of liver.

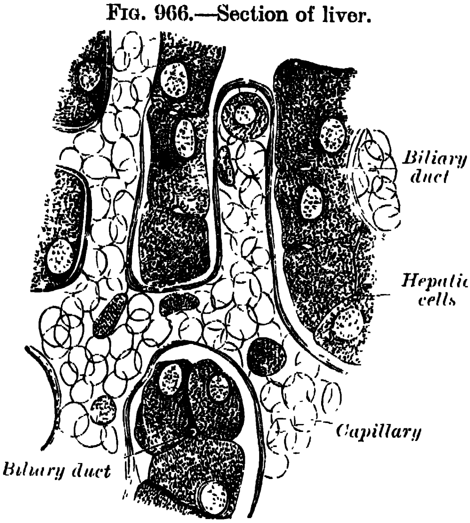


Fig. 967.—A transverse section of a small portal canal and its vessels. (After Kiernan.)

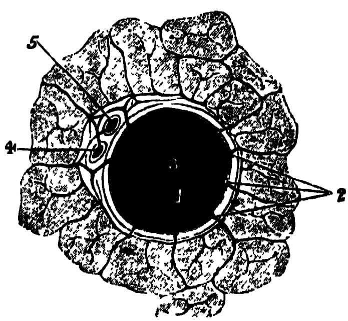


1. Portal vein. 2. Interlobular branches. 3. Vaginal branches. 4. Hepatic duct. 5. Hepatic artery.

which are formed between the cells, and which have been termed *intercellular biliary passages* or *bile capillaries*, although some authorities maintain that they have an intracellular origin. These passages are merely little channels or spaces left between the contiguous surfaces of two cells, or in the angle where three or more liver-cells meet (fig. 966), and they are always separated from the blood capillaries by at least half the width of a liver-cell. The channels thus formed radiate to the circumference of the lobule, and form a plexus (*interlobular*) between the lobules. From this plexus ducts are derived which pass into the portal canals, become enclosed in Glisson's capsule, and, accompanying the portal vein and hepatic artery (fig. 967), join with other ducts to form two main trunks, which leave the liver at the transverse fissure, and by their union form the *hepatic duct*.

Structure of the ducts.—The walls of the biliary ducts consist of a connective-tissue coat, in which are muscle-cells, arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells resting on a distinct basement-membrane.

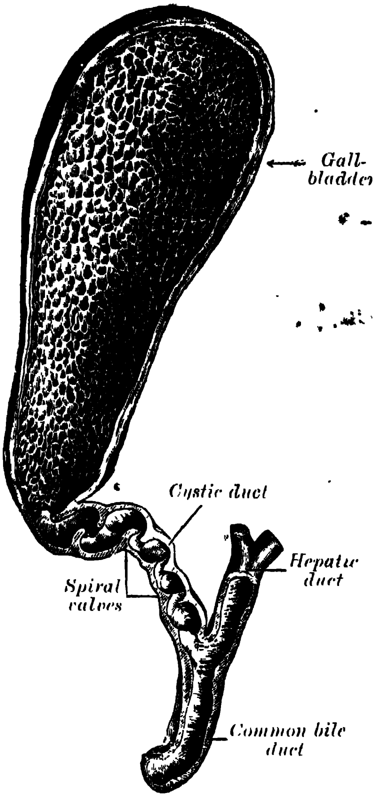
Excretory Apparatus of the Liver

The excretory apparatus of the liver consists of (1) the *hepatic duct*, formed, as we have seen, by the junction of the two main ducts, which pass out of the liver at the transverse fissure; (2) the *gall-bladder*, which serves as a reservoir for the bile; (3) the *cystic duct*, or the duct of the gall-bladder; and (4) the *common bile-duct*, formed by the junction of the hepatic and cystic ducts.

The hepatic duct.—Two main trunks of nearly equal size issue from the liver at the transverse fissure, one from the right, the other from the left lobe; these unite to form the hepatic duct (ductus hepaticus), which then passes downwards and to the right for about an inch and a half, between the layers of the lesser omentum, where it is joined at an acute angle by the cystic duct, and so forms the common bile-duct (ductus choledochus). The hepatic duct is accompanied by the hepatic artery and portal vein.

The **gall-bladder** (vesica fellea) (fig. 968) is a conical or pear-shaped musculo-membranous sac, lodged in a fossa on the under surface of the right lobe of the liver, and extending from near the right extremity of the transverse fissure to the anterior border of the organ. It is from three to four inches in length, one inch in breadth at its widest part, and holds from eight to ten drachms. It is divided into a fundus, body, and neck. The *fundus*, or broad extremity, is directed downwards, forwards, and to the right, and projects beyond the anterior border of the liver; the *body* and *neck* lie in the fossa vesicalis, and are directed upwards and backwards to the left. The upper surface of the gall-bladder is attached to the liver by connective tissue and vessels. The under surface is covered by peritoneum, which is reflected on to it from the surface of the liver. Occasionally the whole of the organ is invested by the serous membrane, and is then connected to the liver by a kind of mesentery.

FIG. 968.—The gall-bladder and bile-ducts laid open. (Spalteholz.)



Relations.—The *body* (corpus vesicæ felleæ) is in relation, by its upper surface, with the liver, to which it is connected by areolar tissue and vessels; by its under surface, with the commencement of the transverse colon; and farther back usually with the upper end of the descending portion of the duodenum, but sometimes with the first portion of the duodenum or pyloric end of the stomach. The *fundus* (fundus vesicæ felleæ) is completely invested by peritoneum; it is in relation, in front, with the abdominal parietes, immediately below the ninth costal cartilage; behind with the transverse arch of the colon. The *neck* (collum vesicæ felleæ) is narrow, and curves upon itself like the letter S; at its point of connection with the cystic duct it presents a well-marked constriction.

Structure (fig. 969).—The gall-bladder consists of three coats: serous, fibrous and muscular, and mucous.

The *external* or *serous coat* is derived from the peritoneum; it completely invests the fundus, but covers the body and neck only on their under surfaces.

The *fibro-muscular coat*, a thin but strong layer forming the framework of the sac, consists of dense fibrous tissue, which interlaces in all directions, and is mixed with plain muscular fibres, disposed chiefly in a longitudinal direction, a few running transversely.

The *internal* or *mucous coat* is loosely connected with the fibrous layer. It is generally of a yellowish-brown colour, and is elevated into minute rugæ. Opposite the neck of the gall-bladder the mucous membrane projects inwards in the form of oblique ridges or folds, forming a sort of spiral valve (valvula spiralis).

The mucous membrane is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the common bile-duct with the mucous membrane of the alimentary canal. It is covered with columnar epithelium, and secretes mucin; in some animals it secretes a nucleo-protein instead of mucin.

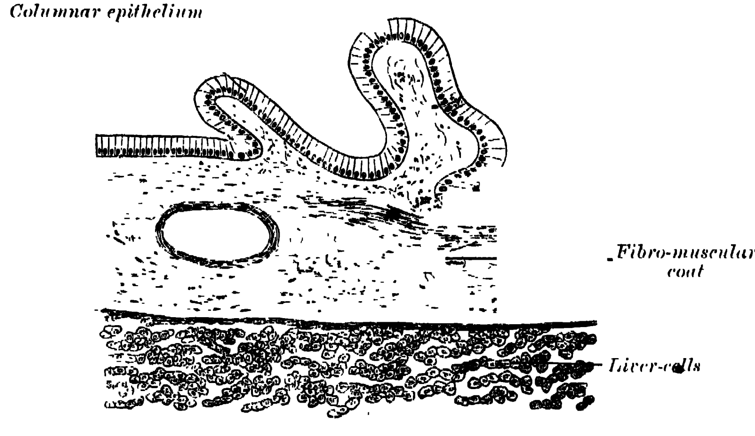
The **cystic duct** (ductus cysticus), about an inch and a half in length, runs backwards, downwards, and to the left from the neck of the gall-bladder, and joins the hepatic duct to form the common bile-duct. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely round

the tube, presenting much the appearance of a continuous spiral valve. When the duct is distended, the spaces between the folds are dilated, so as to give to its exterior a twisted appearance.

The **common bile-duct** (ductus choledochus) is formed by the junction of the cystic and hepatic ducts; it is about three inches in length, and of the diameter of a goose-quill.

It descends along the right border of the lesser omentum behind the first portion of the duodenum, in front of the portal vein, and to the right of

FIG. 969.—Transverse section of gall-bladder.



the hepatic artery; it then passes between the head of the pancreas and descending portion of the duodenum, and, running for a short distance along the right side of the terminal part of the pancreatic duct, passes with it, obliquely between the mucous and muscular coats. The two ducts unite and open by a common orifice upon the summit of a papilla, situated at the inner side of the descending portion of the duodenum, a little below its middle and about three or four inches from the pylorus (fig. 941). The short tube formed by the union of the two ducts is dilated into an ampulla, the *ampulla of Vater*.

Structure.—The coats of the large biliary ducts are an external or fibrous, and an internal or mucous. The fibrous coat is composed of strong fibro-areolar tissue, with a certain amount of muscular tissue, arranged, for the most part, in a circular manner around the duct. The mucous coat is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum; and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous mucous glands, which are lobulated and open by minute orifices scattered irregularly in the larger ducts.

Surface Relations.—The liver is situated mainly in the right hypochondriac and the epigastric regions, and is moulded to the dome of the Diaphragm. In the greater part of its extent it lies under cover of the lower ribs and their cartilages, but in the epigastric region it comes in contact with the abdominal wall, in the subcostal angle. The *upper limit of the right lobe of the liver* may be defined in the middle line by the junction of the meso-sternum with the ensiform cartilage; on the right side the line must be carried upwards as far as the fifth rib cartilage in the line of the nipple, and then downwards to reach the seventh rib at the side of the chest. The *upper limit of the left lobe* may be defined by continuing this line to the left, with an inclination downwards, to a point about two inches to the left of the sternum on a level with the sixth left costal cartilage. The *lower limit of the liver* may be indicated by a line drawn half an inch below the lower border of the thorax on the right side, as far as the ninth right costal cartilage, and thence obliquely upwards across the subcostal angle to the eighth left costal cartilage. A slightly curved line with its convexity to the left from this point, i.e. the eighth left costal cartilage, to the termination of the line indicating the upper limit, will denote the left margin of the liver. Birmingham teaches that the limits of the normal liver may be marked out on the surface of the body in the following manner. Take three points: 1, half an inch below the right nipple; 2, half an inch below the tip of the tenth rib; and 3, one inch below the left nipple. Join 1 and 3 by a line slightly convex upwards; join 1 and 2 by a line

slightly convex outwards, and 2 and 3 by a line slightly convex downwards. The fundus of the gall-bladder approaches the surface behind the anterior extremity of the ninth costal cartilage, close to the outer margin of the right Rectus muscle.

It must be remembered that the liver is subject to considerable alterations in position, and the student should make himself acquainted with the different circumstances under which this occurs, as they are of importance in determining the existence of enlargement or other diseases of the organ.

The position of the liver varies according to the posture of the body. In the erect position in the adult male, the edge of the liver projects about half an inch below the lower edge of the right costal cartilages, and its anterior border can often be felt in this situation if the abdominal wall is thin. In the supine position the liver gravitates backwards, and recedes above the lower margin of the ribs, and cannot then be detected by the finger. In the prone position it falls forward, and can then generally be felt in a patient with loose and lax abdominal walls. Its position varies also with the ascent or descent of the Diaphragm. In a deep inspiration the liver descends below the ribs; in expiration it is raised behind them. Again, in emphysema, where the lungs are voluminous and the Diaphragm descends very low, the liver is pushed down: in some other diseases, as phthisis, where the Diaphragm is much arched, the liver rises very high up. Pressure from without, as in tight-lacing, by compressing the lower part of the chest, displaces the liver considerably; its anterior edge frequently extending as low as the crest of the ilium; and its convex surface is often at the same time deeply indented from the pressure of the ribs. Again, its position varies greatly according to the greater or less distension of the stomach and intestines. When the intestines are empty, the liver descends in the abdomen; but when they are distended, it is pushed upwards. Its relations to surrounding organs may also be changed by the growth of tumours, or by collections of fluid in the thoracic or abdominal cavities. Ptosis of the liver, or hepatoptosis, from abnormal laxity of its ligaments and failure of the support it usually receives from the subjacent viscera, is an occasional cause of various nervous and gastro-intestinal disturbances. It has been very fully described by Glénard and his pupils.

Applied Anatomy.—On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the other abdominal viscera. The rupture may vary from a slight scratch to an extensive and complete laceration of its substance, dividing it into two parts. Sometimes an internal rupture, without laceration of the peritoneal covering, takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hæmorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. It may be injured by stabs or other punctured wounds, and when these are inflicted through the chest-wall the pleural and peritoneal cavities may both be opened up, and both lung and liver wounded. In cases of wound of the liver from the front, hernia of a part of this viscus may take place, but generally can be easily replaced. In cases of laceration of the liver, when there is evidence that bleeding is going on, the abdomen must be opened, the laceration sought for, and the bleeding arrested. This may be done temporarily by introducing the forefinger into the foramen of Winslow and placing the thumb on the gastro-hepatic omentum, and compressing the hepatic artery and portal vein between the two. Any bleeding points can then be seen and tied, and the margins of the laceration, if small, brought together and sutured by means of a blunt curved needle passed from one side of the wound to the other. All sutures must be passed before any are tied, and this must be done with the greatest gentleness, as the liver substance is very friable. When the laceration is extensive it must be packed with gauze, the end of which is allowed to hang out of the external wound.

Abscess of the liver is of not infrequent occurrence. The so-called *tropical abscess* is due to absorption from the intestine of the amœba of dysentery, which reaches the liver through the portal system and causes the formation of a large chronic abscess; this may open in many different ways on account of the relations of the liver to other organs. Thus it has been known to burst into the lungs when the pus is coughed up, or into the stomach when the pus is vomited; it may burst into the colon, or duodenum; or, by perforating the Diaphragm, it may empty itself into the pleural cavity. It often makes its way forwards, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardial cavities. Abscesses of the liver frequently require opening, and this must be done by an incision in the abdominal wall, in the thoracic wall, or in the lumbar region, according to the direction in which the abscess is tracking. The incision through the abdominal wall is to be preferred when possible. The abdominal wall is incised over the swelling, and, unless the peritoneum is adherent, gauze is packed all round the exposed liver surface and the abscess opened, and a large drainage tube inserted. Hydatid cysts are more often found in the liver than in any of the other viscera. The reason of this is not far to seek. The embryo of the egg of the tænia echinococcus, being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a blood-vessel, and is carried by the blood-stream to the hepatic capillaries,

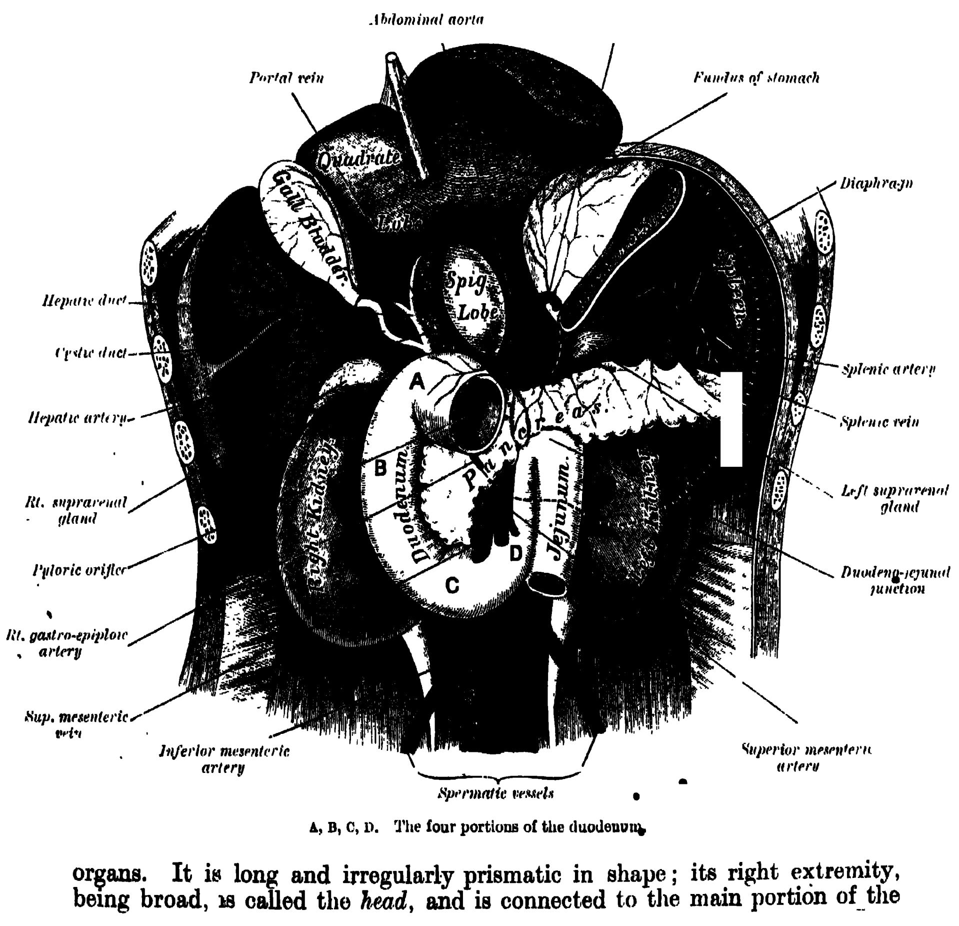
where its onward course is arrested, and where it undergoes development into the fully formed hydatid.

The gall-bladder may become distended in cases of obstruction of its duct or the common bile-duct, or from a collection of gall-stones in its interior, thus forming a large tumour. The swelling is pear-shaped, and projects downwards and forwards to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve this condition, the gall-bladder must be opened (*cholecystotomy*) and the gall-stones removed. The operation is performed by an incision, two or three inches long, through the outer part of the right Rectus muscle, commencing at the costal margin. The peritoneal cavity is opened, and, the tumour having been found, gauze is packed round it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised; any gall-stones in the bladder are now removed and the interior of the sac sponged dry. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct; or it may be crushed from without by the fingers or carefully padded forceps. If this does not succeed, the safest plan is to incise the duct, extract the stone, and close the incision by fine sutures in two layers. After all obstruction has been removed, the edges of the incision in the gall-bladder may be sutured to the anterior sheath of the Rectus and a fistulous communication established between the gall-bladder and the exterior; this fistulous opening usually closes in the course of a few weeks. The gall-bladder may be completely removed if it be quite certain that no cause for biliary obstruction remain: this is also done for primary malignant growth of the viscus.

The Pancreas

The **pancreas** is a compound racemose gland, analogous in its structure to the salivary glands, though softer and less compactly arranged than those

Fig. 970.—The duodenum and pancreas.
The liver has been lifted up and the greater part of the stomach removed. (Testut.)



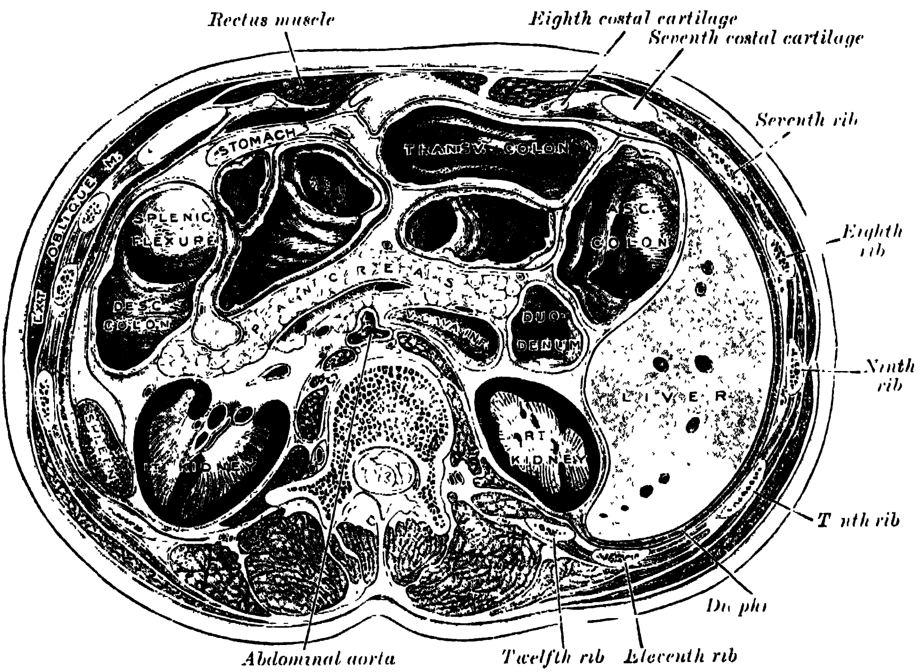
A, B, C, D. The four portions of the duodenum.

organs. It is long and irregularly prismatic in shape; its right extremity, being broad, is called the *head*, and is connected to the main portion of the

organ, or *body*, by a slight constriction, the *neck*; while its left extremity gradually tapers to form the *tail*. It is situated transversely across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions. Its length varies from five to six inches, and its weight from two to three and a half ounces.

Relations (figs. 970, 971, 972).—The **head** (caput pancreatis) is flattened from before backwards, and is lodged within the curve of the duodenum. Its upper border is in contact with the first part of the duodenum and its lower overlaps the third part; its right and left borders overlap in front, and insinuate themselves behind, the second and fourth parts of the duodenum respectively. The angle of junction of the lower and left lateral borders forms a prolongation, termed the *processus uncinatus*. In the groove between the duodenum and the right lateral and lower borders in front are the anastomosing superior and inferior pancreatico-duodenal arteries; the common bile-duct descends behind, along the right border, to its termination in the second part of the duodenum.

FIG. 971.—Transverse section through the middle of the first lumbar vertebra, showing the relations of the pancreas. (Braune.)



Anterior surface.—The greater part of the right half of this surface is in contact with the transverse colon, only areolar tissue intervening. From its upper part the *neck* originates, its right limit being marked by a groove for the gastro-duodenal artery. The lower part of the right half, below the transverse colon, is covered by peritoneum continuous with the inferior layer of the transverse mesocolon, and is in contact with the coils of the small intestine. The superior mesenteric artery passes down in front of the left half across the processus uncinatus; the superior mesenteric vein runs upwards on the right side of the artery and, behind the neck, joins with the splenic vein to form the portal vein.

Posterior surface.—The posterior surface is in relation with the inferior vena cava, the renal veins, the right crus of the Diaphragm, and the aorta.

The neck springs from the right upper portion of the front of the head. It is about an inch in length, and is directed at first upwards and forwards, and then upwards and to the left to join the body; it is somewhat flattened from above downwards and backwards. Its antero-superior surface supports the

pylorus; its postero-inferior surface is in relation with the commencement of the portal vein; on the right it is grooved by the gastro-duodenal artery.

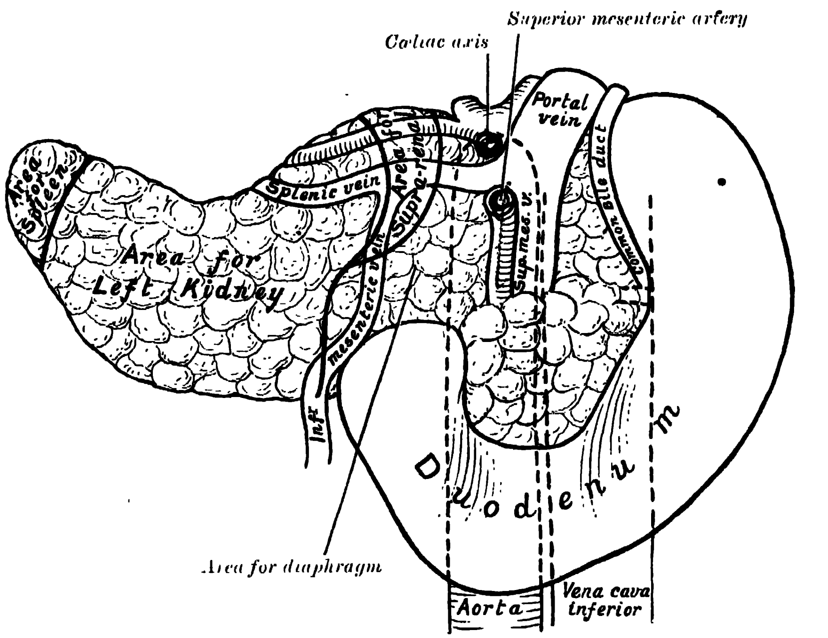
The **body** (corpus pancreatis) is somewhat prismatic in shape, and has three surfaces: anterior, posterior, and inferior.

The *anterior surface* (facies anterior) is somewhat concave, and is directed forwards and upwards: it is covered by the postero-inferior surface of the stomach which rests upon it, the two organs being separated by the lesser sac of the peritoneum. Where it joins the neck there is a well-marked prominence, the *tuber omentale*, which abuts against the posterior surface of the small omentum.

The *posterior surface* (facies posterior) is devoid of peritoneum, and is in contact with the aorta, the splenic vein, the left kidney and its vessels, the left suprarenal gland, the origin of the superior mesenteric artery, and the crura of the Diaphragm.

The *inferior surface* (facies inferior) is narrow on the right but broader on the left, and is covered by peritoneum; it lies upon the duodeno-jejunal

Fig. 972.—The pancreas and duodenum from behind. (Drawn from His' model.)



flexure and on some coils of the jejunum; its left extremity rests on the splenic flexure of the colon.

The *superior border* (margo superior) is blunt and flat to the right; narrow and sharp to the left, near the tail. It commences on the right in the omental tuberosity, and is in relation with the cœliac axis, from which the hepatic artery courses to the right just above the gland, while the splenic artery runs towards the left in a groove along this border.

The *anterior border* (margo anterior) separates the anterior from the inferior surface, and along this border the two layers of the transverse mesocolon diverge from one another: one passing upwards over the anterior surface, the other backwards over the inferior surface.

The *inferior border* separates the posterior from the inferior surface; the superior mesenteric vessels emerge under its right extremity.

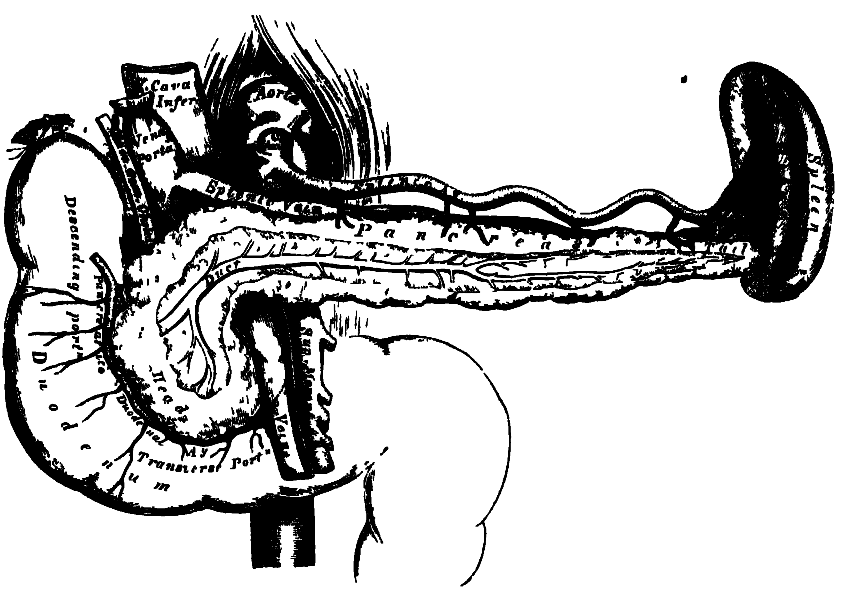
The **tail** (cauda pancreatis) is narrow; it extends to the left as far as the lower part of the gastric surface of the spleen, and it is in contact with the splenic flexure of the colon.

Birmingham describes the body of the pancreas as projecting forwards as a prominent ridge into the abdominal cavity and forming a sort of shelf on

which the stomach lies. He says: 'The portion of the pancreas to the left of the middle line has a very considerable antero-posterior thickness; as a result the anterior surface is of considerable extent; it looks strongly upwards, and forms a large and important part of the shelf. As the pancreas extends to the left towards the spleen it crosses the upper part of the kidney, and is so moulded on to it that the top of the kidney forms an extension inwards and backwards of the upper surface of the pancreas and extends the bed in this direction. On the other hand, the extremity of the pancreas comes in contact with the spleen in such a way that the plane of its upper surface runs with little interruption upwards and backwards into the concave gastric surface of the spleen, which completes the bed behind and to the left, and, running upwards, forms a partial cap for the wide end of the stomach.' *

The **pancreatic duct** or **canal of Wirsung** (ductus pancreaticus) extends transversely from left to right through the substance of the pancreas (fig. 973). It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from left to right through the body, it receives the ducts of the various lobules composing the gland. Considerably augmented in size, it reaches the neck, and turning downwards, backwards, and to the

Fig. 973.—The pancreas and its ducts.



right, it comes into relation with the common bile-duct, which lies to its right side; leaving the head of the gland, it passes very obliquely through the mucous and muscular coats of the duodenum, and terminates by an orifice common to it and the common bile-duct upon the summit of an elevated papilla, situated at the inner side of the descending portion of the duodenum, three or four inches below the pylorus (fig. 941).

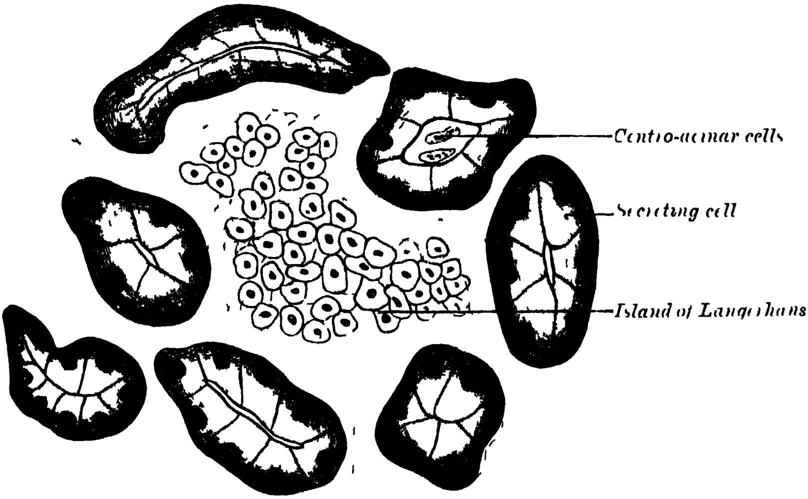
Sometimes the pancreatic duct and the common bile-duct open separately into the duodenum. Frequently there is an accessory duct, which is given off from the canal of Wirsung in the neck of the pancreas and passes horizontally to the right to open into the duodenum about an inch above the orifice of the main duct. It receives the ducts from the lower part of the head, and is known as the *ductus pancreaticus accessorius* or *ductus Santorini.*

The pancreatic duct, near the duodenum, is about the size of an ordinary quill: its walls are thin, consisting of two coats, an external fibrous and an internal mucous; the latter is smooth, and furnished near its termination with a few scattered follicles.

* *Journal of Anatomy and Physiology*, vol. xxxi pt 1, p. 102.

Structure (fig. 974).—In structure, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture. It is not enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips into its interior, and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, terminating in a number of cæcal pouches or alveoli, which are tubular and somewhat convoluted. The minute ducts connected with the alveoli are narrow and lined with flattened cells. The alveoli are almost completely filled with secreting cells, so that scarcely any lumen is visible. In some animals those cells which occupy the centre of the alveolus are spindle-shaped, and are known as the *centro-acinar cells of Langerhans*. The true secreting cells which line the wall of the alveolus are very characteristic. They are columnar in shape and present two zones: an outer one, clear and finely striated next the basement-membrane, and an inner granular one next the lumen. During activity the granular zone gradually diminishes in size, and when exhausted is only seen as a small area surrounding the lumen. During the resting stages it gradually increases until it fills nearly three-fourths of the cell. In some of the secreting cells of the pancreas is a spherical mass, staining more easily than the rest of the cell; this is termed the *paranucleus*, and is believed to be an extension from the nucleus. The connective tissue between the alveoli presents in certain parts collections of cells, which are termed *inter-alveolar cell-islets*, or islands of Langerhans. The cells stain lightly and are more or less polyhedral in shape, forming a network in which ramify many capillaries. These cell-islets were formerly supposed to secrete an 'internal secretion'

FIG. 974.—Section of a portion of the pancreas.



which influenced carbohydrate metabolism, but have been demonstrated by Dale to be alveoli in a stage of exhaustion, which after a time become re-converted into fresh alveoli.

Vessels and Nerves.—The *arteries of the pancreas* are derived from the splenic, and the pancreatico-duodenal branches of the hepatic and superior mesenteric. Its *veins* open into the splenic and superior mesenteric veins. Its *lymphatics* are described on page 787. Its *nerves* are filaments from the splenic plexus.

Surface Relations.—The pancreas lies in front of the second lumbar vertebra, and can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about three inches above the umbilicus.

Applied Anatomy.—Inflammation of the pancreas has of late years received considerable attention. It appears to be due to infection of the pancreatic ducts by micro-organisms from the duodenum in cases of gastro-duodenal catarrh, or from the biliary passages in which a gall-stone is lodged. Acute cases usually terminate fatally and are frequently of the hæmorrhagic type; chronic inflammation of the pancreas produces few symptoms of disease unless it is extensive, when attacks of abdominal pain, loss of appetite, progressive weakness and wasting, and the passage of whitish fatty motions, are likely to follow. Extensive fibrosis of the pancreas is also one of the commonest lesions found post-mortem in cases of diabetes mellitus. Cysts of the pancreas are sometimes met with. They may be the result of traumatism, when they generally contain blood, or they may be due to retention from obstruction of a duct, or from pressure on the main duct by a gall-stone. They may attain a large size, and cause symptoms by pressing on the stomach, Diaphragm, or common bile-duct. They generally push their way forwards between the stomach and transverse colon, and may then be felt as a definite tumour in

the middle line of the upper part of the abdomen. The tumour is fixed and does not move with respiration. The treatment consists in opening the abdomen in the middle line, incising the cyst, evacuating its contents, and fixing its walls to the deeper layers of the abdominal wall. Drainage in the left loin, just below the last rib, can sometimes be established. When they are situated in the tail of the pancreas they may be removed. The pancreas is often the seat of cancer; this usually affects the head, and therefore speedily involves the common bile-duct, leading to persistent jaundice; or it may press upon the portal vein, causing ascites, or involve the stomach, causing pyloric obstruction. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found, in company with other viscera, in rare cases of diaphragmatic hernia.

UROGENITAL ORGANS

The urogenital organs (apparatus urogenitalis) consist of (*a*) the urinary organs for the secretion and discharge of the urine and (*b*) the genital organs, which are concerned with the process of reproduction.

THE URINARY ORGANS

The urinary organs comprise the *kidneys*, which secrete the urine; the *ureters*, or ducts, which convey it to the *bladder*, where it is for a time retained; and the *urethra*, through which it is discharged from the body.

The Kidneys

The **kidneys** (renes) are situated in the posterior part of the abdomen, one on either side of the vertebral column, behind the peritoneum, and surrounded by a mass of fat and loose areolar tissue. Their upper extremities are on a level with the upper border of the twelfth thoracic vertebra, their lower extremities on a level with the third lumbar. The right kidney is usually slightly lower than the left, probably on account of the vicinity of the liver. The long axis of each kidney is directed from above downwards and outwards; the transverse axis from within backwards and outwards.

Each kidney is about four and a half inches in length, two to two and a half in breadth, and rather more than one inch in thickness. The left is somewhat longer, and narrower, than the right. The weight of the kidney in the adult male varies from four and a half ounces to six ounces, in the adult female from four to five and a half ounces. The combined weight of the two kidneys in proportion to that of the body is about 1 to 240.

The kidney has a characteristic form, and presents for examination two surfaces, two borders, and an upper and lower extremity.

Relations (figs. 975, 976, 977).—The *anterior surface* (facies anterior) of each kidney is convex, and looks forwards and outwards. Its relations to adjacent viscera differ so completely on the two sides that separate descriptions are necessary.

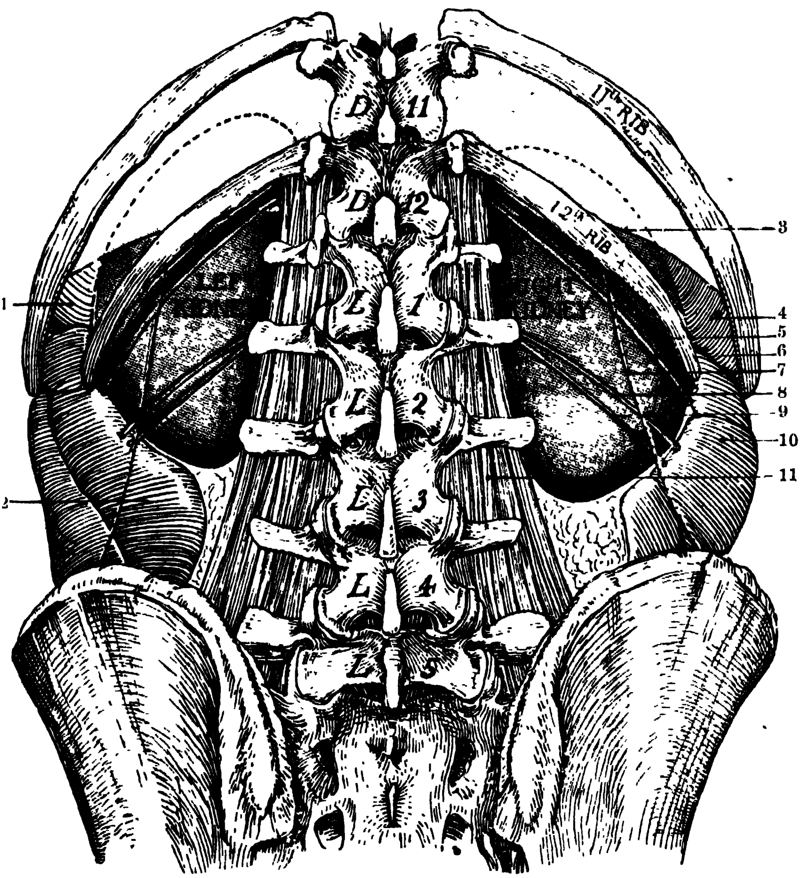
(*a*) *Anterior surface of right kidney.*—A narrow portion at the upper extremity is in relation with the suprarenal gland. Immediately below this a large area, involving about three-fourths of the surface, lies in the renal impression on the inferior surface of the liver, and a narrow but somewhat variable area near the inner border is in contact with the second part of the duodenum. The lower part of the anterior surface is in contact externally with the hepatic flexure of the colon, and internally with the small intestine. The areas in relation with the liver and intestine are covered by peritoneum; the suprarenal, duodenal, and colic areas are devoid of peritoneum.

(*b*) *Anterior surface of left kidney.*—A small area along the upper part of the inner border is in relation with the suprarenal gland, and close to the outer border is a narrow strip in contact with the renal impression on the spleen. A broad, somewhat quadrilateral field, about the middle of the anterior surface, marks the site of contact with the body of the pancreas, on the deep surface of which are the splenic vessels. Above this is a small

triangular portion, between the suprarenal and splenic areas, in contact with the postero-inferior surface of the stomach. Below the pancreatic area the outer part is in relation with the splenic flexure of the colon, the inner with the small intestine. The area in contact with the stomach is covered by the peritoneum of the lesser sac, while that in relation to the small intestine is covered by the peritoneum of the greater sac; behind the latter are some branches of the left colic vessels.

The *posterior surface* (facies posterior) of each kidney is directed backwards and inwards. It is entirely devoid of peritoneal covering, and imbedded in areolar and fatty tissue. It lies upon the Diaphragm, the external and internal arcuate ligaments, the Psoas muscle, the anterior layer of the lumbar

FIG. 975.—The relations of the kidneys, from behind.



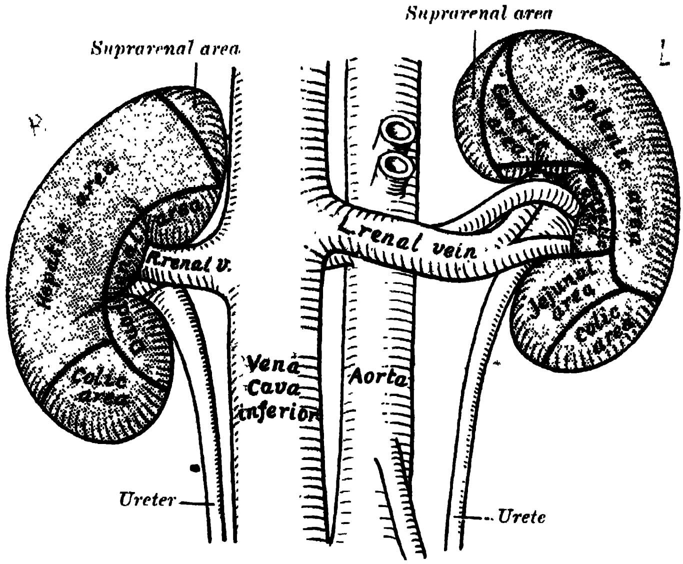
1. Spleen. 2. Descending colon. 3. Line of pleural reflection. 4. Liver. 5. Subcostal artery. 6. Last thoracic nerve. 7. Line indicating outer edge of Quadratus lumborum. 8. Ilio-inguinal nerve. 9. Ilio-hypogastric nerve. 10. Ascending colon. 11. Psoas.

aponeurosis (which separates it from the Quadratus lumborum), and the tendon of the Transversalis muscle, one or two of the upper lumbar arteries, and the last thoracic, ilio-hypogastric, and ilio-inguinal nerves. The right kidney rests upon the twelfth rib, the left usually on the eleventh and twelfth. The Diaphragm separates the kidney from the pleura, which dips down to form the phrenico-costal sinus, but frequently the muscular fibres of the Diaphragm are defective or absent over a triangular area immediately above the external arcuate ligament, and when this is the case the perinephric areolar tissue is in actual contact with the diaphragmatic pleura.

The *external border* (margo lateralis) is convex, and is directed outwards and backwards, towards the postero-lateral wall of the abdomen. On the left side it is in contact, at its upper part, with the spleen.

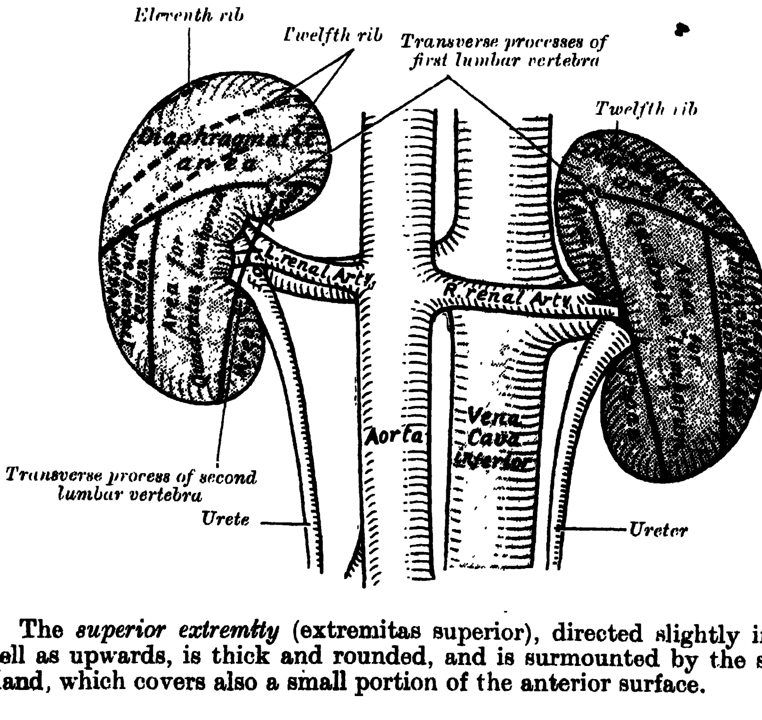
The *internal border* (margo medialis) is concave in the centre and convex towards either extremity; it is directed forwards and a little downwards. Its central part presents a deep longitudinal fissure, bounded by prominent

FIG. 976.—The anterior surfaces of the kidneys, showing the areas of contact of neighbouring viscera.



overhanging anterior and posterior lips. This fissure is named the *hilus*, and allows of the transmission of the vessels, nerves, and ureter.

FIG. 977.—The posterior surfaces of the kidneys, showing areas of relation to the parietes.



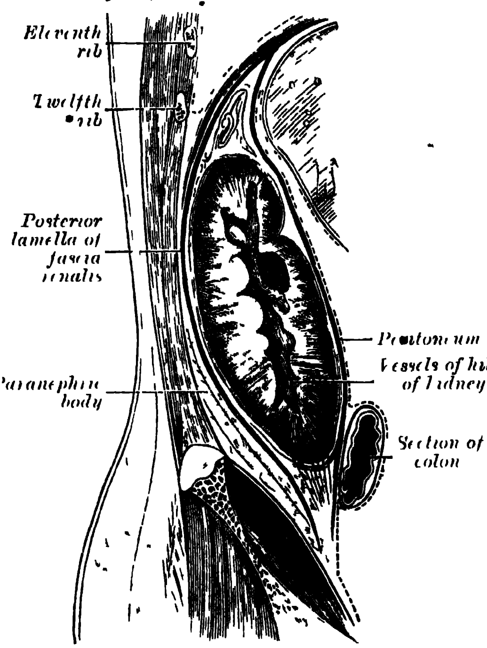
The *superior extremtty* (extremitas superior), directed slightly inwards as well as upwards, is thick and rounded, and is surmounted by the suprarenal gland, which covers also a small portion of the anterior surface.

The *inferior extremity* (extremitas inferior), directed a little outwards as well as downwards, is smaller and thinner than the superior, and extends to within two inches of the crest of the ilium.

The relative position of the main structures in the hilus is as follows: the vein is in front, the artery in the middle, and the ureter behind and directed downwards. Frequently, however, branches of both artery and vein are placed behind the ureter.

Fixation of the kidney (figs. 978, 979).—The kidney and its vessels are imbedded in a mass of fatty tissue, termed the *capsula adiposa*, which is thickest at the margin of the kidney and is prolonged through the hilus into the renal sinus. The kidney and the capsula adiposa are enclosed in a sheath of fibrous tissue continuous with the subperitoneal fascia, and named the *fascia renalis*. At the outer border of the kidney the fascia renalis splits into an anterior and a posterior layer. The anterior layer is carried inwards in front of the kidney and its vessels, and is continuous over the aorta with the corresponding layer of the opposite side. The posterior layer extends inwards behind the kidney and blends with the fascia on the Quadratus lumborum and Psoas and through this fascia is attached to the vertebral column. At the upper margin of the suprarenal gland the two layers of the fascia renalis fuse, and unite with the fascia of the Diaphragm; below they remain separate, and are gradually lost in the subperitoneal fascia of the iliac fossa. The fascia renalis is connected to the fibrous capsule of the kidney by numerous trabeculæ, which traverse the capsula adiposa, and are strongest near the lower end of the organ. Behind the fascia renalis is a considerable quantity of fat, which constitutes the *paranephric body*. The kidney is held in position partly through the attachments of the fascia renalis and partly by the apposition of the neighbouring viscera.

Fig. 978.—Sagittal section through posterior abdominal wall, showing the relations of the capsule of the kidney. (After Gerota.)



General structure of the kidney.—The kidney is invested by a capsule of fibrous tissue (tunica fibrosa), which forms a firm, smooth covering to the organ. The capsule can be easily stripped off, but in doing so, numerous fine processes of connective tissue and small blood-vessels are torn through. Beneath this coat, a thin wide-meshed network of unstriped muscular fibre forms an incomplete covering to the organ. When the capsule is stripped off, the surface of the kidney is found to be smooth and even, and of a deep red colour. In infants, fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland. The kidney is dense in texture, but is easily lacerable by mechanical force. If a vertical section of the kidney be made from its convex to its concave border, and the loose tissue and fat removed from around the vessels and the excretory duct it will be seen that the kidney consists of a central cavity surrounded at all parts but one by the proper kidney-substance (fig. 980). This central cavity is called the *renal sinus*, and is lined by a prolongation of the capsule, which is continued round the lips of the hilus. Through the hilus the blood-vessels of the kidney and its excretory duct pass, and therefore these structures, upon entering or leaving the kidney, are contained within the sinus. The excretory duct or *ureter* begins by several short truncated branches termed *calyces* or *infundibula* (calyces renales), which unite to form two or three short tubes; these in turn expand into a wide funnel-shaped sac named

the *pelvis of the kidney* (pelvis renalis), from the neck of which the ureter issues. The calyces and pelvis lie within the sinus; the blood-vessels of the kidney, after passing

FIG. 979.—Transverse section, showing the relations of the capsule of the kidney. (After Gerota.)

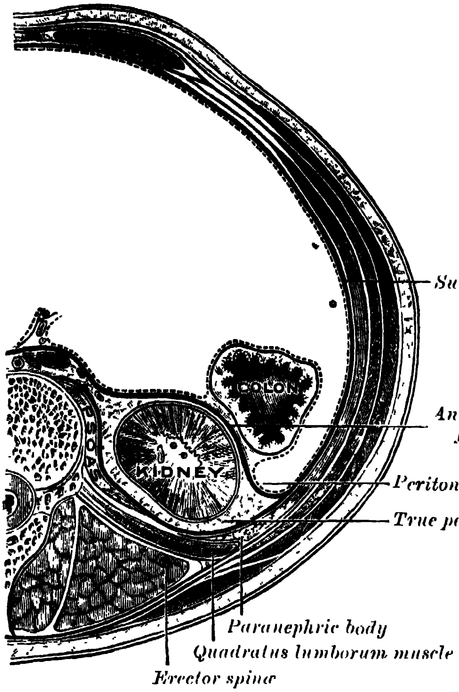


FIG. 980.—Vertical section of kidney.

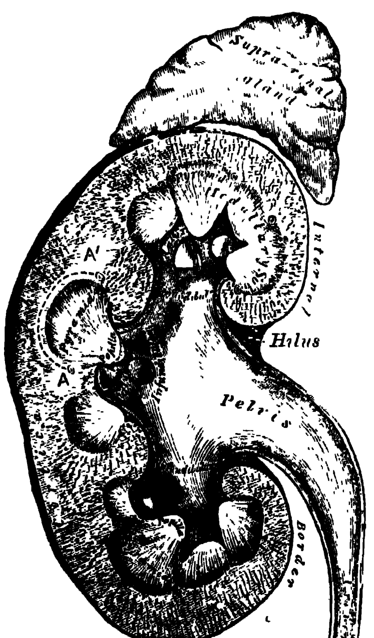


through the hilus, are also contained in the sinus, lying between its lining membrane and the excretory apparatus.

The kidney is composed of an internal *medullary* and an external *cortical* portion.

The *medullary portion* (substantia medullaris) consists of a series of red-coloured striated conical masses, termed the *medullary pyramids* or *pyramids of Malpighi* (pyramides renales), the bases of which are directed towards the circumference of the kidney, while their apices converge towards the renal sinus, where they form prominent papillæ (*papillæ renales*) projecting into the interior of the calyces; each calyx receives from one to three papillæ.

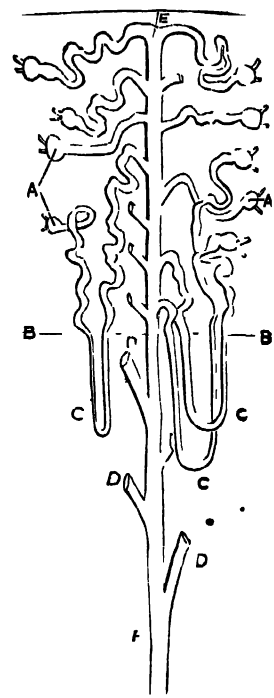
The *cortical portion* (substantia corticalis) is reddish-brown in colour and soft and granular in consistence. It lies immediately beneath the capsule, arches over the bases of the pyramids, and dips in between adjacent pyramids towards the renal sinus. The parts dipping in between the pyramids are named the *cortical columns* (columnæ renales [Bertini]), while the portions which connect the cortical columns to each other and intervene between the bases of the pyramids and the capsule are called the *cortical arches* (indicated between A and A′ in fig. 980). If the cortex be examined with a lens, it will be seen to consist of a series of lighter-coloured, conical areas, termed *medullary rays* (pars radiata) and a darker-coloured intervening substance, which from the complexity of its structure is named the *labyrinth* (pars convoluta). The medullary rays gradually taper towards the circumference

of the kidney, and consist of a series of outward prolongations from the base of each medullary pyramid.

The *cortical* and *medullary* parts, so dissimilar in appearance, are very similar in structure, being made up of urinary tubes and blood-vessels, united and bound together by a connecting stroma.

Minute Anatomy.—The *tubuli uriniferi* (tubuli renales), of which the kidney is for the most part made up, commence in the cortical portion of the kidney, and after pursuing a very circuitous course through the cortical and medullary parts, finally terminate at the apices of the medullary pyramids by open mouths (fig. 981), so that the fluid which they contain is emptied, through the calyces, into the pelvis of the kidney. If the surface of one of the papillæ be examined with a lens, it will be seen to be studded over with minute openings, the orifices of the tubuli uriniferi, from sixteen to twenty in number, and if pressure be made on a fresh kidney, urine will be seen to exude from these orifices. The tubuli uriniferi commence in the labyrinth and cortical columns of the kidney as the *Malpighian bodies*, which are small rounded masses of a deep red colour, varying in size, but of an average of about $\frac{1}{120}$ of an inch in diameter. Each of these little bodies is composed of two parts: a central glomerulus of vessels, called a *Malpighian tuft*; and a membranous envelope, the *Malpighian capsule*, or *capsule of Bowman*, which is the small pouch-like commencement of a uriniferous tubule.

Fig. 981.—Plan of uriniferous tubes.

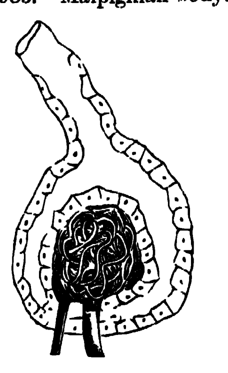


A A. Malpighian bodies. B B. Margin of medullary structure. C C C. Loops of Henle. D D D. Straight tubes cut off. E. Commencing straight tubes. F. Termination of straight tube.

The *Malpighian tuft*, or vascular glomerulus, is a network of convoluted capillary blood-vessels, held together by scanty connective tissue. This capillary network is derived from a small arterial twig, the *afferent vessel*, which pierces the wall of the capsule, generally at a point opposite to that at which the latter is connected with the tube; and the resulting vein, the *efferent vessel*, emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (fig. 982). The *Malpighian*, or *Bowman's capsule*, which surrounds the glomerulus, is formed of a hyaline membrane, supported by a small amount of connective tissue, which is continuous with the connective tissue of the tube. It is lined on its inner surface by a layer of squamous epithelial cells,

Fig. 982.—Minute structure of kidney.

Fig. 983.—Malpighian body.

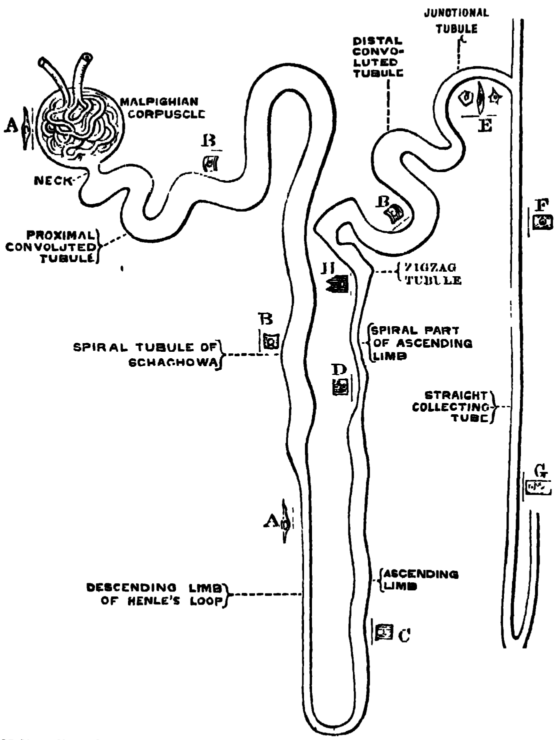


which are reflected from the lining membrane on to the glomerulus, at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells, on a delicate supporting membrane (fig. 983). Thus between the glomerulus and the capsule a space is left, forming a cavity lined by a

continuous layer of squamous cells; this cavity varies in size according to the state of secretion and the amount of fluid present in it. In the fœtus and young subject the cells are polyhedral or even columnar.

The *tubuli uriniferi*, commencing in the Malpighian bodies, present, during their course, many changes in shape and direction, and are contained partly in the medullary and partly in the cortical portions of the organ. At their junction with the Malpighian capsule they exhibit a somewhat constricted portion, which is termed the *neck*. Beyond this the tube becomes convoluted, and pursues a considerable course in the cortical structure constituting the *proximal convoluted tube*. After a time the convolutions disappear, and the tube approaches the medullary portion of the kidney in a more or less spiral manner; this section of the tube has been called the *spiral tube*. Throughout this portion of their course the tubuli uriniferi are contained entirely in the cortical structure, and present a fairly uniform calibre. They now enter the medullary portion, suddenly become much smaller, quite straight in direction, and dip down for a variable depth into the pyramids, constituting the *descending limb of Henle's loop*. Bending on themselves, they form what is termed the *loop of Henle*, and re-ascending, they become suddenly enlarged and again spiral in direction, forming the *ascending limb of Henle's loop*, and re-enter the cortical structure. This portion of the tube does not present a uniform calibre, but becomes narrower as it ascends, and is irregular in outline. As a narrow tube it enters the cortex and ascends for a short distance, when it again becomes dilated, irregular, and angular. This section is termed the *zig-zag tubule*; it terminates in a convoluted tube, which exactly resembles the proximal convoluted tubule, and is called the *distal convoluted tubule*. This again terminates in a narrow *junctional tube*, which enters the straight or collecting tube.

Fig. 984.—Uriniferous tube.



N.B.—For the sake of clearness the epithelial cells have been represented more highly magnified than the tubes in which they are contained.

The *straight* or *collecting tubes* commence in the medullary rays of the cortex, where they receive the curved extremities of the distal convoluted tubules. They unite at short intervals with one another, the resulting tubes presenting a considerable increase in calibre, so that a series of comparatively large tubes passes from the bases of the medullary rays into the medullary pyramids. In the medulla the tubes of each pyramid converge to join a central tube which finally opens on the summit of one of the papillæ; the contents of the tube are therefore discharged into one of the calyces.

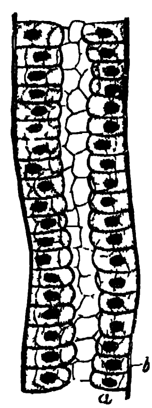
It will be seen from the above description that the tubes are continuous from their commencement in the Malpighian bodies to their termination at the orifices on the apices of the pyramids of Malpighi; and that the urine, the secretion of which commences in the capsule, will find its way through these tubes into the calyces of the kidney, and so into the ureter. Commencing at the capsule, the tube first presents a narrow constricted portion, (1) the neck. (2) It forms a wide convoluted tube, the *proximal convoluted tube*. (3) It becomes spiral, the *spiral tubule*. (4) It enters the medullary structure as a narrow, straight tube, the *descending limb of Henle's loop*. (5) It forms *Henle's loop*, and, becoming dilated, it ascends somewhat spirally, and, gradually diminishing in calibre, again enters the cortical structure, the *ascending limb of Henle's loop*. (6) It now becomes irregular and angular in outline, the *zig-zag tubule*. (7) It then becomes convoluted, the *distal convoluted tubule*. (8) Diminishing in size, it forms a curve, the *junctional tubule*. (9) Finally it joins a straight tube, the *straight collecting tube*, which is continued downwards through the medullary substance to open at the apex of a pyramid.

Structure of the tubuli uriniferi.—The tubuli uriniferi consist of basement-membrane lined with epithelium. The epithelium varies considerably in different sections of the uriniferous tubes. In the neck the epithelium is continuous with that lining the Malpighian capsule, and like it consists of flattened cells each containing an oval nucleus (fig. 984, A). In the proximal convoluted tubule and the spiral tubule the epithelium is polyhedral in shape, the sides of the cells not being straight, but interlocking with each other, and in some animals so fused together that it is impossible to make out the lines of junction. In the human kidney the cells often present an angular projection of the surface next the basement-membrane. These cells are made up of more or less rod-like fibres, which rest by one extremity on the basement-membrane, while the other projects towards the lumen of the tube. This gives to the cells the appearance of distinct striation (Heidenhain) (fig. 984, B). In the descending limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat, clear epithelial plates, each with an oval nucleus (figs. 984, A; 985). In the ascending limb, on the other hand, the cells partake more of the character of those described as existing in the proximal convoluted tubule, being polyhedral in shape, and presenting the same appearance of striation. The nucleus, however, is not situated in the centre of the cell, but near the lumen (fig. 984, C). After the ascending limb of Henle's loop becomes narrower upon entering the cortical structure, the striation appears to be confined to the outer part of the cell; at all events it is much more distinct in this situation; the nucleus, which appears flattened and angular, being still situated near the lumen (fig. 984, D). In the

FIG. 985.*—Longitudinal section of Henle's descending limb.

a. Membrana propria
b Epithelium

FIG. 986.—Longitudinal section of straight tube.



a Cylindrical or cubical epithelium
b Membrana propria

irregular tubule, the cells undergo a still further change, becoming very angular, and presenting thick bright rods or markings, which render the striation much more distinct than in any other section of the urinary tubules (fig. 984, H). In the distal convoluted tubule the epithelium appears to be somewhat similar to that which has been described as existing in the proximal convoluted tubule, but presents a peculiar refractive appearance (fig. 984, B). In the junctional tubule, just before its entrance into the straight collecting tube, the epithelium varies greatly as regards the shape of the cells, some being angular with short processes, others spindle-shaped, others polyhedral (fig. 984, E).

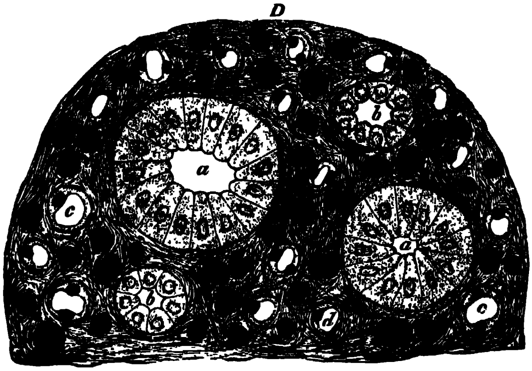
In the straight tube the epithelium is more or less columnar: in its papillary portion the cells are distinctly columnar and transparent (fig. 986); but as the tube approaches the cortex the cells are less uniform in shape: some are polyhedral, and others angular with short processes (fig. 984, F and G).

The **renal blood-vessels**.—The kidney is plentifully supplied with blood by the renal artery, a large offset of the abdominal aorta. Before it enters the kidney, each artery divides into four or five branches; at the hilus these branches lie between the renal vein and ureter, the vein being in front, the ureter behind: one branch usually lies behind the ureter. Each vessel gives off some small branches to the suprarenal glands to the ureter, and to the surrounding cellular tissue and muscles. Frequently a second renal artery, termed the *inferior renal*, is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney, whilst occasionally an additional artery enters the upper part of the kidney. The branches of the renal artery, while in the sinus, give off a few twigs for the nutrition of the surrounding tissues, and terminate in the *arteriæ propriæ renales*, which enter the kidney proper in the columns of Bertin. Two of these

* From the *Handbook for the Physiological Laboratory*.

pass to each medullary pyramid, and run along its sides for its entire length, giving off, as they advance, the afferent vessels of the Malpighian bodies in the columns. Having arrived at the bases of the pyramids, they form arterial arches or arcades which lie between the bases of the pyramids and the cortical arches, and break up into two distinct sets of branches devoted to the supply of the remaining portions of the kidney.

FIG. 987.—Transverse section of pyramidal substance of kidney of pig, the blood-vessels of which are injected.



a. Large collecting tube, cut across, lined with cylindrical epithelium. *b.* Branch of collecting tube, cut across, lined with epithelium with shorter cylinders. *c, d.* Henle's loops cut across. *e.* Blood-vessels cut across. D. Connective-tissue ground-substance.

The *first set*, the ***interlobular arteries*** (figs. 988, 989, B), are given off at right angles from the side of the arterial arcade looking towards the cortical substance, and pass directly outwards between the medullary rays to reach the fibrous capsule, where they terminate in the capillary network of this part. These vessels do not anastomose with each other, but form what are called *end-arteries*. In their outward course they give off lateral branches;

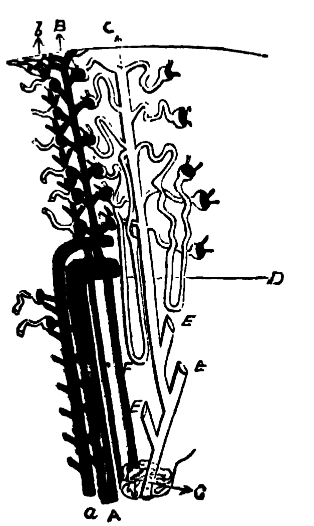

FIG. 989.—A portion of fig. 988 enlarged. (The references are the same.)

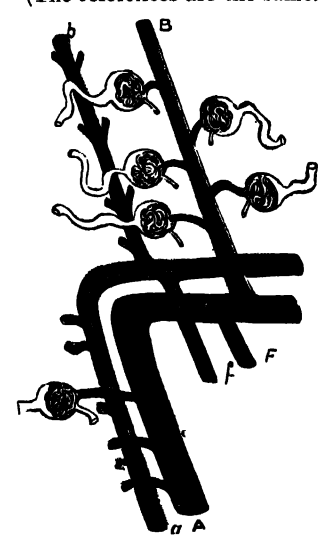

A *a.* Proper renal artery and vein, the former giving off the renal afferents, the latter receiving the renal efferents. B *b.* Interlobular artery and vein, the latter commencing from the stellate veins, and receiving branches from the plexus around the tubuli contorti, the former giving off renal afferents. C. Straight tube, surrounded by tubuli contorti, with which it communicates, as more fully shown in fig. 981. D. Margin of medullary substance. E E E. Receiving tubes, cut off. F *f.* Arteriolæ et venæ rectæ, the latter arising from (G) the plexus at the medullary apex.

these are the *afferent vessels* for the Malpighian bodies (see page 1185); they pierce the capsule, and end in the Malpighian tufts. From each tuft the corresponding *efferent vessel* arises, and, having made its egress from the capsule near to the point where the afferent vessel enters, breaks up into a number of branches, which form a dense *plexus* around the adjacent urinary tubes (fig. 990).

The *second set of branches* from the arterial arcades supply the medullary pyramids, which they enter at their bases; and, passing straight through their substance to their apices, terminate in the venous plexuses found in that situation. They are called the *arteriæ rectæ* (figs. 988, 989, F).

The *renal veins* arise from three sources, viz. the veins beneath the capsule, the plexuses around the convoluted tubules in the cortical arches, and the plexuses situated at the apices of the pyramids of Malpighi. The veins beneath the capsule (*venæ stellatæ*) are stellate in arrangement, and are derived from the capillary network, into which the terminal branches of the interlobular arteries break up. These join to form the *venæ interlobulares*, which pass inwards between the medullary rays, receive branches from the plexuses around the convoluted tubules, and, having arrived at the bases of the Malpighian pyramids, join with the venæ rectæ, next to be described (figs. 988, 989, *b*).

The *venæ rectæ* are branches from the plexuses at the apices of the medullary pyramids, formed by the terminations of the arteriæ rectæ. They run outwards in a straight course between the tubes of the medullary structure, and joining, as above stated, the venæ interlobulares, form venous arcades; these in turn unite and form veins which pass along the sides of the pyramids (figs. 988, 989, F).

These vessels, *venæ propriæ renales*, accompany the arteries of the same name, running along the entire length of the sides of the pyramids; and, having received in their course the efferent vessels from the Malpighian bodies in the adjacent cortical structure, quit the kidney substance to enter the sinus. In this cavity they join the corresponding veins from the other pyramids to form the *renal vein*, which emerges from the kidney at the hilus and opens into the inferior vena cava; the left vein is longer than the right, and crosses in front of the abdominal aorta.

Nerves of the kidney.—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the renal plexus, which is formed by branches from the solar plexus, the lower and outer part of the semilunar ganglion and aortic plexus, and from the lesser and smallest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testicle in affections of the kidney. So far as they have been traced, they seem to accompany the renal artery and its branches, but their exact mode of termination is not known.

The *lymphatics* of the kidney are described on pages 787, 788.

Connective tissue, or *intertubular stroma.*—Although the tubules and vessels are closely packed, a small amount of connective tissue, continuous with the capsule, binds them firmly together. This tissue was first described by Goodsir, and subsequently by Bowman. Ludwig and Zawarykin have observed distinct fibres passing around the Malpighian bodies; and Henle has seen them between the straight tubes composing the medullary structure.

Surface Marking.—The kidneys, being situated at the back part of the abdominal cavity and deeply placed, cannot be felt unless enlarged or misplaced. The greater part of each kidney lies in the epigastric region, i.e. internal to the mid-Poupart plane, but a small part is situated outside this plane, viz. in the hypochondriac region. The lower end of the left kidney is usually on a level with the subcostal plane: that of the right extends for about half an inch below this plane. The left is somewhat higher than the right. According to Morris, the position of the kidney may be thus defined: *Anteriorly.* '1. A horizontal line through the umbilicus is below the lower edge of each kidney. 2. A vertical line carried upwards to the costal arch from the middle of Poupart's ligament has one-third of the kidney to its outer side, and two-thirds to its inner side, i.e. between this line and the median line of the body.' In adopting these lines it must be borne in mind that the axes of the kidneys are not vertical, but oblique, and if continued upwards would meet about the ninth thoracic vertebra. *Posteriorly.* The upper end of the left kidney would be defined by a line drawn horizontally outwards from the spinous processes of the eleventh thoracic vertebra, and its lower end by a point two inches above the iliac crest. The right kidney would be half to three-quarters of an inch lower. Morris lays down the following rules for indicating the position of the kidney on the posterior surface of the body: 1. A line parallel with, and one inch from the vertebral column between the lower edge of the tip of the spinous process

of the eleventh thoracic vertebra, and the lower edge of the spinous process of the third lumbar vertebra. 2. A line from the top of this first line outwards at right angles to it for two and three-quarter inches. 3. A line from the lower end of the first transversely outwards for two and three-quarter inches. 4. A line parallel to the first and connecting the outer extremities of the second and third lines just described.

The hilus of the kidney lies about two inches from the middle line of the back at the level of the spinous process of the first lumbar vertebra.

Applied Anatomy.—Malformations of the kidney are not uncommon. There may be an entire absence of one kidney, but, according to Morris, the number of these cases is 'excessively small': or there may be congenital atrophy of one kidney, when the kidney is very small, but usually healthy in structure. These cases are of great importance, and must be duly taken into account when nephrectomy is contemplated. A more common malformation is where the two kidneys are fused together. They may be joined together only at their lower ends by means of a thick mass of renal tissue, so as to form a horse-shoe-shaped body, or they may be completely united, forming a disc-like kidney, from which two ureters descend into the bladder. These fused kidneys are generally situated in the middle line of the abdomen, but may be misplaced as well. In some mammals (e.g. ox and bear) the kidney consists of a number of distinct lobules; this lobulated condition is characteristic of the kidney of the human fœtus, and traces of it may persist in the adult. Sometimes the pelvis is duplicated, while a double ureter is not very uncommon. In some rare instances a third kidney may be present.

One or both kidneys may be misplaced as a congenital condition, and remain fixed in this abnormal position. They are then very often misshapen. They may be situated higher, though this is very uncommon, or lower than normal or removed farther from the vertebral column than usual; or they may be displaced into the iliac fossa, over the sacro-iliac joint, on to the promontory of the sacrum, or into the pelvis between the rectum and bladder or by the side of the uterus. In these latter cases they may give rise to very serious trouble. The kidney may also be misplaced as a congenital condition, but may not be fixed, it is then known as a *floating kidney.* It is believed to be due to the fact that the kidney is completely enveloped by peritoneum which then passes backwards to the vertebral column as a double layer, forming a mesonephron which permits of movement taking place. The kidney may also be misplaced as an acquired condition; in these cases the kidney is mobile in the tissues by which it is surrounded, moving with the capsule in the perinephric tissues. This condition is known as *movable kidney,* and is more common in the female than in the male. It occurs in badly nourished people, or in those who have become emaciated from any cause. It must not be confounded with the *floating kidney,* which is a congenital condition due to the development of a mesonephron. The two conditions cannot, however, be distinguished until the abdomen is opened or the kidney explored from the loin.

Injuries of the kidney are generally due to some severe crushing force, as from being run over by a heavy waggon or cart, or from the abdomen being compressed between the buffers of two railway carriages. When a laceration occurs on the posterior surface of the organ, infiltration of blood and urine takes place into the retro-peritoneal connective tissue; this is often followed by suppuration, and death may ensue from septic poisoning. When the laceration is in front, the peritoneum may be torn and extravasation of blood and urine take place into the peritoneal cavity. Death may occur from hæmorrhage or peritonitis. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and hydronephrosis follow. Sometimes the kidney may be bruised by blows in the loin, or by being compressed between the lower ribs and the ilium when the body is violently bent forwards. This is followed by a little transient hæmaturia, which, however, speedily passes off.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting *perinephric abscess.* This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighbouring parts. The abscess tends to point externally in the groin or loin.

Tumours of the kidney, of which perhaps sarcoma, in children, is the most common, may be recognised by their position; by the resonant colon lying in front of them; and by their rounded outline not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded.

The *hypernephroma,* a benign or malignant tumour arising from the suprarenal gland, or from suprarenal 'rests' or inclusions in the cortex or medulla of the kidney, is not infrequent. When occurring in children it is often associated with precocious growth of the body generally and of the hair and sexual organs in particular. Arising, as it often does, in the kidney, a hypernephroma may be indistinguishable from a true renal tumour so far as the physical signs and symptoms go; it is really, however, a tumour of the suprarenal gland substance.

The examination of the kidney should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forwards; while the other hand is buried in the abdominal wall, over the situation of the organ. Manipulation of the kidney frequently produces a peculiar sickening sensation, with sometimes faintness.

The kidney may require exposure for exploration or the evacuation of pus (nephrotomy); it may be incised for the removal of stone (nephro-lithotomy); it may be sutured when movable or floating (nephrorrhaphy); or it may be removed (nephrectomy). It may be exposed either by a lumbar or an abdominal incision; except in cases of very large tumours, a lumbar incision is best, as it has the advantages of not opening the peritoneum, and of affording admirable drainage. An oblique incision should be made, starting at the outer border of the Erector spinæ, half an inch below the last rib and directed downwards and forwards towards a point an inch in front of the anterior superior spine of the ilium. The structures divided are the skin, the superficial fascia with the cutaneous nerves, the deep fascia, the posterior border of the External oblique muscle of the abdomen, and the outer border of the Latissimus dorsi; the Internal oblique and the posterior aponeurosis of the Transversalis muscle; the outer border of the Quadratus lumborum; the deep layer of the lumbar aponeurosis, and the transversalis fascia. The fatty tissue around the kidney is now exposed to view, and must be separated by the fingers, or a director, in order to reach the kidney. The operations of *nephro-lithotomy*, for the removal of calculi from the kidney, and *nephrotomy*, or incision of the kidney for abscess, &c., are generally performed by the lumbar incision. This route is also generally chosen for *nephrectomy*. The abdominal operation is best performed by an incision through the outer part of the Rectus on the side of the kidney to be removed; the kidney is then reached from the outer side of the colon, ascending or descending, as the case may be, and the vessels of the colon are not interfered with. The incision commencing just below the costal arch is made of varying length, according to the size of the kidney. The abdominal cavity is opened. The intestines are drawn inwards and the peritoneum over the kidney to the outer side of the colon incised, so that the fingers can be introduced behind the peritoneum. The kidney must now be enucleated, and the vessels firmly ligatured and divided with the ureter, the latter being tied, or if thought necessary stitched to the edge of the wound. The particular advantage of the abdominal operation is that the condition of the other kidney can be ascertained by manual examination, before the removal of the diseased kidney is finally decided upon.

Nephrorrhaphy is the name given to the operation for fixing a movable kidney. The kidney is reached by the lumbar incision, and its posterior surface denuded of its fatty capsule. Three stitches of medium thickness are passed through the transversalis fascia and muscles and through the cortical portion of the kidney, securing a good hold of it. When these sutures are tied, the kidney is tightly anchored in position; cases which are seen sometimes afterwards seem however to show that it does not always remain fixed.

The Ureters

The **ureters** are the two tubes which convey the urine from the kidneys to the bladder. Each commences within the sinus of the corresponding kidney as a number of short cup-shaped tubes, termed *calyces* or *infundibula*, which encircle the *renal papillæ*. Since a single calyx may enclose more than one papilla the calyces are generally fewer in number than the pyramids—the former varying from seven to thirteen, the latter from eight to eighteen. The calyces join to form two or three short tubes, and these unite to form a funnel-shaped dilatation, wide above and narrow below, named the **pelvis of the kidney**, which is situated behind the renal vessels and lies partly inside and partly outside the renal sinus. It is usually placed on a level with the spinous process of the first lumbar vertebra.

The **ureter proper** measures from ten to twelve inches in length, and is a thick-walled narrow cylindrical tube which is directly continuous near the lower end of the kidney with the tapering extremity of the pelvis. It runs downwards and inwards in front of the Psoas muscle and, entering the pelvic cavity, finally opens into the base of the bladder.

The *abdominal part* (pars abdominalis) lies behind the peritoneum on the inner part of the Psoas muscle, and is crossed obliquely by the spermatic vessels. It enters the pelvic cavity by crossing either the termination of the common, or the commencement of the external, iliac vessels.

At its origin the *right* ureter is usually covered by the second part of the duodenum, and in its course downwards lies to the right of the inferior vena cava, and is crossed by the right colic artery, while near the pelvic brim it passes behind the lower part of the mesentery and the terminal part of the ileum. The *left* ureter is crossed by the left colic artery, and near the brim of the pelvis passes behind the pelvic colon and its mesentery.

The *pelvic part* (pars pelvina) runs at first downwards on the lateral wall of the pelvic cavity under cover of the peritoneum, lying in front of the internal

iliac vessels and on the inner side of the obliterated hypogastric artery and the obturator nerve and vessels. Opposite the lower part of the great sacro-sciatic foramen it inclines inwards behind the vas deferens (which crosses to its inner side) and reaches the base of the bladder, where it is situated in front of the upper end of the seminal vesicle and at a distance of about two inches from the opposite ureter. Finally, the ureters run obliquely for about three-quarters of an inch through the wall of the bladder and open by slit-like apertures into the cavity of the viscus at the lateral angles of the trigone. When the bladder is distended the openings of the ureters are about two inches apart, but when it is empty and contracted the distance between them is diminished by one-half. Owing to their oblique course through the coats of the bladder, their upper and lower walls become closely applied to each other when the viscus is distended, and, acting as valves, prevent regurgitation of urine from the bladder.

In the *female*, the ureter forms, as it lies in relation to the wall of the pelvis, the posterior boundary of a shallow depression named the *fossa ovarii*, in which the ovary is situated. It then runs inwards and forwards on the lateral aspect of the cervix uteri and upper part of the vagina to reach the base of the bladder. In this part of its course it is accompanied for about an inch by the uterine artery, which then crosses in front of the ureter and ascends between the two layers of the broad ligament. The ureter is distant about three-quarters of an inch from the lateral aspect of the neck of the uterus.

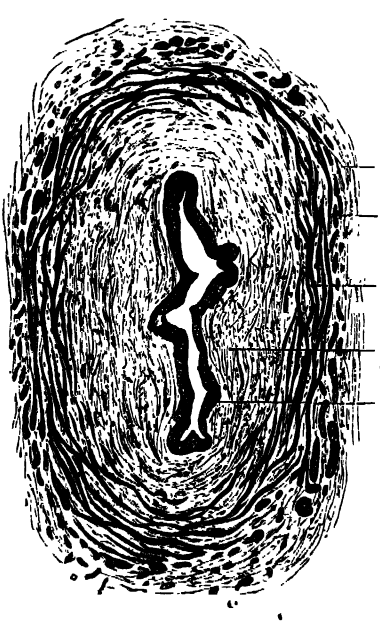
The ureter is sometimes duplicated, and the two tubes may remain distinct as far as the base of the bladder. On rare occasions they open separately into the bladder cavity.

Structure (fig. 991).—The ureter is composed of three coats: fibrous, muscular, and mucous.

The *fibrous coat* is continuous at one end with the capsule of the kidney on the floor of the sinus; while at the other it is lost in the fibrous structure of the bladder.

In the pelvis of the kidney the *muscular coat* consists of two layers, longitudinal and circular: the longitudinal fibres become lost upon the sides of the papillæ at the extremities of the calyces; the circular fibres may be traced surrounding the medullary structure in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers: an external longitudinal, a middle circular, and an internal, less distinct than the other two, but having a general longitudinal direction. According to Kölliker this internal layer is found only in the neighbourhood of the bladder.

FIG. 991.—Transverse section of ureter.



The *mucous coat* is smooth, and presents a few longitudinal folds which become effaced by distension. It is continuous with the mucous membrane of the bladder below, while it is prolonged over the papillæ of the kidney above. Its epithelium is of a transitional character, and resembles that found in the bladder (see fig. 996, page 1197). It consists of several layers of cells, of which the innermost — that is to say, the cells in contact with the urine—are quadrilateral in shape, with concavities on their deep surfaces into which the rounded ends of the cells of the second layer fit. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with rounded internal extremities which fit into the concavities of the cells of the first layer, and narrow external extremities which are wedged in between the cells of the third layer. The external or third layer

consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement-membrane. Beneath the epithelium, and separating it from the muscular coats, is a dense layer of fibrous tissue containing many elastic fibres.

The *arteries* supplying the ureter are branches from the renal, spermatic, internal iliac, and inferior vesical.

The *nerves* are derived from the inferior mesenteric, spermatic, and pelvic plexuses.

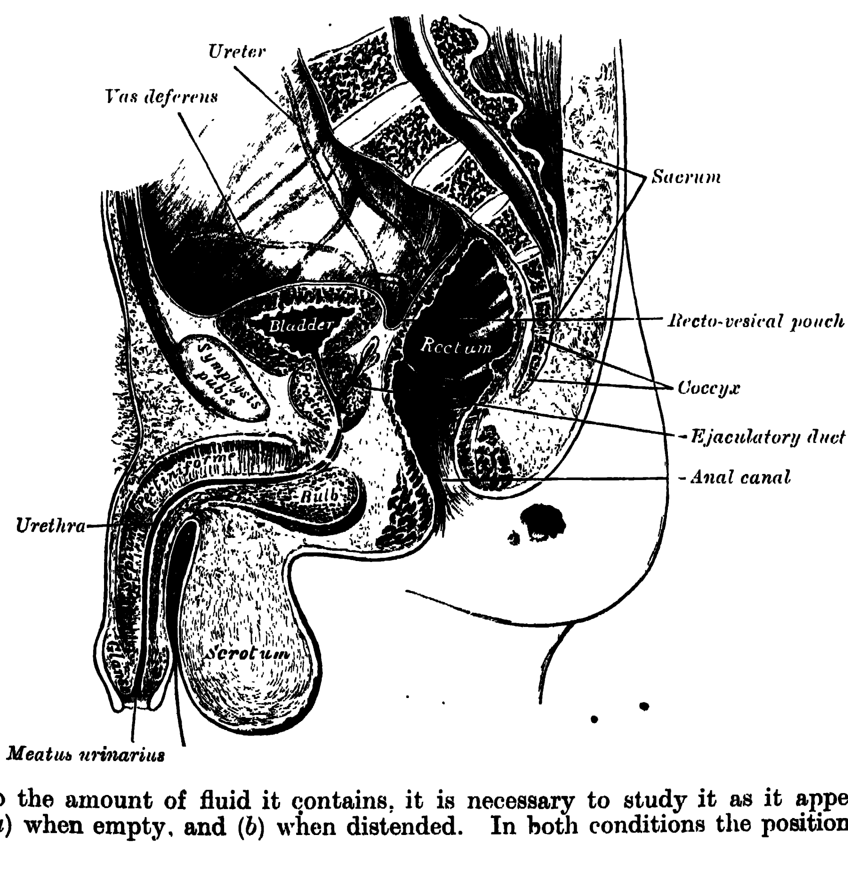
Applied Anatomy.—Rupture of the ureter is not a common accident, but occasionally occurs. If it be torn completely across, the urine collects in the retro-peritoneal tissues; if it be not completely divided, the lumen of the tube may become strictured and hydronephrosis or pyonephrosis result. The ureter may be accidentally wounded in some pelvic operations, such as removal of the uterus; if this should happen the divided ends must be sutured together, or failing to accomplish this an attempt may be made to implant the upper end into the bladder or rectum. If this cannot be carried out the only alternative is to remove the kidney immediately.

Stones not uncommonly become impacted in the ureter. These may occur at any part, but most commonly either at the point where the tube is crossing the pelvic brim or at the termination, where it is passing obliquely through the muscular wall of the bladder. In the former case, an incision with its centre opposite, and one inch internal to, the anterior superior spine of the ilium dividing all the structures down to the peritoneum, enables the operator to reach the ureter by pushing the unopened peritoneum inwards; the stone can then be felt in the ureter, the wall of which is incised, and the stone extracted, free drainage being provided for the escaping urine. When the stone is impacted at the vesical end of the tube a preliminary incision into the bladder is required, and by scratching through the mucous membrane overlying it the calculus can be removed.

The Bladder (fig. 992)

The **bladder** (vesica urinaria) is a musculo-membranous sac which acts as a reservoir for the urine; and as its size, position, and relations vary according

Fig. 992.—Median sagittal section of male pelvis.



to the amount of fluid it contains, it is necessary to study it as it appears (*a*) when empty, and (*b*) when distended. In both conditions the position of

the bladder varies with the condition of the rectum, being pushed upwards and forwards when the rectum is distended.

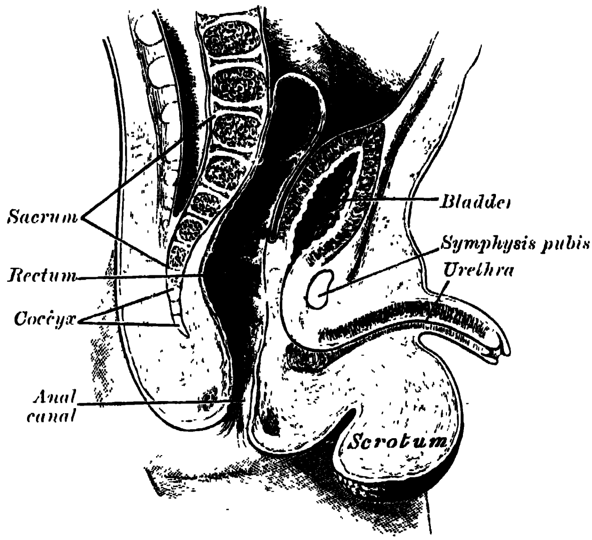
The empty bladder.—When hardened *in situ*, the empty bladder has the form of a flattened tetrahedron, with its apex tilted forwards. It presents a base, an apex, a superior and an inferior surface. The *base* is triangular in shape, and is directed downwards and backwards towards the rectum, from which it is separated by the recto-vesical fascia, the vesiculæ seminales, and the terminal portions of the vasa deferentia. The *apex* is directed forwards towards the upper part of the symphysis pubis, and from it a fibrous cord is continued upwards on the back of the anterior abdominal wall to the umbilicus. This cord is named the *urachus*, and represents the fibrous remains of the intra-abdominal part of the fœtal allantois (see page 175). The peritoneum is carried by it from the apex of the bladder on to the abdominal wall to form what is termed the anterior or superior false ligament of the bladder. The *superior surface* is triangular, bounded on either side by a lateral border which separates it from the inferior surface, and behind by a posterior border, represented by a line joining the two ureters, which intervenes between it and the base. The lateral borders extend from the ureters to the bladder apex, and from them the peritoneum is carried to the walls of the pelvis as the lateral false ligaments of the bladder. On either side of the bladder the peritoneum shows a depression, which is named the *paravesical fossa*. The superior surface is directed upwards, is covered by peritoneum, and is in relation with the pelvic colon and some of the coils of the small intestine. When the bladder is empty and firmly contracted, this surface is convex and the lateral and posterior borders are rounded; whereas if the bladder be relaxed it is concave, and the interior of the viscus, as seen in a vertical mesial section, presents the appearance of a V-shaped slit with a shorter posterior and a longer anterior limb—the apex of the V corresponding with the orifice of the urethra. The *inferior* surface is directed downwards and is uncovered by peritoneum. It may be divided into a posterior or prostatic area and two infero-lateral surfaces. The prostatic area is somewhat triangular: it rests upon and is in direct continuity with the base of the prostate gland; this area is usually named the *neck*, or *cervix*, of the bladder, and from it the urethra emerges. There is, however, no tapering part which would constitute a true neck, as the bladder suddenly contracts to the opening of the urethra. The infero-lateral portions of the inferior surface are directed downwards and outwards: in front, they are separated from the symphysis pubis by a mass of fatty tissue which is named the *retro-pubic pad*; behind, they are in contact with the fascia which covers the Levatores ani and Obturator internus muscles.

When the bladder is empty it is placed entirely within the pelvis, below the level of the obliterated hypogastric arteries, and below the level of those portions of the vasa deferentia which are in contact with the lateral wall of the pelvis; after they cross the ureters the vasa deferentia come into contact with the base of the bladder. As the viscus becomes filled, its base, being more or less fixed, is only slightly depressed; while its superior surface gradually rises into the abdominal cavity, carrying with it its peritoneal covering, and at the same time rounding off the posterior and lateral borders.

The distended bladder.—When the bladder is moderately full it contains about a pint and assumes an oval form; the long diameter of the oval measures about five inches and is directed upwards and forwards. In this condition it presents a postero-superior, an antero-inferior, and two lateral surfaces, a base and a summit. The postero-superior surface is directed upwards and backwards, and is covered by peritoneum: behind, it is separated from the rectum by the recto-vesical pouch of peritoneum, while its anterior part is in contact with the coils of the small intestine. The antero-inferior surface is devoid of peritoneum, and rests, below, against the pubic bones, above which it is in contact with the back of the anterior abdominal wall. The lower parts of the lateral surfaces are destitute of peritoneum, and are in contact with the lateral walls of the pelvis. The line of peritoneal reflection from the lateral surface is raised to the level of the obliterated hypogastric artery. The base or fundus undergoes little alteration in position, being only slightly lowered. It exhibits, however, a narrow triangular area, which is separated from the rectum merely by the recto-vesical fascia. This area is bounded

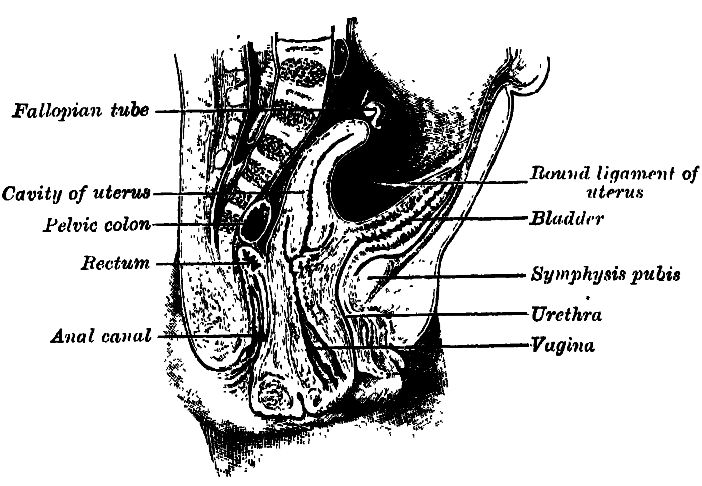
below by the prostate, above by the recto-vesical fold of peritoneum, and laterally by the vasa deferentia. The vasa deferentia frequently come in contact with each other above the prostate, and under such circumstances the lower part of the triangular area is obliterated. The line of reflection of the peritoneum from the rectum to the bladder appears to undergo little or no

Fig. 993.—Sagittal section through the pelvis of a newly born male child.



change when the latter is distended; it is situated about four inches from the anus. The summit is directed upwards and forwards above the point of attachment of the urachus, and hence the peritoneum, which follows the urachus, forms a pouch of varying depth between the summit of the bladder and the anterior abdominal wall.

Fig. 994.—Sagittal section through the pelvis of a newly born female child.

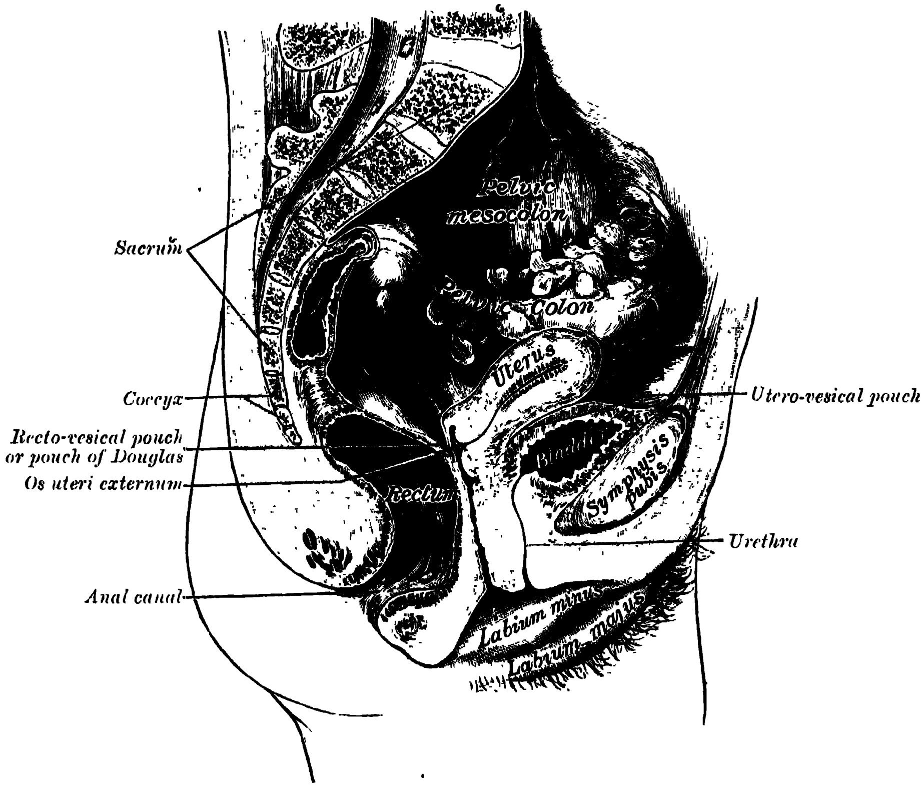


The bladder in the child (figs. 993, 994).—In the new-born child the urethral orifice of the bladder is at the level of the upper border of the symphysis pubis; the bladder therefore lies relatively at a much higher level in the infant than in the adult. Its anterior surface is 'in contact with about the lower two-thirds of that part of the abdominal wall which lies between

the symphysis pubis and the umbilicus' (Symington).* Its posterior surface is clothed with peritoneum as far as the level of the orifice of the urethra. Although the bladder of the infant is usually described as an abdominal organ, Symington has pointed out that only about one-half of it lies above the plane of the pelvic inlet. Disse maintains that the urethral orifice sinks rapidly during the first three years, and then more slowly until the ninth year, after which it remains stationary until puberty, when it again slowly descends and reaches its adult position.

The female bladder (fig. 995).—In the female, the bladder is in relation behind with the uterus and the upper part of the vagina. It is separated from the anterior surface of the body of the uterus by the utero-vesical pouch of peritoneum, but below the level of this pouch it is connected to the front of the cervix uteri and the upper part of the anterior wall of the vagina by areolar tissue. When the bladder is empty the uterus rests upon its superior surface.

Fig. 995.—Median sagittal section of female pelvis.



The female bladder is said by some to be more capacious than that of the male, but probably the opposite is the case.

Ligaments.—The bladder is retained in its place by ligaments, which are divided into true and false. The true ligaments are five in number: two anterior, two lateral, and the urachus. The false ligaments, also five in number, are formed by folds of the peritoneum.

The *anterior true ligaments* (pubo-prostatic) extend from the back of the pubic bones, one on either side of the symphysis, to the front of the neck of the bladder, over the anterior surface of the prostate gland. These ligaments are formed by the fascia endopelvina, and contain a few muscular fibres prolonged from the bladder.

The *lateral true ligaments*, also formed by the fascia endopelvina, are broader and thinner than the preceding. They are attached to the lateral parts of the prostate, and to the sides of the base of the bladder.

* *The Anatomy of the child.*

The *urachus* is the fibro-muscular cord already mentioned, extending between the summit of the bladder and the umbilicus. It is broad below, at its attachment to the bladder, and becomes narrower as it ascends.

The *false ligaments of the bladder* are two posterior, two lateral, and one anterior or superior.

The *two posterior* ligaments form the sacro-genital folds, already described (page 1124); they pass forwards from the sides of the rectum to the posterior and lateral aspects of the vesiculæ seminales, and form the lateral boundaries of the recto-vesical pouch of the peritoneum.

The *two lateral ligaments* are reflections of the peritoneum, from the lateral walls of the pelvis to the sides of the bladder.

The *anterior* or *superior ligament* (ligamentum suspensorium) is the fold of peritoneum extending from the summit of the bladder to the abdominal wall. It is carried off from the bladder by the urachus.

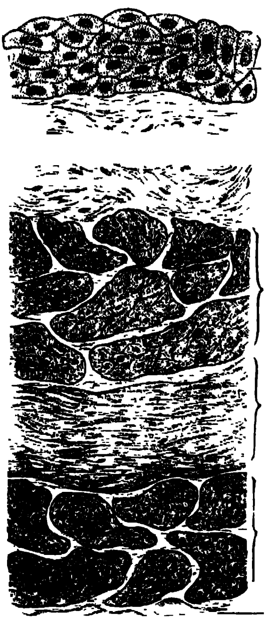
Structure (fig. 996).—The bladder is composed of four coats: serous, muscular, submucous, and mucous.

The *serous coat* is a partial one, and is derived from the peritoneum. It invests the superior surface and the upper parts of the lateral surfaces, and is reflected from these on to the abdominal and pelvic walls.

The *muscular coat* consists of three layers of unstriped muscular fibres: an external layer, composed of fibres having for the most part a longitudinal arrangement; a middle layer, in which the fibres are arranged, more or less, in a circular manner; and an internal layer, in which the fibres have a general longitudinal arrangement.

The *fibres of the external longitudinal layer* arise from the posterior surface of the body of the pubis in both sexes (*musculi pubo-vesicales*), and in the male from the adjacent part of the prostate gland and its capsule. They pass, in a more or less longitudinal manner, up the anterior surface of the bladder, over its apex, and then descend along its posterior surface to its base, where they become attached to the prostate in the male, and to the front of the vagina in the female. At the sides of the bladder the fibres are arranged obliquely and intersect one another. This layer has been named the *Detrusor urinæ muscle*.

Fig. 996.—Vertical section of bladder.



The *fibres of the middle circular layer* are very thinly and irregularly scattered on the body of the organ, and, although to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Towards the lower part of the bladder, round the neck and commencement of the urethra, they are disposed in a thick circular layer, forming the *Sphincter vesicæ*, which is continuous with the muscular fibres of the prostate gland.

The *internal longitudinal layer* is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction.

Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate gland, and are inserted by means of a fibrous process, into the middle lobe of that organ. They are the *muscles of the ureters*, described by Sir C. Bell, who supposed that during the contraction of the bladder they serve to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The *submucous coat* consists of a layer of areolar tissue, connecting together the muscular and mucous coats, and intimately united to the latter.

The *mucous coat* is thin, smooth, and of a pale rose colour. It is continuous above through the ureters with the lining membrane of the uriniferous tubes, and below with that of the urethra. It is connected loosely to the muscular coat by a layer of areolar tissue, and is therefore thrown into folds or *rugæ* when the bladder is empty. Over the trigonum vesicæ the mucous membrane is closely attached to the muscular coat, and is not thrown into folds, but is smooth and flat. The epithelium covering it is of the transitional variety, consisting of a superficial layer of polyhedral flattened cells, each with one, two,

or three nuclei; beneath these is a stratum of large club-shaped cells, with their narrow extremities directed downwards and wedged in between smaller spindle-shaped cells,

Fig. 997.—Superficial layer of the epithelium of the bladder. Composed of polyhedral cells of various sizes, each with one, two, or three nuclei. (Klein and Noble Smith.)

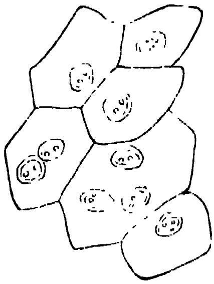


Fig. 998.—Deep layers of the epithelium of the bladder, showing large club-shaped cells above, and smaller, more spindle-shaped cells below, each with an oval nucleus. (Klein and Noble Smith.)

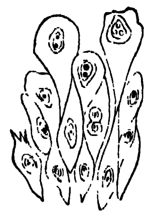


containing oval nuclei (figs. 997, 998). There are no true glands in the mucous membrane of the bladder, though certain mucous follicles which exist, especially near the neck of the bladder, have been regarded as such.

Interior of the bladder.—The mucous membrane lining the bladder is, over the greater part of the viscus, loosely attached to the muscular coat, and appears wrinkled or folded when the bladder is contracted: in the distended condition of the bladder the folds are effaced. Over a small triangular area, termed the *trigonum vesicæ*, immediately above and behind the orifice of the urethra, the mucous membrane is firmly bound to the muscular coat, and is always smooth. The anterior angle of the trigonum vesicæ is formed by the opening of the urethra: its postero-lateral angles by the orifices of the ureters. Stretching behind the latter openings is a slightly curved ridge, the *torus uretericus*, forming the base of the trigone and produced by an underlying bundle of non-striped muscular fibres. The lateral parts of this ridge extend beyond the openings of the ureters, and are named the *plicæ uretericæ*; they are produced by the terminal portions of the ureters as they traverse obliquely the bladder-wall. When the bladder is illuminated the torus uretericus appears as a pale band and forms an important guide during the operation of introducing a catheter into the ureter.

The *orifices of the ureters* are placed at the postero-lateral angles of the trigonum vesicæ, and are usually slit-like in form. In the contracted bladder they are about an inch apart and about the same distance from the orifice of the urethra; in the distended viscus these measurements may be increased to about two inches.

The *urethral orifice* is placed at the apex of the trigonum vesicæ, and is usually somewhat crescentic in form; the mucous membrane immediately behind it presents a slight elevation, named the *uvula vesicæ*.

Vessels and Nerves.—The *arteries* supplying the bladder are the superior, middle, and inferior vesical, derived from the anterior trunk of the internal iliac. The obturator and sciatic arteries also supply small visceral branches to the bladder, and in the female additional branches are derived from the uterine and vaginal arteries.

The *veins* form a complicated plexus round the neck, sides, and base of the bladder, and terminate in the internal iliac veins.

The *lymphatics* are described on page 788.

The *nerves* are derived from the pelvic plexuses of the sympathetic and from the third and fourth sacral nerves; the former supplying the upper part of the organ, the latter its base and neck. According to F. Darwin, the sympathetic fibres have ganglia connected with them, which send branches to the vessels and muscular coat.

Surface Form.—The surface form of the bladder varies with its degree of distension and under other circumstances. In the young child it is represented by a conical figure, the apex of which, even when the viscus is empty, is situated in the hypogastric region, above the level of the symphysis pubis. In the adult, when the bladder is empty, its apex does not reach above the level of the upper border of the symphysis pubis, and the

whole organ is situated in the pelvis; the neck, in the male, corresponding to a line drawn horizontally backwards through the symphysis, a little below its middle. As the bladder becomes distended it gradually rises out of the pelvis into the abdomen, and forms a swelling in the hypogastric region, which is perceptible to the hand, as well as to percussion. In extreme distension it reaches into the umbilical region. Under these circumstances the lower part of its anterior surface, for a distance of about two inches above the symphysis pubis, is closely applied to the abdominal wall, without the intervention of peritoneum, so that it can be tapped by an opening in the middle line just above the symphysis pubis, without any fear of wounding the serous membrane. When the rectum is distended, the prostatic portion of the urethra is elongated and the bladder lifted out of the pelvis and the peritoneum pushed upwards.

When distended the bladder can be felt in the male, from the rectum, behind the prostate, and fluctuation can be perceived by a bimanual examination, one finger being introduced into the rectum and the distended bladder tapped on the front of the abdomen with the finger of the other hand. This portion of the bladder—that is, the portion felt in the rectum by the finger—is also uncovered by peritoneum, and the bladder may here be punctured from the rectum, in the middle line, without risk of wounding the serous membrane.

Applied Anatomy.—A defect of development, in which the bladder is implicated, is known under the name of *extroversion of the bladder.* In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the posterior surface of the bladder presents on the abdominal surface, and is pushed forwards by the pressure of the viscera within the abdomen, forming a red vascular tumour on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra, a condition known as *epispadias.* The pelvic bones are also arrested in development (see page 331).

The bladder may be ruptured by violence applied to the abdominal wall, when the viscus is distended, without any injury to the bony pelvis, or it may be torn in cases of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal: that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lembert's suture is resorted to, with a very considerable amount of success. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition, and one is inserted just beyond each end of the wound. The bladder should be tested as to whether it is water-tight before closing the external incision.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the *fasciculated bladder.* Between these muscular bundles the mucous membrane may bulge out, forming sacculi, constituting the *sacculated bladder,* and in these little pouches phosphatic concretions may collect, forming *encysted calculi.* The mucous membrane is very loosely attached, except over the trigone, to allow of the distension of the viscus.

Various forms of tumour have been found springing from the wall of the bladder. The commonest innocent tumour is the villous papilloma. Of the malignant tumours, epithelioma is the most common, but sarcoma is occasionally found in the bladder of children.

In doubtful cases the cystoscope proves a valuable aid in diagnosis. This instrument consists of a tube in which is fixed a small electric light, the wires of which run through the shaft of the instrument. Upon introducing this down the urethra, the bladder can be examined with the eye, and a villous growth or other tumour, a calculus, or an ulcer can be detected; or the orifices of the ureters can be examined, and renal hæmaturia diagnosed, and it can be definitely settled from which kidney the blood comes. Again, the presence of minute tuberculous ulceration near the mouth of the ureter on the affected side may establish the diagnosis, not only of tuberculous kidney, but also of the side in which the disease is located. Caspar has utilised the cystoscope in catheterising the ureter, by causing a groove to be made on one side of the shaft of the instrument, along which a fine bougie can be passed. The mouth of the ureter is first found by the surgeon, and the bougie then projected into the field of vision and guided directly into the opening.

Puncture of the bladder may be performed either above the symphysis pubis or through the rectum, in both cases without wounding the peritoneum. The former plan is generally to be preferred, since in puncture by the rectum a permanent fistula may be left from abscess forming between the rectum and the bladder; or pelvic cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a canula in the rectum. In some cases, in performing this operation the recto-vesical pouch of peritoneum has been wounded, inducing fatal peritonitis. Puncture through the rectum, therefore, has been almost completely abandoned in favour of the suprapubic route.

Access to the bladder, for the purpose of removing calculi, or an enlarged prostate, is almost always effected by the suprapubic route, the old perineal operation being now rarely resorted to. In the female, owing to the shortness of the urethra, and its ready

dilatability, calculi and foreign bodies and new growths, when of small size, may be removed by the urethral route.

Suprapubic cystotomy is performed by first injecting ten or twelve ounces of some weak antiseptic fluid into the bladder. Then, with or without distending the rectum, a vertical median incision, from three to four inches in length, is made in the hypogastric region immediately above the symphysis, and extended between the Pyramidales and Recti muscles until the transversalis fascia is reached. This is divided and some fatty tissue exposed (space of Retzius). Upon separating this, the anterior surface of the bladder will be exposed and will be recognised by its muscular fibres. A needle should be passed through its coats on either side of the spot selected for the opening, and two long pieces of silk inserted. The bladder is incised between these stays, which are held by an assistant and form a useful guide to the opening in the bladder when the fluid has escaped.

It is important that the bladder should be emptied by catheter as a routine measure in women, prior to operations on the lower part of the abdomen or pelvis. Neglect of this precaution has, not uncommonly, led to that viscus being opened by accident. Women especially are apt to acquire an atonic distension of the bladder, and the fact that some quantity of urine has been passed immediately before operation is no guarantee that the viscus is not distended. If the accident should occur, the bladder wall must be carefully sutured before the peritoneum is opened.

The Male Urethra

The **male urethra** (urethra virilis) extends from the neck of the bladder to the meatus urinarius at the end of the penis. It presents a double curve in the ordinary relaxed state of the penis (fig. 992). Its length varies from seven to eight inches; and it is divided into three portions, the *prostatic*, *membranous*, and *spongy*, the structure and relations of which are essentially different. Except during the passage of the urine or semen, the urethra is a mere transverse cleft or slit, with its upper and under surfaces in contact. At the meatus urinarius the slit is vertical, and in the prostatic portion somewhat arched.

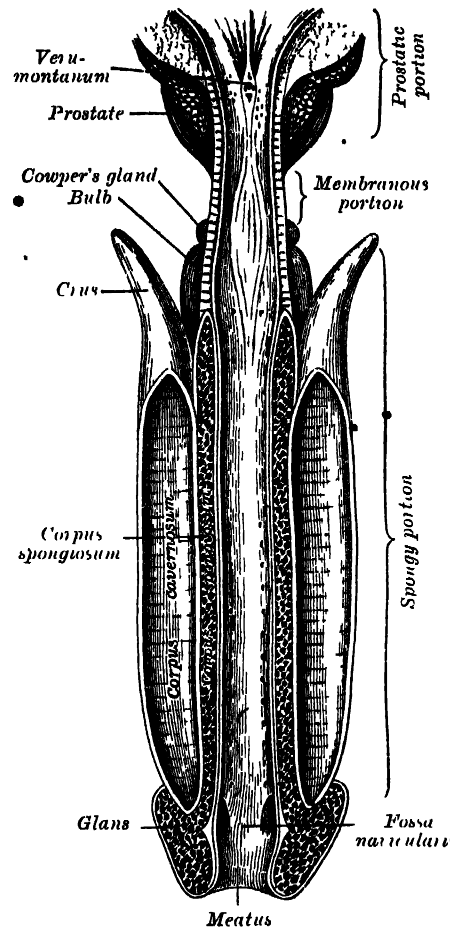
The **prostatic portion** (pars prostatica) (figs. 992, 999), the widest and most dilatable part of the canal, is about an inch and a quarter in length. It runs almost vertically through the prostate gland, from its base to its apex, lying nearer its anterior than its posterior surface; the form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest below, where it joins the membranous portion. A transverse section of the canal as it lies in the prostate is horseshoe-shaped, the convexity being directed forwards, since the direction of the canal is nearly vertical.

Upon the posterior wall or floor is a narrow longitudinal ridge, the *verumontanum*, or *caput gallinaginis* (crista urethralis), formed by an elevation of the mucous membrane and its subjacent tissue. It is from 15 to 17 mm. in length, and about 3 mm. in height, and contains, according to Kobelt, muscular and erectile tissues. When distended, it may serve to prevent the passage of the semen backwards into the bladder. On either side of the verumontanum is a slightly depressed fossa, the *prostatic sinus*, the floor of which is perforated by numerous apertures, the *orifices of the prostatic ducts* from the lateral lobes of the prostate gland; the ducts of the middle lobe open behind the verumontanum. At the fore-part of the verumontanum, in the middle line, is a depression, the *sinus pocularis* (utriculus prostaticus), upon or within the margins of which are the slit-like openings of the ejaculatory ducts. The sinus pocularis forms a *cul-de-sac* about a quarter of an inch in length, which runs upwards and backwards in the substance of the prostate behind the middle lobe; its prominent anterior wall partly forms the verumontanum. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane, and numerous small glands open on its inner surface. It has been called by Weber, who discovered it, the *uterus masculinus*, from its being developed from the united lower ends of the atrophied Müllerian ducts, and therefore homologous with the uterus and vagina in the female.

The **membranous portion** (pars membranacea) (figs. 992, 999) extends between the apex of the prostate and the bulb of the corpus spongiosum. It is the narrowest part of the canal (excepting the meatus), and measures three-quarters of an inch along its upper, but only half an inch along its lower surface, in consequence of the bulb projecting backwards beneath it. Its anterior concave surface is placed about an inch below and behind the pubic

arch, from which it is separated by the dorsal vessels and nerves of the penis, and some muscular fibres. Its posterior convex surface is separated from the rectum by a triangular space, which constitutes the perinæum. The membranous portion of the urethra lies between the inferior and superior layers of the triangular ligament. As it pierces the inferior layer, the fibres around the opening are prolonged over the tube. It is surrounded by the Compressor urethræ muscle.

Fig. 999.—The male urethra, laid open on its anterior (upper) surface. (Testut.)



The **spongy portion** (pars cavernosa) (figs. 992, 999) is the longest part of the urethra, and is contained in the corpus spongiosum. It is about six inches in length, and extends from the termination of the membranous portion to the meatus urinarius. Commencing just below the triangular ligament, it passes forwards for a short distance; and then, in the flaccid condition of the penis, it bends downwards and forwards. It is narrow, and of uniform size in the body of the penis, measuring about a quarter of an inch in diameter; it is dilated behind, within the bulb, and again anteriorly within the glans penis, where it forms the *fossa navicularis urethræ*.

The *bulbous portion* is a name sometimes given to the posterior part of the spongy portion contained within the bulb.

The *meatus urinarius* (orificium urethræ externum) is the most contracted part of the urethra; it is a vertical slit, about a quarter of an inch in length, bounded on each side by two small labia.

The inner surface of the lining membrane of the urethra, especially on the floor of the spongy portion, presents the orifices of numerous mucous glands and follicles situated in the submucous tissue, and named the *glands of Littré*. Besides these there are a number of small pit-like recesses, or *lacunæ*, of varying sizes. Their orifices are directed forwards, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunæ, larger than the rest, is situated on the upper surface of the fossa navicularis; it is called the *lacuna magna*. Into the bulbous portion are found opening the ducts of Cowper's glands.

Structure.—The urethra is composed of mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The *mucous coat* forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally, with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra, viz. Cowper's glands and the prostate gland; and into the vasa deferentia and vesiculæ seminales, through the ejaculatory ducts. In the spongy and membranous portions the mucous membrane is arranged in longitudinal folds when the

tube is empty. Small papillæ are found upon it, near the orifice; in the upper two-thirds its epithelial lining is of the transitional variety; it then becomes columnar in shape until near the meatus, where it is squamous and stratified.

The *submucous tissue* consists of a vascular erectile layer; outside this is a layer of unstriped muscular fibres, arranged in a circular direction, which separates the mucous membrane and submucous tissue from the tissue of the corpus spongiosum.

Applied Anatomy.—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perinæum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perinæum and the history of the accident, will point to the nature of the injury. Rupture of the urethra is due in other cases to the perforation of a periurethral abscess. Extravasation of urine most frequently takes place into the perinæum in front of the triangular ligament, i.e. under the fascia of Colles. Both these layers of fascia are attached firmly to the ischio-pubic rami. It is clear, therefore, that when extravasation of fluid takes place between them, it cannot pass backwards, because the two layers are continuous with each other around the Transversus perinæi muscles; it cannot extend laterally, on account of the connection of both these layers to the rami of the pubis and ischium; it cannot find its way into the pelvis, because the opening into this cavity is closed by the triangular ligament, and, therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forwards into the areolar tissue of the scrotum and penis, and thence on to the anterior wall of the abdomen.

Gonorrhœa is an acute inflammatory infection of the mucous membrane of the urethra which is very prevalent. The causative organisms (gonococci) pass through the mucous membrane into the submucous tissue, and most serious complications and results may follow. In most cases the disease remains limited to the part of the urethra in front of the 'shut-off muscle,' or Compressor urethræ, but in some (about 10 per cent.) the 'posterior urethra' becomes involved in the process, leading to an inflammation of the openings of the prostatic follicles. Such a condition is apt to continue as a very chronic form of prostatitis, and in many cases the infection will spread along the vas, giving rise to epididymitis.

The anatomy of the urethra is of considerable importance in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatability, so that, excepting through the external meatus, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The orifice of the urethra is not so dilatable, and therefore frequently requires slitting. A recognition of this dilatability caused Bigelow to very considerably modify the operation of lithotrity and introduce that of litholapaxy. In passing catheters, especially fine ones, the point of the instrument should be kept as far as possible along the upper wall of the canal, as it is otherwise very liable to enter one of the lacunæ.

Stricture of the urethra is a disease of very common occurrence, and is generally situated in the spongy part of the urethra, most commonly in the bulbous portion, just in front of the membranous urethra, but in a very considerable number of cases in the penile or ante-scrotal part of the canal. The stricture usually results from the contraction of inflammatory products in the submucous tissue, the result, in the vast majority of all cases, of a prolonged gleet following gonorrhœa. Urethral stricture, however, follows rupture of that tube resulting from falls on the perinæum, and in this variety is very dense, and is a most unsatisfactory condition with regard to treatment. Congenital stricture is also occasionally met with, and in such cases multiple strictures may be present throughout the whole length of the spongy portion.

Congenital defects of the urethra occur occasionally. The one most frequently met with is where there is a cleft on the floor of the urethra owing to an arrest of union in the middle line. This is known as *hypospadias*, and the cleft may vary in extent. The simplest and by far the most common form is where the deficiency is confined to the glans penis. The urethra ends at the point where the extremity of the prepuce joins the body of the penis, in a small valve-like opening. The prepuce is also cleft on its under surface and forms a sort of hood over the glans. There is a depression on the glans in the position of the normal meatus. This condition produces no disability and requires no treatment. In more severe cases the penile portion of the urethra is cleft throughout its entire length, and the opening of the urethra is at the point of junction of the penis and scrotum. The under surface of the penis in the middle line presents a furrow lined by a moist mucous membrane, on either side of which is often more or less dense fibrous tissue stretching from the glans to the opening of the urethra, which prevents complete erection taking place. Great discomfort is induced during micturition, and connection is impossible. The condition may be remedied by a series of plastic operations. The worst form of this condition is where the urethra is deficient as far back as the perinæum, and the scrotum is cleft. The penis is small and bound down between the two halves of the scrotum, so as to resemble an hypertrophied clitoris. The testes are often retained. The condition of parts, therefore, very much resembles the external organs of generation of the female, and many children the victims of this malformation have been brought up as girls. The halves of the scrotum, deficient of testes, resemble the labia, the cleft between them looks like the

orifice of the vagina, and the diminutive penis is taken for an enlarged clitoris. There is no remedy for this condition.

A much more uncommon form of malformation is where there is an apparent deficiency of the upper wall of the urethra; this is named *epispadias*. The deficiency may vary in extent; when it is complete the condition is associated with extroversion of the bladder (see page 1199). In less extensive cases, where there is no extroversion, there is an infundibuliform opening into the bladder. The penis is usually dwarfed and turned upwards, so that the glans lies over the opening.

THE FEMALE URETHRA (fig. 995)

The **female urethra** (urethra muliebris) is a narrow membranous canal, about an ~~inch and~~ a half in length, extending from the neck of the bladder to the meatus urinarius. It is placed behind the symphysis pubis, imbedded in the anterior wall of the vagina, and its direction is obliquely downwards and forwards; it is slightly curved with the concavity directed forwards and upwards. Its diameter when undilated is about a quarter of an inch. It perforates the triangular ligament, and its external orifice is situated directly in front of the vaginal opening and about an inch behind the glans clitoridis.

Structure.—The urethra consists of three coats: muscular, erectile, and mucous.

The *muscular coat* is continuous with that of the bladder; it extends the whole length of the tube, and consists of circular fibres. In addition to this, between the two layers of the triangular ligament, the female urethra is surrounded by the Compressor urethræ, as in the male.

A *thin layer of spongy erectile tissue*, containing a plexus of large veins, intermixed with bundles of unstriped muscular fibres, lies immediately beneath the mucous coat.

The *mucous coat* is pale; it is continuous externally with that of the vulva, and internally with that of the bladder, and is thrown into longitudinal folds, one of which, placed along the floor of the canal, resembles the verumontanum in the male urethra. It is lined by stratified epithelium, which becomes transitional near the bladder. Its external orifice is surrounded by a few mucous follicles.

MALE REPRODUCTIVE ORGANS

The male reproductive organs (organa genitalia virilia) include the *testes*, the *vasa deferentia*, the *vesiculæ seminales*, the *ejaculatory ducts*, and the *penis*, together with the following accessory structures, viz. the *prostate gland* and *Cowper's glands*.

THE TESTES AND THEIR COVERINGS (fig. 1000)

The **testes** are two glandular organs, which secrete the semen; they are situated in the scrotum, being suspended by the spermatic cords. At an early period of fœtal life the testes are contained in the abdominal cavity, behind the peritoneum. Before birth they descend to the inguinal canal, along which they pass with the spermatic cord, and, emerging at the external abdominal ring, they descend into the scrotum, becoming invested in their course by coverings derived from the serous, muscular, and fibrous layers of the abdominal parietes, as well as by the scrotum.

The **coverings of the testes** are, the

Skin } Scrotum.	Cremasteric fascia.
Dartos } Scrotum.	Infundibuliform fascia.
Intercolumnar fascia.	Tunica vaginalis.

The **scrotum** is a cutaneous pouch which contains the testes and parts of the spermatic cords. It is divided on its surface into two lateral portions by a ridge, or *raphe* (raphe scroti), which is continued forwards to the under surface of the penis, and backwards along the middle line of the perinæum to the anus. Of these two lateral portions the left is longer than the right, to correspond with the greater length of the left spermatic cord. Its external aspect varies under different circumstances: thus, under the influence of warmth, and in old and debilitated persons, it becomes elongated and flaccid; but, under

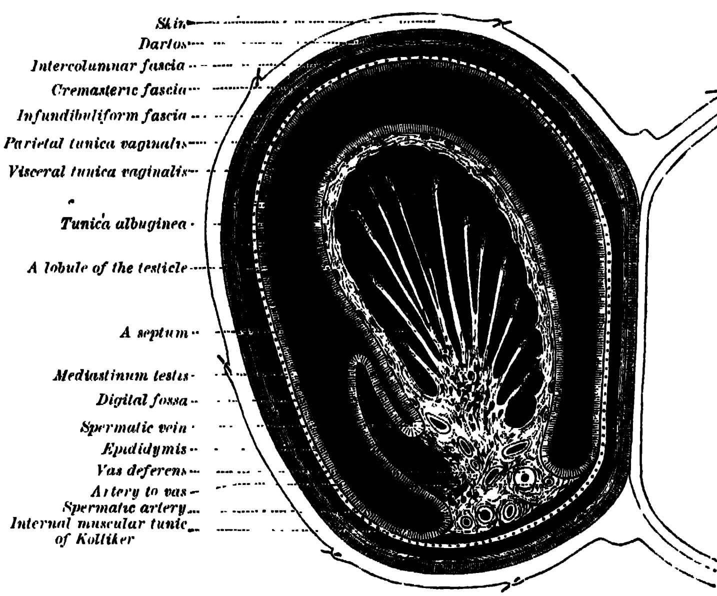
the influence of cold, and in the young and robust, it is short, corrugated, and closely applied to the testes.

The scrotum consists of two layers, the integument and the dartos.

The **integument** is very thin, of a brownish colour, and generally thrown into folds or rugæ. It is provided with sebaceous follicles, the secretion of which has a peculiar odour, and is beset with thinly scattered, crisp hairs, the roots of which are seen through the skin.

The **dartos** (tunica dartos) is a thin layer of non-striped muscular fibres, and is continuous, around the base of the scrotum, with the two layers of the superficial fascia of the groin and of the perinæum, and sends inwards a septum, *septum scroti*, which divides the scrotal pouch into two cavities for the testes, the septum extending between the raphe and the under surface of the penis, as far as its root.

Fig. 1000.—Transverse section through the left side of the scrotum and the left testicle. The sac of the tunica vaginalis is represented in a distended condition. (Diagrammatic.) (Delépine.)



The dartos is closely united to the skin externally, but connected with the subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility.

The **intercolumnar fascia** is a thin membrane, prolonged downwards around the surface of the cord and testis (see page 509). It is separated from the dartos by loose areolar tissue.

The **cremasteric fascia** consists of scattered bundles of muscular fibres (*Cremaster muscle*), connected together into a continuous covering by intermediate areolar tissue (see page 511).

The **infundibuliform fascia** is a thin layer, which loosely invests the cord; it is a continuation downwards of the fascia transversalis (see page 515).

The **tunica vaginalis** is described with the testis.

Vessels and Nerves.—The *arteries* supplying the coverings of the testes are: the superficial and deep external pudic branches of the femoral, the superficial perineal branch of the internal pudic, and the cremasteric branch from the deep epigastric. The *veins* follow the course of the corresponding arteries. The *lymphatics* terminate in the inguinal glands. The *nerves* are the ilio-inguinal and genito-crural branches of the lumbar plexus, the two superficial perineal branches of the internal pudic nerve, and the inferior pudendal branch of the small sciatic nerve.

The **inguinal** or **spermatic canal** (canalis inguinalis) contains the spermatic cord in the male, and the round ligament in the female. It is an

oblique canal, about an inch and a half in length, directed downwards and inwards, and placed parallel with, and a little above, Poupart's ligament. It commences, above, at the internal or deep abdominal ring, which is the point where the cord enters the inguinal canal; and terminates, below, at the external or superficial ring. It is bounded, *in front*, by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; *behind*, by the triangular fascia, the conjoined tendon of the Internal oblique and Transversalis, the transversalis fascia, and the subperitoneal fat and peritoneum; *above*, by the arched fibres of the Internal oblique and Transversalis; *below*, by the union of the transversalis fascia with Poupart's ligament.

The **spermatic cord** (funiculus spermaticus) extends from the internal or deep abdominal ring, where the structures of which it is composed converge, to the back part of the testicle. In the abdominal wall the cord passes obliquely along the inguinal canal, lying at first beneath the Internal oblique, and upon the fascia transversalis; but nearer the pubis, it rests upon Poupart's ligament, having the aponeurosis of the External oblique in front of it, and the conjoined tendon behind it. It then escapes at the external ring, and descends nearly vertically into the scrotum. The left cord is rather longer than the right, consequently the left testis hangs somewhat lower than its fellow.

Structure of the spermatic cord.—The spermatic cord is composed of arteries, veins, lymphatics, nerves, and the excretory duct of the testicle. These structures are connected together by areolar tissue, and invested by the layers brought down by the testis in its descent.

The *arteries of the cord* are: the spermatic, from the aorta; the artery of the vas deferens, from the superior vesical; and the cremasteric, from the deep epigastric.

The *spermatic artery*, a branch of the abdominal aorta, escapes from the abdomen at the internal or deep abdominal ring, and accompanies the other constituents of the spermatic cord along the inguinal canal and through the external abdominal ring into the scrotum. It then descends to the testis, and, becoming tortuous, divides into several branches, two or three of which accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens: the others supply the substance of the testis.

The *cremasteric artery* is a branch of the deep epigastric artery. It accompanies the spermatic cord and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery.

The *artery of the vas deferens*, a branch of the superior vesical, is a long slender vessel, which accompanies the vas deferens, ramifying upon the coats of that duct, and anastomosing with the spermatic artery near the testis.

The *spermatic veins* emerge from the back of the testis, and receive tributaries from the epididymis: they unite and form a convoluted plexus (*plexus pampiniformis*), which forms the chief mass of the cord; the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external or superficial abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal or deep abdominal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava, at an acute angle, and on the left side into the renal vein, at a right angle.

The *lymphatic vessels* terminate in the lumbar glands.

The *nerves* are the spermatic plexus from the sympathetic, joined by filaments from the pelvic plexus which accompany the artery of the vas deferens.

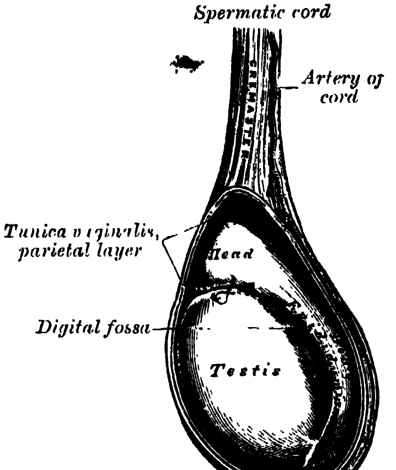
Applied Anatomy.—The scrotum forms an admirable covering for the protection of the testes. These bodies, lying suspended and loose in the cavity of the scrotum and surrounded by serous membrane, are capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distension, and on account of the looseness and amount of subcutaneous tissue, the scrotum becomes greatly enlarged in cases of œdema, to which this part is especially liable as a result of its dependent position. The scrotum is occasionally the seat of epithelioma; this is no doubt due to the rugæ on its surface, which favour the lodgment of dirt, and this, producing irritation, is the exciting cause of the disease, which is especially common in chimney-sweeps from the lodgment of soot. The disease is very much less common than it used to be; this is probably due to the better hygienic conditions of the working classes. The scrotum is also the part most frequently affected by elephantiasis.

On account of the looseness of the subcutaneous tissue, large extravasations of blood may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local

blood-letting from this part is judged to be desirable. The muscular fibre in the dartos causes contraction and considerable diminution in the size of a wound of the scrotum, as after the operation of castration, and is of assistance in keeping the edges together, and covering the exposed parts.

The **testes** are suspended in the scrotum by the spermatic cords, the left testis hanging somewhat lower than its fellow. The average dimensions of the testis are from one and a half to two inches in length, an inch in breadth, and an inch and a quarter in the antero-posterior diameter; its weight varies from six to eight drachms. Each testis is of an oval form (fig. 1001), compressed laterally, and having an oblique position in the scrotum; the upper extremity is directed forwards and a little outwards; the lower, backwards and a little inwards; the anterior convex border looks forwards and downwards; the posterior or straight border, to which the cord is attached, backwards and upwards.

FIG. 1001.—The testis *in situ*, the tunica vaginalis having been laid open.



The anterior border and lateral surfaces, as well as both extremities of the organ, are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying upon the outer edge of this posterior border is a long, narrow, flattened body, named, from its relation to the testis, the *epididymis*. It consists of a central portion, or *body* (corpus); an upper enlarged extremity, the *globus major*, or head (caput); and a lower pointed extremity, the *globus minor*, or tail (cauda), which is continuous with the vas deferens or duct of the testis. The globus major is intimately connected with the upper end of the testis by means of the efferent ducts of the gland; the globus minor is connected with the lower end by cellular tissue, and a reflection of the tunica vaginalis. The outer surface and upper and lower ends of the epididymis are free and covered by the serous membrane; the body is also completely invested by it, excepting along its posterior border; whilst between the body and the testis is a pouch, named the *digital fossa* (sinus epididymidis). The epididymis is connected to the back of the testis by a fold of the serous membrane. Attached to the upper end of the testis, close to the globus major, are two small pedunculated bodies. One of them is pear-shaped, and attached by its narrow stalk, the other is small and sessile; they are believed to be the remains of the upper extremity of the Müllerian duct (page 170), and are termed the *hydatids of Morgagni*; some observers, however, regard the stalked hydatid as being a rudiment of the pronephros.

The testis is invested by three tunics: the tunica vaginalis, tunica albuginea, and tunica vasculosa.

The **tunica vaginalis** is the serous covering of the testis. It is a pouch of serous membrane, derived from the peritoneum during the descent of the testis, in the fœtus, from the abdomen into the scrotum. After its descent, that portion of the pouch which extends from the internal ring to near the upper part of the gland becomes obliterated; the lower portion remains as a shut sac, which invests the outer surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and parietal portion.

The *visceral portion* (lamina visceralis) covers the greater part of the testis and epididymis, connecting the latter to the testis by means of a distinct fold. From the posterior border of the gland it is reflected on to the internal surface of the scrotum.

The *parietal portion* (lamina parietalis) is far more extensive than the visceral portion, extending upwards for some distance in front and on the inner side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is free, smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal layers of this membrane constitutes the cavity of the tunica vaginalis.

The obliterated portion of the pouch may generally be seen as a fibro-cellular thread lying in the loose areolar tissue around the spermatic cord; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia (page 1159). In other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.

The **tunica albuginea** is the fibrous covering of the testis. It is a dense membrane, of a bluish-white colour, composed of bundles of white fibrous tissue which interlace in every direction. Its outer surface is covered by the tunica vaginalis, except at the points of attachment of the epididymis to the testis, and along its posterior border, where the spermatic vessels enter the gland. Its inner surface is applied to the tunica vasculosa over the glandular substance of the testis, and, at its posterior border, is reflected into the interior of the gland, forming an incomplete vertical septum, called the *mediastinum testis* (*corpus Highmori*).

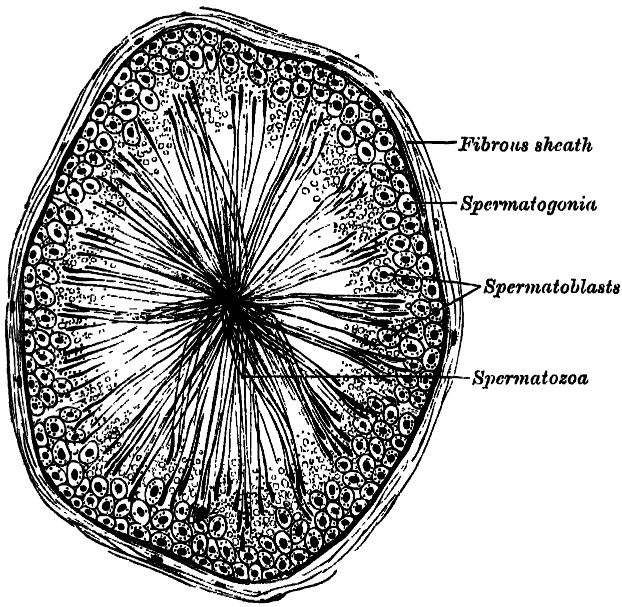
The *mediastinum testis* extends from the upper, nearly to the lower extremity of the gland, and is wider above than below. From the front and sides of this septum numerous slender fibrous cords and imperfect septa (*trabeculæ*) are given off, which radiate towards the surface of the organ, and are attached to the inner surface of the tunica albuginea. They therefore divide the interior of the organ into a number of incomplete spaces which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the vessels and ducts of the testis in their passage to and from the substance of the gland.

The **tunica vasculosa** is the vascular layer of the testis, consisting of a plexus of blood-vessels, held together by delicate areolar tissue. It covers the inner surface of the tunica albuginea and the different septa in the interior of the gland, and therefore forms an internal investment to all the spaces of which the gland is composed.

Structure.—The glandular structure of the testis consists of numerous lobules (*lobuli testis*). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules are conical in shape, the base being directed towards the circumference of the organ, the apex towards the mediastinum. Each lobule is contained in one of the intervals between the fibrous cords and the vascular processes which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three, or more, minute convoluted tubes, the *tubuli seminiferi*. The tubes may be separately unravelled, by careful dissection under water, and may be seen to commence either by free cæcal ends or by anastomotic loops. The total number of tubes is estimated by Lauth at 840, and their average length two feet and a quarter. Their diameter varies from $\frac{1}{200}$ to $\frac{1}{150}$ of an inch. The tubuli are pale in colour in early life, but in old age they acquire a deep yellow tinge, from containing much fatty matter. Each tube consists of a basement layer, formed of epithelioid cells united edge to edge, outside which are other layers of flattened cells arranged in interrupted laminæ, which give to the tube an appearance of striation in cross-section. The cells of the outer layers gradually pass into the interstitial tissue. Within the basement-membrane are epithelial cells arranged in several irregular layers, which are not always clearly separated, but which may be arranged in three different groups (fig. 1002). Among these cells may be seen the *spermatozoa* in different stages of development. 1. Lining the basement-membrane and forming the outer zone is a layer of cubical cells, with small nuclei; these are known as the *lining cells* or *spermatogonia*. The nucleus of some of them may be seen to be in process of indirect division (*karyokinesis*, page 4), and in consequence of this daughter cells are formed, which constitute the second zone. 2. Within this first layer is to be seen a number of larger polyhedral cells, with clear

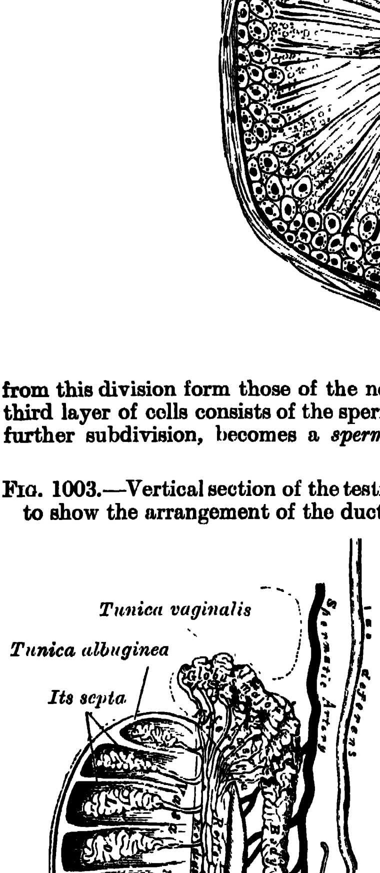
nuclei, arranged in two or three layers; these are the ***intermediate cells*** or ***spermatocytes.*** Most of these cells are in a condition of karyokinetic division, and the cells which result

FIG. 1002.—Transverse section of a seminiferous tubule.



from this division form those of the next layer, the *spermatoblasts* or *spermatids.* 3. The third layer of cells consists of the spermatoblasts or spermatids, and each of these, without further subdivision, becomes a *spermatozoon.* They are ill-defined granular masses of protoplasm, of an elongated form, with a nucleus, which becomes the head of the future spermatozoon. In addition to these three layers of cells others are seen, which are termed the *supporting cells,* or *cells of Sertoli.* They are elongated and columnar, and project inwards from the basement-membrane towards the lumen of the tube. They give off numerous lateral branches, which form a reticulum for the support of the three groups of cells just described. As development of the spermatozoa proceeds the latter group themselves around the inner extremities of the supporting cells. The nuclear portion of the spermatozoon, which is partly imbedded in the supporting cell, is differentiated to form the head of the spermatozoon, while the cell protoplasm becomes lengthened out to form the middle piece and tail, the latter projecting into the lumen of the tube. Ultimately the heads are liberated and the spermatozoa are set free. The structure of the spermatozoa is described on page 81.

FIG. 1003.—Vertical section of the testicle, to show the arrangement of the ducts.



In the apices of the lobules, the tubuli become less convoluted, assume a nearly straight course, and unite together to form from twenty to thirty larger ducts, of about $\frac{1}{50}$ of an inch in diameter, and these, from their straight course, are called *vasa recta* (fig. 1003).

The *vasa recta* (tubuli recti) enter the fibrous tissue of the mediastinum, and pass upwards and backwards, forming, in their ascent, a close network of anastomosing tubes which are merely channels in the fibrous stroma, lined by flattened epithelium, and having no proper walls; this constitutes the *rete testis.* At the upper end of the mediastinum,

the vessels of the rete testis terminate in from twelve to fifteen or twenty ducts, the *vasa efferentia* (ductuli efferentes testis); they perforate the tunica albuginea, and carry the seminal fluid from the testis to the epididymis. Their course is at first straight; they then become enlarged, and exceedingly convoluted, and form a series of conical masses, the *coni vasculosi*, which together constitute the globus major of the epididymis. Each cone consists of a single convoluted duct, from six to eight inches in length, the diameter of which gradually decreases from the testis to the epididymis. Opposite the bases of the cones the efferent vessels open at narrow intervals into a single duct, which constitutes, by its complex convolutions, the body and globus minor of the epididymis. When the convolutions of this tube are unravelled, it measures upwards of twenty feet in length; it increases in diameter and thickness as it approaches the vas deferens. The convolutions are held together by fine areolar tissue, and by bands of fibrous tissue.

The vasa recta have very thin walls; like the channels of the rete testis they are lined by a single layer of flattened epithelium. The vasa efferentia and the tube of the epididymis have walls of considerable thickness, on account of the presence in them of muscular tissue, which is principally arranged in a circular manner. These tubes are lined by columnar ciliated epithelium.

Applied Anatomy.—The testis, developed in the lumbar region, may be arrested or delayed in its transit to the scrotum. It may be retained in the abdomen; or it may be arrested at the internal abdominal ring, or in the inguinal canal; or it may just pass out of the external ring without finding its way to the bottom of the scrotum. When retained in the abdomen it gives rise to no symptoms, other than the absence of the testis from the scrotum; but when it is retained in the inguinal canal it is subjected to pressure and may become inflamed and painful. The testis when first formed is believed to be normal, but if retained it undergoes degenerative changes and becomes functionally useless; so that a man in whom both testes are retained (*anorchism*) is sterile, though he may not be impotent. The absence of one testicle is termed *monorchism*. When a testis is retained in the inguinal canal it is often complicated with a congenital hernia, the funicular process of the peritoneum not being obliterated. In addition to the cases above described, where there is some arrest in the descent of the testis, this organ may descend through the inguinal canal, but may miss the scrotum and assume some abnormal position. The most common form is where the testis, emerging at the external abdominal ring, slips down between the scrotum and thigh and comes to rest in the perinæum. This is known as *perineal ectopia testis*. With all varieties of abnormality in the position of the testis, it is very common to find concurrently a congenital hernia, or, if a hernia be not actually present, the funicular process is usually patent, and almost invariably so if the testis is in the inguinal canal.

The testis, finally reaching the scrotum, may occupy an abnormal position in it. It may be inverted, so that its posterior or attached border is directed forwards and the tunica vaginalis is situated behind. Should a hydrocele occur, and tapping be resorted to, the trocar may be thrust into the testis, if the operation is performed in the ordinary way, and care is not taken beforehand to ascertain the position of the gland.

A number of instances of torsion of the spermatic cord, resulting in acute strangulation of the testis, have been recorded. In some it has been attributed to a strain or twist, and in several patients the condition has been associated with a late descent of the organ. Symptoms of this condition closely simulate those of a strangulated hernia. In consequence of the torsion the circulation is partly arrested and the organ swells and becomes acutely painful, and the condition may be accompanied with shock and vomiting. Gangrene of the testis, however, rarely follows, and the condition, if left without operation, ends in atrophy of the organ. Torsion of the body of the testis also sometimes occurs within the tunica vaginalis in those cases in which a persistent mesorchium is present.

Fluid collections of a serous character are very frequently found in the scrotum. To these the term *hydrocele* is applied. The most common form is the ordinary *vaginal hydrocele*, in which the fluid is contained in the sac of the tunica vaginalis, which is separated, in its normal condition, from the peritoneal cavity by the whole extent of the inguinal canal. In another form, the *congenital hydrocele*, the fluid is in the sac of the tunica vaginalis, but this cavity communicates with the general peritoneal cavity, its tubular process remaining pervious. A third variety, known as an *infantile hydrocele*, occurs in those cases where the tubular process becomes obliterated only at its upper part, at or near the internal abdominal ring. It resembles the vaginal hydrocele, except as regards its shape, the collection of fluid extending up the cord into the inguinal canal. Fourthly, the funicular process may become obliterated both at the internal ring and above the epididymis, leaving a central unobliterated portion, which may become distended with fluid, giving rise to a condition known as the *encysted hydrocele of the cord*.

Encysted hydrocele of the epididymis or *spermatocele* is the name given to a cyst usually found in connection with the globus major of the epididymis. Among its contents are found, in many instances, a varying number of spermatozoa, and it is probably a retention cyst of one of the tubules.

The testis frequently requires removal for malignant disease; in tuberculous disease; in cases of large *hernia testis*, and in some instances of incompletely descended or misplaced

testes. The operation of castration was formerly performed for enlargement of the prostate, but has now been entirely abandoned in favour of the direct operation on the enlarged prostate. Castration is in most cases best carried out by the 'high' operation, an incision being made through the skin and fascia in the region of the external abdominal ring. The testis, with its deeper coverings, is then pushed up into the wound and separated from the scrotal tissues. The cord is then isolated, and an aneurysm needle, armed with a ligature, passed through it, as high as it is thought necessary, and the cord tied and divided. In cases of malignant and tuberculous disease, it is desirable to open the inguinal canal and tie the cord as near the internal abdominal ring as possible. When removing the testis in this manner the tunica vaginalis is not opened and its folds of reflection to the scrotal tissues do not need division. The whole of the tunica vaginalis is thus removed with the cord and its coverings.

Acute inflammation of the testis, or *orchitis*, is common in gonorrhœa; a chronic fibrosing form of orchitis is frequent in syphilis, and leads to skrinkage and hardening of the testis. In tabes dorsalis the testis often becomes quite insensitive to pressure, which, in the healthy adult, readily produces a severe and peculiar sickening sensation.

Vas Deferens

The **vas deferens** (ductus deferens), the excretory duct of the testis, is the continuation of the canal of the epididymis. Commencing at the lower part of the globus minor, it is at first very tortuous, but gradually becoming less twisted it ascends along the posterior border of the testis and inner side of the epididymis, and along the back part of the spermatic cord, through the inguinal canal to the internal or deep abdominal ring. From the ring it curves round the outer side of the deep epigastric artery, and ascends for about an inch in front of the external iliac artery. It is next directed backwards and slightly downwards, and, crossing the external iliac vessels obliquely, enters the pelvic cavity, where it lies between the peritoneal membrane and the lateral wall of the pelvis, and passes on the inner side of the obliterated hypogastric artery and the obturator nerve and vessels. It then crosses in front of the ureter, and, reaching the inner side of this tube, bends to form an acute angle, and runs inwards and slightly forwards between the base of the bladder and the upper end of the seminal vesicle. Reaching the inner side of the seminal vesicle, it is directed downwards and inwards in contact with it, gradually approaching the vas of the opposite side. Here it lies between the base of the bladder and the rectum, where it is enclosed, together with the seminal vesicle, in a sheath derived from the recto-vesical portion of the fascia endopelvina. Lastly, it is directed downwards to the base of the prostate, where it becomes greatly narrowed, and is joined at an acute angle by the duct of the seminal vesicle to form the ejaculatory duct, which traverses the prostate gland behind its middle lobe and opens into the prostatic portion of the urethra, close to the sinus pocularis. The vas deferens presents a hard and cord-like sensation to the fingers, and is of cylindrical form; its walls are dense, and its canal is extremely small. At the base of the bladder it becomes enlarged and tortuous, and this portion is termed the *ampulla*. A small triangular area of the base of the bladder, between the vasa deferentia laterally and the bottom of the recto-vesical pouch of peritoneum above, is in contact with the rectum.

Structure.—The vas deferens consists of three coats: (1) an external or areolar coat; (2) a muscular coat, which in the greater part of the tube consists of two layers of unstriped muscular fibre: an outer, longitudinal in direction, and an inner, circular; but in addition to these, at the commencement of the vas deferens, there is a third layer, consisting of longitudinal fibres, placed internal to the circular stratum, between it and the mucous membrane; (3) an internal, or mucous coat, which is pale, and arranged in longitudinal folds. The mucous coat is lined by columnar epithelium which is non-ciliated throughout the greater part of the tube; a variable portion of the testicular end of the tube is lined by two strata of columnar cells and the cells of the superficial layer are ciliated.

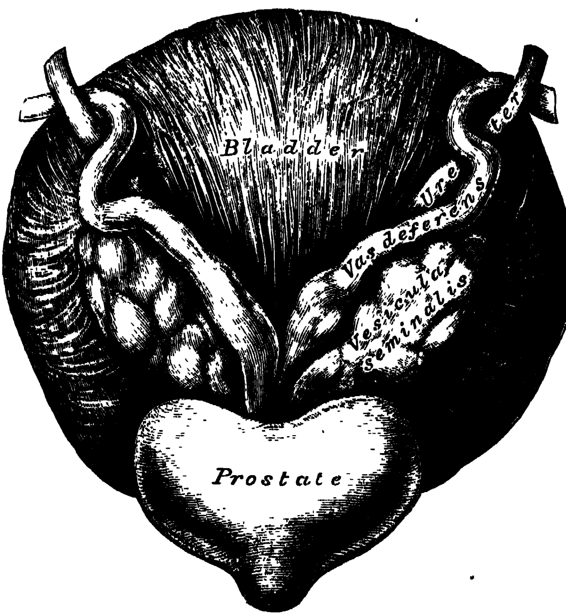
A long narrow tube, the *vas aberrans of Haller*, is occasionally found connected with the lower part of the canal of the epididymis, or with the commencement of the vas deferens. It extends up into the cord for about two or three inches, where it terminates by a blind extremity, which is sometimes bifurcated. Its length varies from an inch and a half to fourteen inches, and it may become dilated towards its extremity; more commonly it retains the same diameter throughout. Its structure is similar to that of the vas deferens. Occasionally it is found unconnected with the epididymis.

Organ of Giraldès.—This term is applied to a small collection of convoluted tubules. situated in front of the lower part of the cord above the globus major of the epididymis, These tubes are lined with columnar ciliated epithelium, and probably represent the remains of a part of the Wolffian body.

Vesiculæ Seminales (fig. 1004)

The **vesiculæ seminales** are two lobulated membranous pouches, placed between the base of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testes. Each sac is somewhat pyramidal in form, the broad end being directed backwards, upwards and outwards. It measures usually about two and a half inches in length, but varies in size, not only in different individuals, but also in the same individual on the two sides. The *anterior surface* is in contact with the base of the bladder, extending from near the termination of the ureter to the base of the prostate gland. The *posterior surface* rests upon the rectum, from which it is separated by the recto-vesical fascia. Their *upper extremities* diverge from each other, and are separated from the bladder by the vas deferens

Fig. 1004.—Base of the bladder with the vesiculæ seminales.



and the lower end of the ureter, and are partly covered by peritoneum. Their *lower extremities* are pointed, and converge towards the base of the prostate gland, where each joins with the corresponding vas deferens to form the ejaculatory duct. Along the inner margin of each vesicle runs the enlarged and tortuous vas deferens.

Each vesicle consists of a single tube, coiled upon itself, and giving off several irregular cæcal diverticula; the separate coils, as well as the diverticula, are connected together by fibrous tissue. When uncoiled, the tube is about the diameter of a quill, and varies in length from four to six inches; it terminates posteriorly in a *cul-de-sac*; its anterior extremity becomes constricted into a narrow straight duct, which joins with the corresponding vas deferens to form the ejaculatory duct.

Structure.—The vesiculæ seminales are composed of three coats: an *external* or *areolar coat*: a *middle* or *muscular coat*, thinner than in the vas deferens and arranged in two layers, an outer longitudinal and inner circular; an *internal* or *mucous coat*, which is pale, of a whitish-brown colour, and presents a delicate reticular structure. The epithelium is columnar, and, in the diverticula, goblet-cells are present, the secretion of which increases the bulk of the seminal fluid.

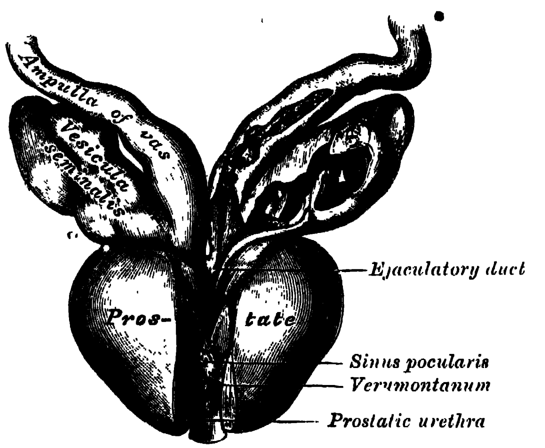
Vessels and Nerves.—The *arteries* supplying the vesiculæ seminales are derived from the middle and inferior vesical, and middle hæmorrhoidal. The veins and lymphatics accompany the arteries. The nerves are derived from the pelvic plexuses.

Applied Anatomy.—The vesiculæ seminales are often the seat of an extension of the disease in cases of tuberculosis of the testis, and should always be examined from the rectum, before deciding to perform castration in this affection. They also become affected in chronic posterior urethritis of gonorrhœal origin.

EJACULATORY DUCTS (fig. 1005)

The **ejaculatory ducts** are two in number, one on either side of the middle line. Each is formed by the union of the duct from the vesicula seminalis with the vas deferens, and is about three-quarters of an inch in length. They commence at the base of the prostate, and run forwards and downwards between its middle and lateral lobes, and along the sides of the sinus pocularis, to terminate by separate slit-like orifices close to or just within the margins of the sinus. The ducts diminish in size, and also converge, towards their terminations.

FIG. 1005.—Vesiculæ seminales and ampullæ of vasa deferentia, seen from the front. The anterior walls of the left ampulla, left seminal vesicle, and prostatic urethra have been cut away.



Structure.—The coats of the ejaculatory ducts are extremely thin. They are: an *outer fibrous layer*, which is almost entirely lost after the entrance of the ducts into the prostate; a *layer of muscular fibres*, consisting of an outer thin circular, and an inner longitudinal, layer; and *mucous membrane*.

THE PENIS

The **penis** is a pendulous organ suspended from the front and sides of the pubic arch and containing the greater part of the urethra. In the flaccid condition it is cylindrical in shape, but when erect assumes the form of a triangular prism with rounded angles, one side of the prism forming the dorsum. It is composed of three cylindrical masses of cavernous tissue bound together by fibrous tissue and covered with skin. Two of the masses are lateral, and are known as the *corpora cavernosa*; the third is median, and is termed the *corpus spongiosum*. (figs. 1006, 1007).

The **corpora cavernosa** (corpora cavernosa penis) form the greater part of the substance of the penis. For their anterior three-fourths they lie in intimate apposition with one another, but behind they diverge in the form of two tapering processes, known as the *crura*, which are firmly connected to the rami of the pubic arch. Traced from behind forwards, each crus commences by a blunt-pointed process in front of the tuberosity of the ischium. Just before it meets its fellow it presents a slight enlargement, named by Kobelt the *bulb of the corpus cavernosum*. Beyond this point the crus undergoes a constriction and merges into the corpus cavernosum proper, which retains a uniform diameter to its anterior end. Each corpus cavernosum terminates abruptly in a rounded extremity some distance from the point of the penis.

The corpora cavernosa are surrounded by a strong fibrous envelope consisting of superficial and deep fibres. The superficial fibres are longitudinal in direction, and form a single tube which encloses both corpora; the deep fibres are arranged circularly round each corpus, and form by their junction

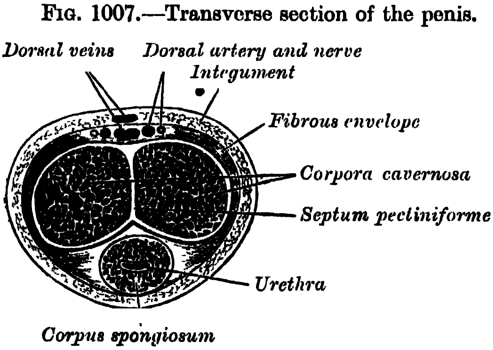
in the mesial plane a partition or septum (septum penis). This is thick and complete behind, but is imperfect in front, where it consists of a series of vertical bands arranged like the teeth of a comb; it is therefore named the *septum pectiniforme.*

FIG. 1006.—The constituent cavernous cylinders of the penis. The glans and anterior part of the corpus spongiosum are detached from the corpora cavernosa and turned to one side.

The **corpus spongiosum** (corpus cavernosum urethræ) contains the urethra. Behind, it is expanded to form the urethral bulb (bulbus urethræ), and lies in apposition with the superficial layer of the triangular ligament, from which it receives a fibrous investment. The urethra enters the bulb nearer to the upper than to the lower surface. On the latter there is a depressed median raphe (sulcus bulbi), from which a thin fibrous septum projects into the substance of the bulb and divides it imperfectly into two lateral lobes or *hemispheres.*

The portion of the corpus spongiosum in front of the bulb lies in a groove on the under surface of the conjoined corpora cavernosa. It is cylindrical in form and tapers slightly from behind forwards. Its anterior extremity is expanded in the form of an obtuse cone, flattened from above downwards. This expansion, termed the *glans penis,* is moulded on the rounded ends of the corpora cavernosa, extending further on their upper than on their lower surfaces. At the summit of the glans is the slit-like vertical urethral orifice or meatus (orificium urethræ externum). The circumference of the base of the glans forms a rounded projecting border, the *corona glandis,* overhanging a deep sulcus (sulcus retroglandularis), behind which is the *neck* (collum penis) of the penis.

FIG. 1007.—Transverse section of the penis.



For descriptive purposes it is convenient to divide the penis into three regions: the root, the body, and the extremity.

The **root** (radix penis) of the penis is triradiate in form, consisting of the diverging crura, one on either side, and the mesial bulb of the corpus spongiosum. Each crus is covered by the Erector penis, while the bulb is surrounded by the Ejaculator urinæ. The root of the penis lies in the perinæum between the superficial layer of the triangular ligament and the fascia of Colles. In addition to being attached to the pubic rami and triangular ligament, it is bound to the

front of the symphysis pubis by the *suspensory ligament* (lig. suspensorium penis). The upper fibres of this ligament pass downwards from the lower end of the linea alba, and the lower fibres from the symphysis pubis; together they form a strong fibrous band, which extends to the upper surface of the root, where it splits into two fasciculi and blends with the fascial sheath of the organ.

The **body** (corpus penis) extends from the root to the ends of the corpora cavernosa, and in it the corpora cavernosa are intimately bound to one another. A shallow groove which marks their junction on the upper surface lodges the deep dorsal vein of the penis, while a deeper and wider groove between them on the under surface contains the corpus spongiosum. The body is ensheathed by fascia, which is continuous above with the fascia of Scarpa, and below with the dartos of the scrotum and the fascia of Colles.

The **extremity** is formed by the glans penis, the expanded anterior end of the corpus spongiosum. It is separated from the body by the constricted neck, which is overhung by the corona glandis.

The integument covering the penis is remarkable for its thinness, its dark colour, its looseness of connection with the deeper parts of the organ and its absence of adipose tissue. At the root of the penis it is continuous with that over the pubes, scrotum, and perinæum. At the neck it leaves the surface and becomes folded upon itself to form the *prepuce* or *foreskin* (præputium penis). The internal layer of the prepuce is directly continuous, along the line of the neck, with the integument over the glans. Immediately behind the urinary meatus it forms a small secondary reduplication, attached along the bottom of a depressed median raphe, which extends from the meatus to the neck; this fold is termed the *frenulum* (frenulum præputii). The integument covering the glans is continuous with the urethral mucous membrane at the meatus; it is devoid of hairs, but projecting from its free surface are a number of small, highly sensitive papillæ. On the corona and neck numerous small glands, the *glandulæ Tysonii odoriferæ* (glandulæ præputii) have been described.* They secrete a sebaceous material of very peculiar odour, which probably contains casein, and readily undergoes decomposition.

The prepuce covers a variable amount of the glans, and is separated from it by a potential sac—the *preputial sac*—which presents two shallow recesses (fossæ frenuli), one on either side of the frenulum.

Structure of the penis.—From the internal surface of the fibrous envelope of the corpora cavernosa as well as from the sides of the septum, numerous bands or cords are given off, which cross the interior of the corpora cavernosa in all directions, subdividing them into a number of separate compartments, and giving the entire structure a spongy appearance. These bands and cords are called *trabeculæ* (trabeculæ corporum cavernosorum), and consist of white fibrous tissue, elastic fibres, and plain muscular fibres. In them are contained numerous arteries and nerves.

The component fibres which form the trabeculæ are larger and stronger round the circumference than at the centres of the corpora cavernosa; they are also thicker behind than in front. The interspaces (cavernous spaces), on the contrary, are larger at the centre than at the circumference, their long diameters being directed transversely. They are filled with blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins.

The arteries bringing the blood to these spaces are the arteries of the corpora cavernosa and branches from the dorsal arteries of the penis, which perforate the fibrous capsule, along the upper surface, especially near the fore-part of the organ.

On entering the cavernous structure the arteries divide into branches, which are supported and enclosed by the trabeculæ. Some of these arteries terminate in a capillary network, the branches of which open directly into the cavernous spaces; others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller *helicine arteries*. They project into the spaces, and from them are given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are most abundant in the back part of the corpora cavernosa (fig. 1008).

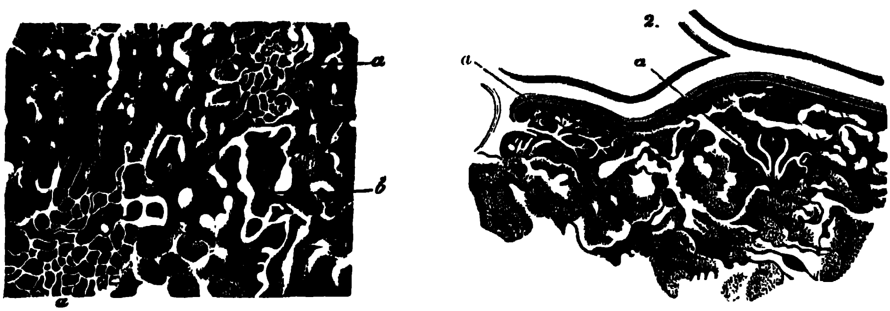
The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and converge on the

* Stieda (*Comptes-rendus du XII Congrès International de Médecine*, Moscow, 1897) asserts that Tyson's glands are never found on the corona glandis, and that what have hitherto been mistaken for glands are really large papillæ.

dorsum of the organ to form the deep dorsal vein; others pass out on the upper surface of the corpora cavernosa and join the same vein; some emerge from the under surface of the corpora cavernosa and, receiving branches from the corpus spongiosum, wind round the sides of the penis to terminate in the deep dorsal vein; but the greater number pass out at the root of the penis and join the prostatic plexus.

The fibrous envelope of the corpus spongiosum is thinner, whiter in colour, and more elastic than that of the corpora cavernosa. The trabeculæ are more delicate, nearly uniform in size, and the meshes between them smaller than in the corpora cavernosa:

Fig. 1008.—From the peripheral portion of the corpus cavernosum penis under a low magnifying power. (Copied from Langer.)



1. *a.* Capillary network. *b.* Cavernous spaces. 2. Connection of the arterial twigs (*a*) with the cavernous spaces.

their long diameters, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus spongiosum is formed partly of unstriped muscular fibre, and a layer of the same tissue immediately surrounds the canal of the urethra.

The *lymphatics of the penis* are described on page 789.

The *nerves* are derived from the internal pudic nerve and the pelvic plexuses. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, and, according to Krause, many of them terminate in peculiar end-bulbs (see page 50).

Applied Anatomy.—The penis occasionally requires removal for malignant disease. Usually, removal of the ante-scrotal portion is all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the rami of the pubes and ischia. The former operation is performed by cutting through the corpora cavernosa from the dorsum, and then separating the corpus spongiosum from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which might otherwise take place. The vessels which require ligature are the two dorsal arteries of the penis, the arteries of the corpora cavernosa, and the artery of the septum. When the entire organ requires removal, the patient is placed in the lithotomy position, and an incision is made through the skin and subcutaneous tissue round the root of the penis, and carried down through the median line of the scrotum as far as the perinæum. The two halves of the scrotum are then separated from each other, and a catheter having been introduced into the bladder as a guide, the spongy portion of the urethra below the triangular ligament is separated from the corpora cavernosa and divided, the catheter having been withdrawn. The suspensory ligament is now severed and the crura separated from the bone with a periosteum scraper, and the whole penis removed. The membranous portion of the urethra, which has not been removed, is now to be attached to the skin at the posterior extremity of the incision in the perinæum. The remainder of the wound is to be brought together, free drainage being provided for.

The Prostate Gland

The **prostate gland** (prostatæ) is a firm, partly glandular and partly muscular body, which is placed immediately below the neck of the bladder and around the commencement of the urethra. It is situated in the pelvic cavity, below the lower part of the symphysis pubis, above the superior layer of the triangular ligament, and in front of the rectum, through which it may be distinctly felt, especially when enlarged. It is about the size of a chestnut and somewhat conical in shape, and presents for examination a base, an apex, an anterior, a posterior, and two lateral surfaces.

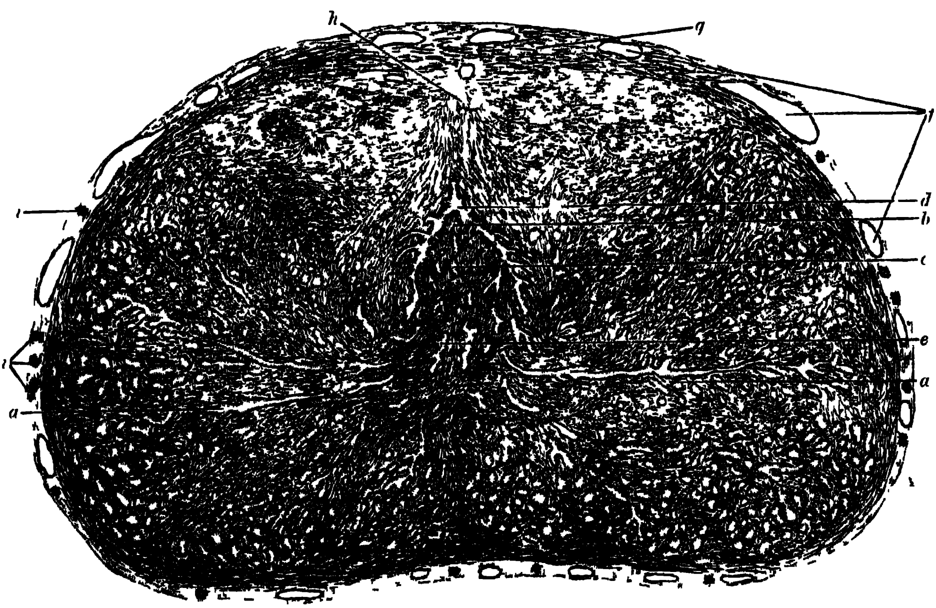
The *base* (basis prostătæ) is directed upwards, and is applied to the under surface of the bladder. The greater part of this surface is directly continuous

with the bladder wall: the urethra penetrates it nearer its anterior than its posterior border.

The *apex* (apex prostatæ) is directed downwards, and is in contact with the deep layer of the triangular ligament.

The *posterior surface* (facies posterior) is flattened from side to side and convex from above downwards; it rests on the rectum, and is distant about an inch and a half from the anus. Near its upper border there is a depression through which the two common ejaculatory ducts enter the prostate. This depression serves to divide the posterior surface into a lower larger and an upper smaller part. The upper smaller part constitutes the *middle lobe* of the prostate and intervenes between the ejaculatory ducts and the urethra; it varies greatly in size, and in some cases is destitute of glandular tissue. The lower larger portion sometimes presents a shallow median furrow, which imperfectly separates it into a *right* and a *left lateral* lobe: these form the main mass of the gland and are directly continuous with each other behind the urethra.

FIG. 1009.—Transverse section of normal prostate through the middle of the verumontanum, from a subject aged nineteen years. (Taylor.)



a, longitudinal section of ducts leading from the lobules of the prostatic glands; *b*, verumontanum; *c*, sinus pocularis; *d*, urethra; *e*, ejaculatory ducts; *f*, arteries, veins, and venous sinuses in sheath of prostate; *g*, nerve trunks in sheath; *h*, point of origin of fibro-muscular bands encircling urethra; *i*, zone of striated voluntary muscle on superior surface.

In front of the urethra they are connected by a band which is named the *anterior commissure*: this consists of the same tissues as the capsule and is devoid of glandular substance.

The *anterior surface* (facies anterior) measures about an inch from above downwards, but is narrow and convex from side to side. It is placed about three-quarters of an inch behind the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fat. It is connected to the pubic bone on either side by the pubo-prostatic ligaments. The urethra emerges from this surface a little above and in front of the apex of the gland.

The *lateral surfaces* (facies laterales) are prominent, and are covered by the anterior portions of the Levatores ani muscles, which are, however, separated from the gland by a plexus of veins.

The prostate measures about an inch and a half transversely at the base, three-quarters of an inch in its antero-posterior diameter, and an inch and a quarter in its vertical diameter. Its weight is about four and a half drachms. It is held in its position by the anterior ligaments of the bladder (*pubo-*

prostaticæ; by the deep layer of the triangular ligament, which invests the commencement of the membranous portion of the urethra and prostate gland; and by the anterior portions of the Levatores ani muscles, which pass backwards from the pubis and embrace the sides of the prostate. These portions of the Levatores ani, from the support they afford to the prostate, are named the *Levatores prostatæ*.

The prostate gland is perforated by the urethra and the ejaculatory ducts. The urethra usually lies along the junction of its anterior with its middle third. The ejaculatory ducts pass obliquely downwards and forwards through the posterior part of the prostate, and open into the prostatic portion of the urethra.

Structure.—The prostate is immediately enveloped by a thin but firm fibrous capsule, distinct from that derived from the fascia endopelvina, and separated from it by a plexus of veins. This capsule is firmly adherent to the prostate and is structurally continuous with the stroma of the gland, being composed of the same tissues, viz. non-striped muscle and fibrous tissue. The substance of the prostate is of a pale reddish-grey colour, of great density, and not easily torn. It consists of glandular substance and muscular tissue.

The *muscular tissue*, according to Kölliker, constitutes the proper stroma of the prostate; the connective tissue being very scanty, and simply forming, between the muscular fibres, thin trabeculæ, in which the vessels and nerves of the gland ramify. The muscular tissue is arranged as follows: immediately beneath the fibrous capsule is a dense layer, which forms an investing sheath for the gland; secondly, around the urethra, as it lies in the prostate, is another dense layer of circular fibres, continuous above with the internal layer of the muscular coat of the bladder, and below blending with the fibres surrounding the membranous portion of the urethra. Between these two layers strong bands of muscular tissue, which decussate freely, form meshes in which the glandular structure of the organ is imbedded. In that part of the gland which is situated in front of the urethra the muscular tissue is especially dense, and there is here little or no gland tissue; while in that part which is behind the urethra the muscular tissue presents a wide-meshed structure, which is densest at the base of the gland—that is, near the bladder—becoming looser and more sponge-like towards the apex of the organ.

The *glandular substance* is composed of numerous follicular pouches, opening into elongated canals, which join to form from twelve to twenty small excretory ducts. The follicles are connected together by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. The epithelium which lines the canals and the terminal vesicles is of the columnar variety. The prostatic ducts open into the floor of the prostatic portion of the urethra, and are lined by two layers of epithelium, the inner layer consisting of columnar and the outer of small cubical cells.

Vessels and Nerves.—The *arteries* supplying the prostate are derived from the internal pudic, vesical, and hæmorrhoidal. Its veins form a plexus around the sides and base of the gland; they receive in front the dorsal vein of the penis, and terminate in the internal iliac veins. The *nerves* are derived from the pelvic plexus.

Applied Anatomy.—By means of the finger introduced into the rectum, the surgeon detects enlargement or other disease of the prostate; he can feel the apex of the gland, which is the guide to Cock's operation for stricture; he is enabled also by the same means to direct the point of a catheter, when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. When the finger is introduced into the bowel, the surgeon may, in some cases, especially in boys, learn the position, as well as the size, of a calculus in the bladder; and in the operation for its removal, if, as is not infrequently the case, it should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upwards the base of the bladder from the rectum. The prostate gland is occasionally the seat of suppuration, due to either gonorrhœa or tuberculous disease. The gland is enveloped in a dense unyielding capsule, which determines the course of the abscess, and also explains the great pain which is present in the acute form of the disease. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may burst into the rectum, or more rarely in the perinæum. In advanced life the prostate sometimes becomes considerably enlarged and projects into the bladder so as to impede the passage of the urine. According to Messer's researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. In some cases the condition affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the middle lobe enlarges most, and even a small enlargement of this lobe may act injuriously, by forming a sort of valve over the urethral orifice, preventing the passage of the urine; and the more the patient strains, the more completely will it block the opening into the urethra. In consequence of the enlargement of the prostate, a pouch is formed at the base of the bladder behind the projection, in which urine collects, and cannot be entirely expelled. It becomes decomposed

and ammoniacal, and leads to cystitis. For this condition *prostatectomy* is sometimes done. The bladder is opened by an incision above the symphysis pubis, the mucous membrane of the post-prostatic pouch is scratched through, and the finger is then introduced into the space between the true capsule of the prostate and outer capsule formed by the fascia endopelvina. Separation in this plane is then carried out below and laterally until the apex of the gland is reached. The whole of the work is done with the finger, which is gradually swept round the sides until the anterior surface is reached and freed. The gland is then, by traction, displaced into the bladder and removed, usually carrying with it the greater portion of the mucous membrane of the prostatic urethra. Hæmorrhage, which may be considerable at times, is checked by hot irrigations, and the bladder is temporarily drained. Very satisfactory results have followed this operation.

The prostate can be reached from the perinæum, and in some cases the enlarged gland has been removed by this route, but the perineal approach is not usually employed except in the case of abscess of or about the gland.

Cowper's Glands

Cowper's glands (glandulæ bulbo-urethrales) are two small, rounded, and somewhat lobulated bodies, of a yellow colour, about the size of peas, placed behind the membranous portion of the urethra, between the two layers of the triangular ligament. They lie close above the bulb, and are enclosed by the transverse fibres of the Compressor urethræ muscle. Their existence is said to be constant: they gradually diminish in size as age advances.

The excretory duct of each gland, nearly an inch in length, passes obliquely forwards beneath the mucous membrane, and opens by a minute orifice on the floor of the bulbous portion of the urethra.

Structure.—Each gland is made up of several lobules, held together by a fibrous investment. Each lobule consists of a number of acini, lined by columnar epithelial cells, opening into one duct, which joins with the ducts of other lobules outside the gland to form the single excretory duct.

FEMALE REPRODUCTIVE ORGANS

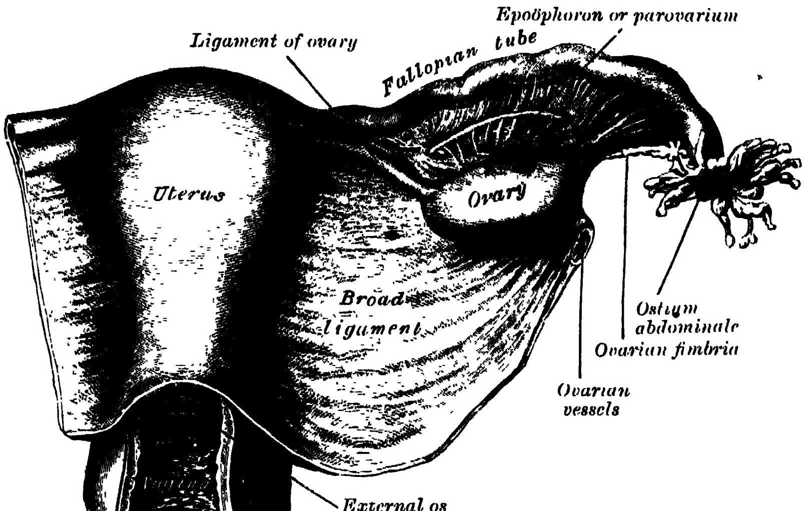
The female reproductive organs (organa genitalia muliebria) consist of an internal and an external group. The *internal organs* are situated within the pelvis, and consist of the ovaries, the Fallopian tubes, the uterus, and the vagina. The *external organs* are placed below the triangular ligament of the urethra and below and in front of the pubic arch. They comprise the mons Veneris, the labia majora et minora, the clitoris, the bulbus vestibuli, and the glands of Bartholin.

The Ovaries

The **ovaries** are homologous with the testes in the male. They are two nodular bodies, situated one on either side of the uterus in relation to the lateral wall of the pelvis, and attached to the back of the broad ligament of the uterus, behind and below the Fallopian tubes (fig. 1010). The ovaries are of a greyish-pink colour, and present either a smooth or a puckered uneven surface. They are each about an inch and a half in length, three-quarters of an inch in width, and about a third of an inch in thickness, and weigh from one to two drachms. Each ovary (ovarium) presents an outer and an inner surface, an upper and a lower extremity, and an anterior and a posterior border. It lies in a shallow depression, named the *fossa ovarii*, on the lateral wall of the pelvis; this fossa is bounded above by the external iliac vessels, in front by the obliterated hypogastric artery, and behind by the ureter. The exact position of the ovary has been the subject of considerable difference of opinion, and the description here given applies to the ovary of the nulliparous woman. The ovary becomes displaced during the first pregnancy, and probably never again returns to its original position. In the erect posture the long axis of the ovary is vertical. The *upper* or *tubal* extremity is near the external iliac vein; to it is attached the ovarian fimbria of the Fallopian tube and a fold of peritoneum, the *suspensory ligament of the ovary*, which is directed upwards over the iliac vessels and contains the ovarian vessels. The *lower* or *uterine*

end is directed downwards towards the pelvic floor; it is usually narrower than the upper, and is attached to the lateral angle of the uterus, immediately behind the Fallopian tube, by a rounded cord termed the *ligament of the ovary*, which lies within the broad ligament and contains some non-striped

Fig. 1010.—Uterus and right broad ligament, seen from behind. The broad ligament has been spread out and the ovary drawn downwards.



muscular fibres. The *outer* surface is in contact with the parietal peritoneum, which lines the fossa ovarii; the *inner* surface is to a large extent covered by the fimbriated extremity of the Fallopian tube. The *anterior* or *straight* border is directed towards the obliterated hypogastric artery, and is attached to the back of the broad ligament by a short fold named the *mes-*

ovarium. Between the two layers of this fold the blood-vessels and nerves pass to reach the hilus of the ovary. The *posterior* or *convex* border is free, and is directed towards the ureter. The Fallopian tube arches over the ovary, running upwards in relation to its anterior border, then curving over its upper or tubal pole, and finally passing downwards on its posterior border and inner surface.

Epoöphoron and paroöphoron (figs. 1010, 1011).—Lying in the broad ligament, between the ovary and the Fallopian tube, is the *epoöphoron* or *parovarium*, also called the *organ of Rosenmüller*. This consists of a few closed convoluted tubes, lined with epithelium, which converge towards the ovary at one end and at the other are united by a longitudinal tube, the *duct of Gärtner*. In the human female this duct terminates in a bulbous enlargement ; in the cow it attains a greater development and opens into the vagina. The *paroöphoron* consists of a few scattered rudimentary tubules, best seen in the child, situated in the broad ligament between the parovarium and the uterus. The epoöphoron and paroöphoron are remnants of the Wolffian body or mesonephros, and the duct of Gärtner is a persistent portion of the Wolffian duct.

In the fœtus, the ovaries are situated, like the testes, in the lumbar region, near the kidneys. They may be distinguished from those bodies at an early period by their elongated and flattened form, and by their position, which is at first oblique and then nearly transverse. They gradually descend into the pelvis.

Structure (fig. 1012).—The surface of the ovary is covered by a layer of columnar cells which constitute the *germinal epithelium of Waldeyer*. This epithelium gives to the ovary a dull grey colour as compared with the shining smoothness of the peritoneum ; and the transition between the pavement epithelium of the peritoneum and the columnar cells which cover the ovary is usually marked by a line around the anterior border of the ovary. The ovary consists of a number of Graafian follicles imbedded in the meshes of a stroma or framework.

The *stroma* is a peculiar soft tissue, abundantly supplied with blood-vessels, consisting for the most part of spindle-shaped cells with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriped muscle-cells, which, indeed, they most resemble ; by others as connective-tissue cells. On the surface of the organ this tissue is much condensed, and forms a layer (*tunica albuginea*) composed of short connective-tissue fibres, with fusiform cells between them.

Graafian follicles.—Upon making a section of an ovary, numerous round transparent vesicles of various sizes are to be seen ; they are the Graafian follicles, or ovisacs containing the ova. Immediately beneath the superficial covering is a layer of stroma, in which are a large number of minute vesicles, of uniform size, about $\frac{1}{100}$ of an inch in diameter. These are the follicles in their earliest condition, and the layer where they are found has been termed the *cortical layer*. They are especially numerous in the ovary of the young child. After puberty, and during the whole of the child-bearing period, large and mature, or almost mature, Graafian follicles are also found in the cortical layer in small numbers, and also 'corpora lutea,' the remains of follicles which have burst and are undergoing atrophy and absorption. Beneath this superficial stratum, other large and more mature follicles are found imbedded in the ovarian stroma. These increase in size as they recede from the surface towards a highly vascular stroma in the centre of the organ, termed the *medullary substance* (*zona vasculosa*, Waldeyer). This stroma forms the tissue of the hilus by which the ovary is attached, and through which the blood-vessels enter : it does not contain any Graafian follicles.

The larger Graafian follicles consist of an external fibro-vascular coat, connected with the surrounding stroma of the ovary by a network of blood-vessels ; and an internal coat, named the *ovicapsule*, which is lined by a layer of nucleated cells, called the *membrana granulosa*. In that part of the mature Graafian follicle which is nearest the surface of the ovary, the cells of the membrana granulosa are connected into a mass which projects into the cavity of the follicle. This is termed the *discus proligerus*, and in it the ovum is imbedded.* The follicle contains a transparent albuminous fluid.

* For a description of the ovum, see page 78.

The ova are usually regarded as being formed from the germinal epithelium on the surface of the ovary. This becomes thickened, and in it are seen some cells which are larger and more rounded than the rest: these are termed the *primordial ova*. The germinal epithelium grows downwards in the form of tubes or columns, termed the *egg tubes* of Pflüger, into the ovarian stroma, which grows outwards between the tubes, and ultimately cuts them off from the germinal epithelium. These tubes are further subdivided into rounded *nests* or groups, each containing a primordial ovum which undergoes further development and growth while the surrounding cells of the nest form the epithelium of the Graafian follicle.

The development and maturation of the Graafian follicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman's life, while their formation commences before birth. Before puberty the ovaries are small, the Graafian follicles contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the Graafian follicles; many, however, never attain full development, but shrink and disappear. At puberty the ovaries enlarge and become more vascular, the Graafian follicles are developed in greater abundance, and their ova are capable of fecundation.

Discharge of the ovum.—The Graafian follicles, after attaining a certain stage of development, gradually approach the surface of the ovary and burst; the ovum and fluid contents of the follicle are liberated on the exterior of the ovary, and carried into the Fallopian tube by peritoneal currents set up by the movements of the cilia covering the mucous membrane of the fimbriæ.

Vessels and Nerves.—The *arteries* of the ovaries and Fallopian tubes are the ovarian from the aorta. Each enters the attached border, or hilus, of the corresponding ovary. The *veins* emerge from the hilus in the form of a plexus, the *pampiniform plexus*; the ovarian vein is formed from this plexus, and leaves the pelvis in company with the artery. The *nerves* are derived from the hypogastric or pelvic plexus, and from the ovarian plexus, the Fallopian tube receiving a branch from one of the uterine nerves.

Applied Anatomy.—The inflammations which affect the ovary are merely an extension of those from the tube. Ovarian new formations are of common occurrence, and are either solid or cystic; the former being the less common. The '*ovarian cysts*' in the majority of cases are cystadenomata which may assume enormous dimensions; in rarer instances they form from the tubules at the hilus of the ovary or those of the organ of Rosenmüller; in other instances a clear watery cyst forms between the layers of the broad ligament. An ovarian cyst, once diagnosed, should always be removed, as it is liable to become affected by suppuration, torsion of its pedicle, or other serious complications. The operation for its removal, badly termed *ovariotomy*, consists in opening the abdomen, and reducing the size of the cyst when large by tapping it before its withdrawal from the abdomen; the pedicle is then clamped with a large forceps, and the cyst is cut free. This pedicle must then be transfixed and securely ligatured by an interlocking ligature, which will not slip off. The pedicle consists of an elongated part of the broad ligament, including the Fallopian tube and ovarian artery, and a great number of large veins. Ovariotomy for a simple uncomplicated cyst presents no special difficulties, but, in cases where there are old adhesions implicating the small intestines, it may present very great difficulties.

The Fallopian Tubes (figs. 1010, 1013)

The **Fallopian tubes**, or **oviducts**, convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on either side, situated in the upper margin of the broad ligament, and extending from either superior angle of the uterus to the side of the pelvis. Each tube is about four inches in length; and is described as consisting of three portions: (1) the *isthmus*, or inner constricted third; (2) the *ampulla*, or outer dilated portion, which curves over the ovary; and (3) the *infundibulum*, with its *ostium abdominale*, surrounded by *fimbriæ*, one of which, the *fimbria ovarica*, is attached to the ovary. The Fallopian tube is directed outwards as far as the lower or uterine pole of the ovary, and then ascends along the anterior border of the ovary to the upper or tubal pole, over which it arches; finally it turns downwards and ends in relation to the posterior border and inner surface of the ovary. The uterine opening is minute, and will only admit a fine bristle; the abdominal opening is somewhat larger. In connection with the fimbriæ of the Fallopian tube, or with the broad ligament close to them, there are frequently one or more small pedunculated vesicles. These are termed the *hydatids of Morgagni*.

Structure.—The Fallopian tube consists of three coats: serous, muscular, and mucous. The *external* or *serous coat* is peritoneal. The *middle* or *muscular coat* consists of

an external longitudinal and an internal circular layer of non-striped muscular fibres continuous with those of the uterus. The *internal* or *mucous coat* is continuous with the mucous lining of the uterus, and, at the free extremity of the tube, with the peritoneum. It is thrown into longitudinal folds, which in the outer, larger part of the tube, or ampulla, are much more extensive than in the narrow canal of the isthmus. The lining epithelium is columnar and ciliated. This form of epithelium is also found on the inner surface of the fimbriæ; while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

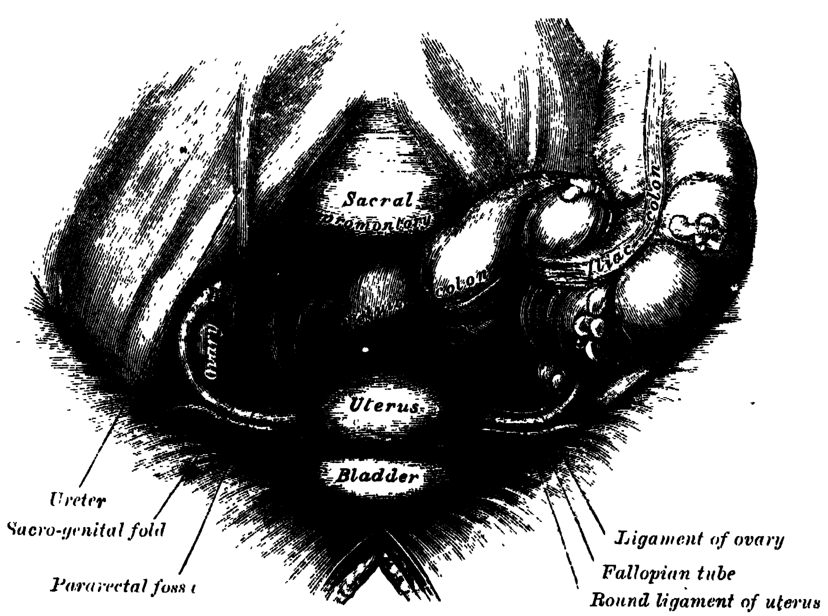
Applied Anatomy.—The majority of the diseases of the Fallopian tube are due to infections which have spread by way of the vagina and uterus, and the disease often does not stop at the Fallopian tube, but passes on to the peritoneum, giving rise to acute general peritonitis, or a localised condition termed *perimetritis* that may be acute or chronic. Perimetritis is often followed by various painful conditions, which are due to the peritoneal adhesions resulting from the inflammation of the serous membrane, and which persist throughout life. Tubal inflammation (*salpingitis*) is usually the result of an infection either by the gonococcus or by septic organisms implanted at the time of labour or abortion. In many cases the fimbriated ends of the tubes become closed by adhesions, pus collects in the tubes, and a *pyosalpinx* results.

Fertilisation of the ovum has been stated (page 83) to occur in the tube, and the fertilised ovum is then normally passed on into the uterus; the ovum, however, may segment whilst it is still in the Fallopian tube, giving rise to the commonest variety of *ectopic gestation*. In such cases the amnion and chorion are formed, but a true decidua is never present; and the gestation usually terminates by extrusion of the ovum through the abdominal ostium, although it is not uncommon for the tube to rupture into the peritoneal cavity, this being accompanied by severe hæmorrhage, and needing surgical interference.

THE UTERUS (figs. 1010, 1013, 1014)

The **uterus**, or **womb**, is a hollow, thick-walled, muscular organ situated deeply in the pelvic cavity between the bladder and rectum. Into its upper part the Fallopian tubes open, one on either side, while below, its cavity communicates with that of the vagina. When the ova are discharged from

FIG. 1013.—Female pelvis and its contents, seen from above and in front.



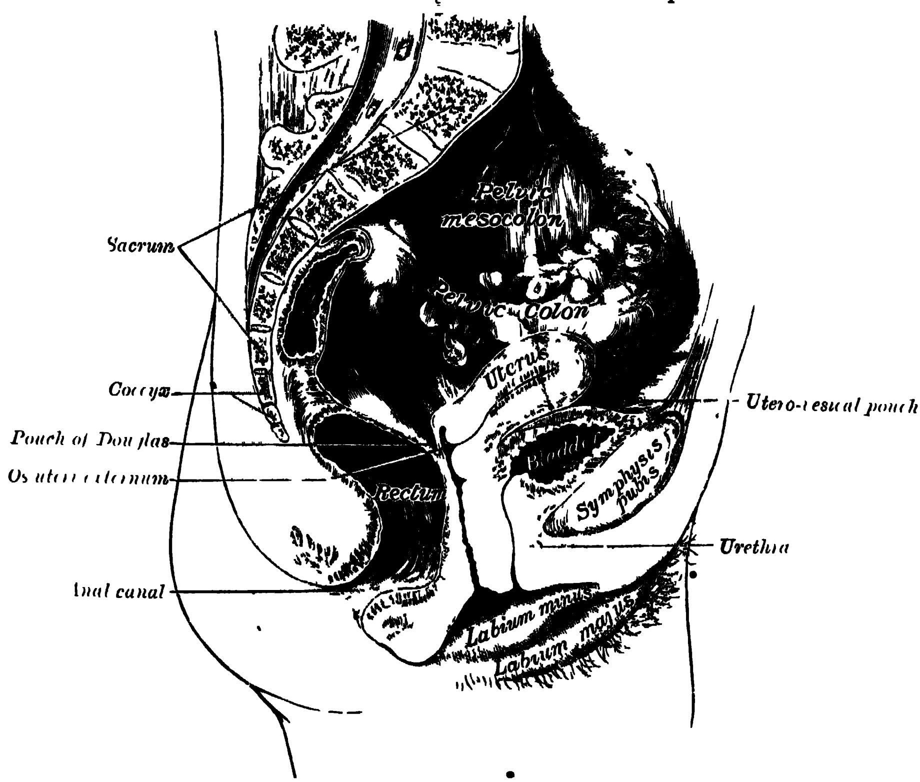
the ovaries they are carried to the uterine cavity through the Fallopian tubes. If an ovum be fertilised it imbeds itself in the uterine wall and is normally retained in the uterus until pre-natal development is completed, the uterus undergoing changes in size and structure to accommodate itself to the needs of the growing embryo (see page 97). After parturition the uterus returns

almost to its former condition, but certain traces of its enlargement remain. It is necessary therefore to describe as the type-form the adult virgin uterus, and then to consider the modifications which are effected as a result of pregnancy.

In the virgin state the uterus is flattened antero-posteriorly and is pyriform in shape, with the apex directed downwards and backwards. It lies between the bladder in front and the pelvic colon and rectum behind, and is completely within the pelvis, so that its base is below the level of the pelvic brim. Its upper part is suspended by the broad and the round ligaments, while its lower portion is imbedded in the fibrous tissue of the pelvis.

The long axis of the uterus usually lies approximately in the axis of the pelvic brim, but as the organ is freely movable its position varies with the state of distension of the bladder and rectum. Except when much displaced by a fully distended bladder, it forms an angle with the vagina, since the axis of the vagina corresponds to the axes of the cavity and outlet of the pelvis.

FIG. 1014.—Median sagittal section of female pelvis.



The uterus measures about three inches in length, two inches in breadth at its upper part, and nearly an inch in thickness; it weighs from an ounce to an ounce and a half. It is divisible into two portions. On the surface, about midway between the apex and base, is a slight constriction, known as the *isthmus* (isthmus uteri), and corresponding to this in the interior is a narrowing of the uterine cavity, the *internal os* (orificium internum uteri). The portion above the isthmus is termed the *body*, and that below, the *cervix*. The part of the body which lies above a plane passing through the points of entrance of the Fallopian tubes is known as the *fundus* (fundus uteri).

Body (corpus uteri).—The body gradually narrows from the fundus to the isthmus.

The *anterior surface* (facies vesicalis) is flattened and covered by peritoneum, which is reflected on to the bladder to form the utero-vesical pouch. The surface lies in apposition with the bladder.

The *posterior surface* (facies intestinalis) is convex transversely, and is covered by peritoneum, which is continued down on to the cervix and vagina.

It is in relation with the pelvic colon, from which it is usually separated by some coils of small intestine.

The *superior surface* is part of the fundus. It is slightly convex in all directions, and covered by peritoneum continuous with that on the anterior and posterior surfaces. On it rest some coils of small intestine, and occasionally the distended pelvic colon.

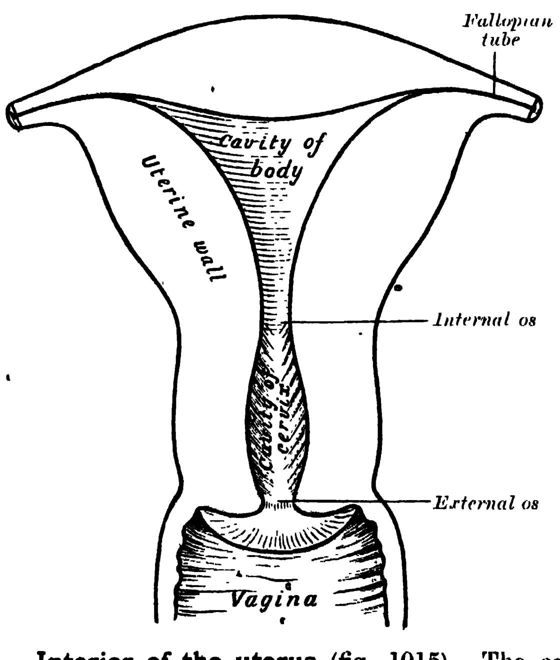
The *lateral margins* (margines laterales) are slightly convex. At the upper end of each the Fallopian tube pierces the uterine wall. Below and in front of this point the round ligament of the uterus is attached, while behind it, is the attachment of the ligament of the ovary. These three structures lie within a fold of peritoneum which is reflected from the margin of the uterus to the wall of the pelvis, and is named the broad ligament.

Cervix (cervix uteri).—The cervix is the lower constricted segment of the uterus. It is somewhat conical in shape, with its truncated apex directed downwards and backwards, but is slightly wider in the middle than either above or below. Owing to its relationships, it is less freely movable than the body, so that the latter may bend on it. The long axis of the cervix is therefore seldom in the same straight line as the long axis of the body. The long axis of the uterus as a whole presents the form of a curved line with its concavity forwards, or in extreme cases may present an angular bend at the region of the isthmus.

The vaginal wall is attached round the cervix, and divides it into two portions: an upper, supravaginal portion, and a lower, vaginal portion.

The *supravaginal portion* (portio supravaginalis) of the cervix is separated *in front* from the bladder by fibrous tissue (*parametrium*), which extends also on to its *sides* and outwards between the layers of the broad ligaments. The uterine arteries reach the margins of the cervix in this fibrous tissue, while on either side the ureter runs downwards and forwards in it at a distance of about three-quarters of an inch from the cervix. *Posteriorly*, the supravaginal cervix is covered by peritoneum, which is prolonged below on to the posterior vaginal wall, whence it is reflected on to the rectum, forming the recto-vaginal pouch or pouch of Douglas. It is in relation with the rectum, from which it may be separated by coils of small intestine.

FIG. 1015.—Vertical transverse section of uterus and upper part of vagina.



The *vaginal portion* (portio vaginalis) of the cervix projects free into the roof of the vagina between the anterior and posterior fornices. On its rounded extremity is a small, depressed, somewhat circular aperture, the *external os* (orificium externum uteri), through which the cavity of the cervix communicates with that of the vagina. The external os is bounded by two lips, an anterior (labium anterius cervicis) and a posterior (labium posterius cervicis), of which the anterior is the shorter and thicker, although, on account of the slope of the cervix, it projects lower than the posterior. Normally both lips are in contact with the posterior vaginal wall.

Interior of the uterus (fig. 1015).—The cavity of the uterus is small in comparison with the size of the organ.

The **cavity of the body** is a mere slit, flattened antero-posteriorly. It is triangular in shape, the base being formed by the internal surface of the fundus between the uterine orifices of the Fallopian tubes, the apex by the internal os through which the cavity of the body communicates with the cavity of the cervix.

The **cavity of the cervix** (canalis cervicis uteri) is somewhat fusiform, flattened from before backwards, and broader at the middle than at either extremity. It communicates above through the internal os with the cavity of the body, and below through the external os with the vaginal cavity. The wall of the canal presents an anterior and a posterior longitudinal ridge, from each of which proceed a number of small oblique columns, giving the appearance of branches from the stem of a tree; to this arrangement the name *arbor vitæ uterina* is applied. The longitudinal ridges are not exactly opposed, but fit against one another so as to close the cervical canal.

The total length of the uterine cavity from the external os to the fundus is about two and a half inches.

Ligaments.—The ligaments of the uterus are eight in number: one anterior; one posterior; two lateral or broad; two utero-sacral; and, lastly, two round ligaments.

The *anterior ligament* consists of the utero-vesical fold of peritoneum, which is reflected on to the bladder from the front of the uterus, at the junction of the cervix and body.

The *posterior ligament* consists of the recto-vaginal fold of peritoneum, which is reflected from the back of the upper fourth of the vagina on to the front of the rectum. It forms the bottom of a deep pouch called *Douglas's pouch*, which is bounded in front by the posterior wall of the uterus, the supravaginal cervix, and the upper fourth of the vagina; behind, by the rectum; and laterally by two crescentic folds of peritoneum which pass backwards from the cervix uteri on either side of the rectum to the posterior wall of the pelvis. These folds are named the *sacro-genital*, or *recto-uterine folds*. They contain a considerable amount of fibrous tissue and non-striped muscular fibres which are attached to the front of the sacrum and constitute the *utero-sacral ligaments*.

The *two lateral* or *broad ligaments* pass from the sides of the uterus to the lateral walls of the pelvis. Together with the uterus they form a septum across the female pelvis, which divides that cavity into two portions. In the anterior part is contained the bladder; in the posterior part, the rectum, and in certain conditions some coils of the small intestine and a part of the pelvic colon. Between the two layers of each broad ligament are contained: (1) the Fallopian tube superiorly; (2) the round ligament; (3) the ovary and its ligament; (4) the parovarium, or organ of Rosenmüller; (5) connective tissue; (6) unstriped muscular fibre; and (7) blood-vessels and nerves. The portion of the broad ligament which stretches from the Fallopian tube to the level of the ovary is known by the name of the *mesosalpinx*. Between the fimbriated extremity of the tube and the lower attachment of the broad ligament is a concave rounded margin, called the *infundibulo-pelvic ligament*.

The *round ligaments* are two flattened bands between four and five inches in length, situated between the layers of the broad ligament in front of and below the Fallopian tubes. Commencing on either side at the superior angle of the uterus, this ligament is directed forwards, upwards, and outwards over the pelvic brim. It then passes through the internal abdominal ring and along the inguinal canal to the labium majus, in which it becomes lost. The round ligament consists principally of muscular tissue, prolonged from the uterus; also of some fibrous and areolar tissue, besides blood-vessels and nerves, enclosed in a duplicature of peritoneum, which, in the fœtus, is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the *canal of Nuck*. It is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the processus vaginalis which precedes the descent of the testis.

In addition to the ligaments just described, there is a band named the *ligamentum transversalis colli* (Mackenrodt) on either side of the cervix uteri. It is attached to the lateral aspect of the cervix uteri and to the vault and lateral fornix of the vagina, and is

continuous externally with the fibrous tissue which surrounds the pelvic blood-vessels. (Consult a note on the lateral fixation of the uterus by Ella G. A. Ovenden, 'Journal of Anatomy and Physiology,' vol. xli., part iv., p. 308.)

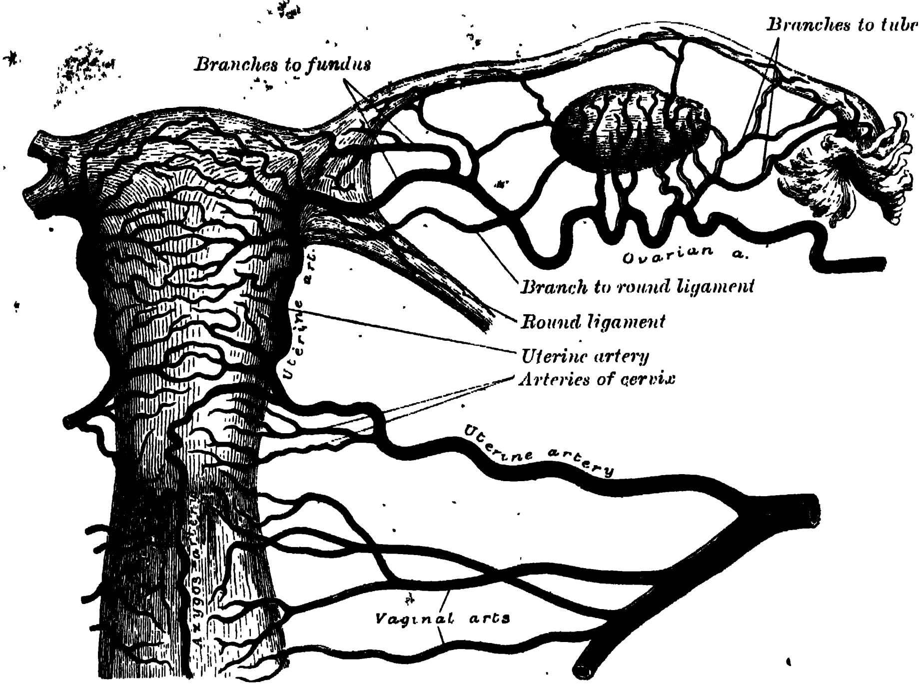
The form, size, and situation of the uterus vary at different periods of life and under different circumstances.

In the fœtus the uterus is contained in the abdominal cavity, projecting beyond the brim of the pelvis (fig. 1017). The cervix is considerably larger than the body.

At puberty the uterus is pyriform in shape, and weighs from eight to ten drachms. It has descended into the pelvis, the fundus being just below the level of the brim of this cavity. The arbor vitæ is distinct, and extends to the upper part of the cavity of the organ.

The position of the uterus in the adult is liable to considerable variation, depending chiefly on the condition of the bladder and rectum. When the bladder is empty the entire uterus is directed forwards, and is at the same time bent on itself at the junction of the body and cervix, so that the body lies upon the bladder. As the latter fills, the uterus gradually becomes more and more erect, until with a fully distended bladder the fundus may be directed backwards towards the sacrum.

Fig. 1016.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)



During menstruation the organ is enlarged, and more vascular, its surfaces rounder; the os externum is rounded, its labia swollen, and the lining membrane of the body thickened, softer, and of a darker colour. According to Sir J. Williams, at each recurrence of menstruation, a molecular disintegration of the mucous membrane takes place, which leads to its complete removal, only the bases of the glands imbedded in the muscle being left. At the cessation of menstruation, by a proliferation of the remaining structures, a fresh mucous membrane is formed.

During pregnancy the uterus becomes enormously enlarged, and in the eighth month reaches the epigastric region. The increase in size is partly due to growth of pre-existing muscle, and partly to development of new fibres.

After parturition the uterus nearly regains its usual size, weighing about an ounce and a half; but its cavity is larger than in the virgin state, its vessels are tortuous, and its muscular layers are more defined; the external orifice is more marked, and its edges present one or more fissures.

In old age the uterus becomes atrophied, and paler and denser in texture; a more distinct constriction separates the body and cervix. The ostium internum is frequently, and the ostium externum occasionally, obliterated, while the labia almost entirely disappear.

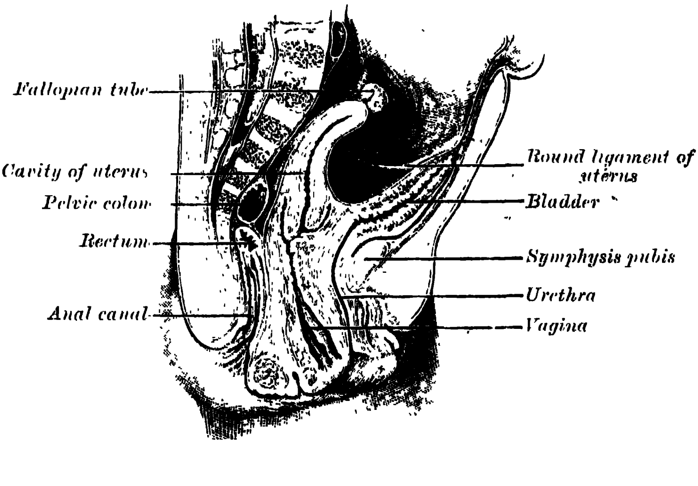
Structure.—The uterus is composed of three coats: an external or serous coat, a middle or muscular coat, and an internal or mucous coat.

The *serous coat* is derived from the peritoneum; it invests the fundus and the whole of the posterior surface of the uterus; but covers the anterior surface only as far as the junction of the body and cervix. In the lower fourth of the posterior surface the peritoneum, though covering the uterus, is not closely connected with it, being separated from it by a layer of loose cellular tissue and some large veins.

The *muscular coat* forms the chief bulk of the substance of the uterus. In the virgin it is dense, firm, of a greyish colour, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the Fallopian tubes. It consists of bundles of unstriped muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. During pregnancy the muscular tissue becomes more prominently developed, and is disposed in three layers: external, middle, and internal.

The external layer, placed beneath the peritoneum, is disposed as a thin plane on the anterior and posterior surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each superior angle of the uterus, are continued on to the Fallopian tube, the round ligament, and the ligament of the ovary: some passing at each side into the broad ligament, and others running backwards from the cervix into the sacro-uterine ligaments. The middle layer of fibres, which is thickest, presents no regularity in its arrangement, being disposed longitudinally, obliquely, and transversely. It contains most blood-vessels. The internal or deep layer consists of circular fibres arranged in the form of two hollow cones, the apices of which surround the orifices of the Fallopian

Fig. 1017.—Sagittal section through the pelvis of a newly born female child.



tubes, their bases intermingling with one another on the middle of the body of the uterus. At the internal os these circular fibres form a distinct sphincter.

The *mucous membrane* is thin, smooth, and closely adherent to the subjacent tissue. It is continuous, through the fimbriated extremity of the Fallopian tubes, with the peritoneum; and, through the os uteri, with the lining of the vagina.

In the body of the uterus the mucous membrane is smooth, soft, of a pale red colour, lined by columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles, arranged perpendicularly to the surface. It is unprovided with any submucosa, but is intimately connected with the innermost layer of the muscular coat, which by some anatomists is regarded as the muscularis mucosæ. The structure of the corium differs from that of ordinary mucous membranes, and consists of an embryonic nucleated and highly cellular form of connective tissue in which run numerous large lymphatics. In it are the tube-like *uterine glands*, which are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged and elongated, presenting a contorted or waved appearance (see page 97). They consist of a delicate membrane lined by an epithelium, which becomes ciliated towards the orifices.

In the cervix the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous oblique ridges, which diverge from an anterior and posterior longitudinal raphe, presenting an appearance which has received the name of *arbor vitæ*. In the upper two-thirds of the canal, the mucous membrane is provided with numerous deep glandular follicles, which secrete a clear viscid alkaline mucus; and, in addition, extending through the whole length of the canal is a variable number of little cysts, presumably follicles which have become occluded and distended with retained

secretion. They are called the *ovula Nabothi.* The mucous membrane covering the lower half of the cervical canal presents numerous papillæ. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and gradually changes to squamous epithelium close to the external os. On the vaginal surface of the cervix the epithelium is similar to that lining the vagina, viz. stratified squamous.

Vessels and Nerves.—The *arteries* of the uterus are the uterine, from the internal iliac; and the ovarian, from the abdominal aorta (fig. 1016). They are remarkable for their tortuous course in the substance of the organ, and for their frequent anastomoses. The termination of the ovarian artery meets the termination of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus, their disposition being, as shown by Sir John Williams, circular. The *veins* are of large size, and correspond with the arteries. They terminate in the uterine plexuses. In the impregnated uterus the arteries carry the blood to, and the veins convey it away from, the maternal blood-sinuses of the placenta (see page 100). The *lymphatics* are described on page 789. The *nerves* are derived from the hypogastric and ovarian plexuses, and from the third and fourth sacral nerves.

Applied Anatomy.—A certain amount of anteversion and retroversion can take place without the condition being regarded as pathological, but when the degree of flexion becomes considerable it must be regarded as a morbid condition. This is especially true of retroversion and retroflexion. The former is a falling back of the whole uterus, so that the cervix points upwards towards the pubes, and the latter is a bending backwards of the body, the cervix remaining in its normal position. The two conditions are usually combined. Prolapse of the uterus is another common infirmity. The organ sinks to an abnormally low level in the pelvis, and sometimes protrudes beyond the vulva. This is due to the supporting mechanism of the uterus being insufficient to sustain the strain thrown upon it.

The uterus may require removal in cases of malignant disease or for fibroid tumours. Carcinoma is the most common form of malignant disease of the uterus, though cases of sarcoma do occur. It may show itself either as a columnar carcinoma or as a squamous carcinoma; the former commencing either in the cervix or body of the uterus, the latter always commencing in the epithelial cells of the mucous covering of the vaginal surface of the cervix. Cancer of the body or of the cervix may be treated in the early stage, before fixation has taken place, by removal of the uterus, either through the vagina or by means of abdominal section, but if the body be much enlarged the former operation is impossible. Vaginal hysterectomy is performed by placing the patient in the lithotomy position and introducing a large duckbill speculum. The cervix is then seized with a volsellum and pulled down as far as possible, and the mucous membrane of the vagina incised around the cervix and as near to it as the disease will allow, especially in front, where the ureters are in danger of being wounded. Douglas's pouch is then opened sufficiently to allow of the introduction of the two forefingers, by means of which the opening is dilated laterally as far as the sacro-uterine ligaments. A somewhat similar proceeding is adopted in front, but here the bladder has to be separated from the anterior wall of the uterus for about an inch before the vesico-uterine fold of peritoneum can be reached. This is done by carefully burrowing upwards with a director and stripping the tissues off the anterior uterine wall. When the vesico-uterine pouch has been opened and the aperture dilated laterally, the uterus remains attached only by the broad ligaments, in which are contained the vessels that supply the uterus. Before division of the ligaments, these vessels have to be dealt with. The forefinger of the left hand is introduced into Douglas's pouch, and an aneurysm needle, armed with a long silk ligature, is inserted into the vesico-uterine pouch, and is pushed through the broad ligament about an inch above its lower level and at some distance from the uterus. One end of the ligature is now pulled through the anterior opening, and in this way we have the lowest inch of the broad ligament, in which is contained the uterine artery (fig. 1016), enclosed in a ligature. This is tied tightly, and the operation is repeated on the other side. The broad ligament is then divided on either side, between the ligature and the uterus, to the extent to which it has been constricted. By traction on the volsellum which grasps the cervix, the uterus can be pulled considerably further down in the vagina, and a second inch of the broad ligament is treated in a similar way. This second ligature will embrace the pampiniform plexus of veins, and, when the broad ligament has been divided on either side, it will be found that a third ligature can be made to pass over the Fallopian tube and top of the broad ligament, after the uterus has been dragged down as far as possible. After the third ligature has been tied and the structures between it and the uterus divided, this organ will be freed from all its connections and can be removed from the vagina. The third ligature will contain the ovarian artery, between the ovary and the uterine cornu, as it lies below the Fallopian tube. The vagina is then sponged out and lightly dressed with gauze; no sutures being used.

In the treatment of uterine fibroids which require operative interference, removal of the whole of the uterus together with the tumours through an abdominal incision gives the most satisfactory results; for, if the tumour is large, its size acts as a barrier to its safe delivery through the pelvis and genital passages. After the abdomen has been opened the uterine vessels are secured and the broad ligaments divided in a manner similar to that

employed in vaginal hysterectomy, except that the proceeding is commenced from above. When the first two ligatures have been tied, and the broad ligament divided, it will be found that the uterus can be raised out of the pelvis. A transverse incision is now made through the peritoneum, where it is reflected from the anterior surface of the uterus on to the back of the bladder, and the serous membrane peeled from the surface of the uterus until the vagina is reached. The anterior wall of this canal is then cut across. The uterus is now turned forwards and the peritoneum at the bottom of Douglas's pouch incised transversely, and the posterior wall of the vagina cut across, until it meets the incision on the anterior wall. The uterus is now almost free, and is held only by the lower part of the broad ligament on either side, containing the uterine artery. A third ligature is made to encircle this as close to the uterus as possible, the position of the ureter being always kept in mind, and, after having been tied, the structures are divided between the ligature and the uterus. The organ can now be removed. The vagina is plugged with gauze, and the external wound closed in the usual way. The vagina acts as a drain, and therefore the opening into it is not sutured.

Inflammation of the cellular tissue surrounding the cervix occasionally takes place. Laceration of the cervix by instruments or by the fœtal head frequently occurs, opening up the cellular planes and so exposing them to any infection that may be present. An inflammatory mass forms in the cellular tissue between the layers of the broad ligament or of the utero-sacral ligaments, and the condition is termed pelvic cellulitis, or *parametritis*. This condition is usually confined to one side of the pelvis, forming a large inflammatory mass which pushes the uterus over to the opposite side. It does not always remain localised, however, but may spread widely, surrounding the rectum or the neck of the bladder, or mounting into the iliac fossa, or even to the perinephric cellular tissue. The condition may resolve or an abscess may form. In the former condition the cicatrisation of the inflammatory products often produces displacements of the uterus towards the affected side of the pelvis, or stricture of the rectum when that viscus has been surrounded by the process. When suppuration ensues, the pus may burst into the bladder, vagina, or rectum, or it may present above Poupart's ligament, or it may mount to the anterior abdominal wall in front of the bladder or to the posterior abdominal wall between the iliac crest and last rib. The abscess may, moreover, make its way into the buttock by passing out of the pelvis through the great sacro-sciatic foramen, or it may pass down between the fibres of the Levator ani and appear as a secondary ischio-rectal abscess.

THE VAGINA (fig. 1014)

The **vagina** extends from the vestibule to the uterus, and is situated behind the bladder and in front of the rectum; it is directed upwards and backwards, its axis forming with that of the uterus an angle of over 90°, opening forwards. Its walls are ordinarily in contact, and the usual shape of its lower part on transverse section is that of an H, the transverse limb being slightly curved forwards or backwards, while the lateral limbs are somewhat convex towards the median line; its middle part has the appearance of a transverse slit. Its length is two and a half to three inches along its anterior wall, and three and a half inches along its posterior wall. It is constricted at its commencement, dilated in the middle, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix uteri, a short distance from the os, its attachment extending higher up on the posterior than on the anterior wall of the uterus. To the recess behind the cervix the term *posterior fornix* is applied, while the smaller recess in front is termed *anterior fornix*.

The *anterior surface* of the vagina is in relation with the base of the bladder, and with the urethra. Its *posterior surface* is connected for the middle two fourths of its extent to the anterior wall of the rectum, the upper fourth being separated from that tube by the recto-vaginal pouch of peritoneum, or pouch of Douglas. The lower fourth is separated from the anal canal by the perinæum. Its sides are enclosed between the Levatores ani muscles. As the terminal portions of the ureters pass forwards and inwards to reach the base of the bladder, they run one on either side of the lateral aspect of the upper part of the vagina.

Structure.—The vagina consists of an internal mucous lining, and a muscular coat, separated by a layer of erectile tissue.

The *mucous membrane* is continuous above with that lining the uterus. Its inner surface presents two longitudinal ridges, one on its anterior and one on its posterior wall. These ridges are called the *columns of the vagina*, and from them numerous transverse ridges or rugæ extend outwards on either side. These rugæ are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillæ; they are most numerous near the orifice of the vagina, especially in females before parturition. The epithelium covering the mucous membrane

is of the stratified squamous variety. The submucous tissue is very loose, and contains numerous large veins, which by their anastomoses form a plexus, together with smooth muscular fibres derived from the muscular coat; it is regarded by Gussenbauer as an erectile tissue. It contains a number of mucous crypts, but no true glands.

The *muscular coat* consists of two layers: an external longitudinal, which is by far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the recto-vesical fascia on each side. The two layers are not distinctly separable from each other, but are connected by oblique decussating fasciculi, which pass from the one layer to the other. In addition to this, the vagina at its lower end is surrounded by a band of striped muscular fibres, the *Sphincter vaginæ* (see page 526).

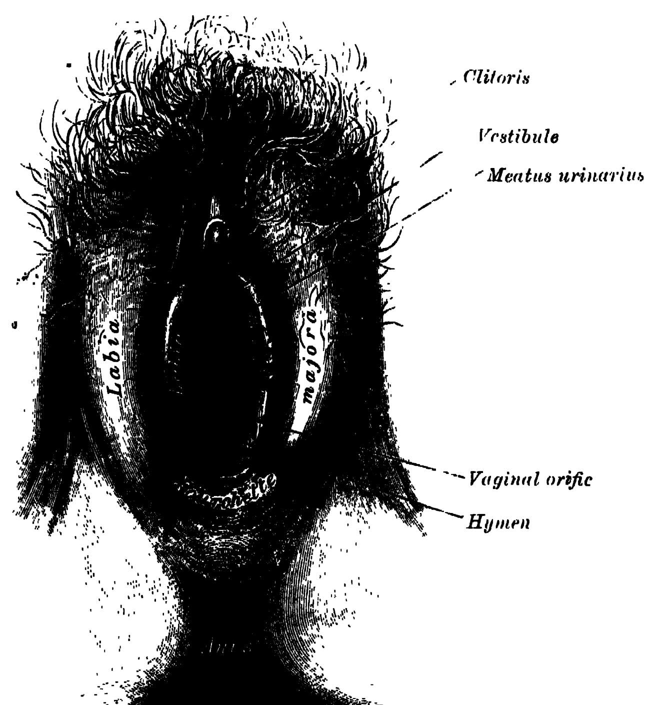
External to the muscular coat is a layer of connective tissue, containing a large plexus of blood-vessels.

The *erectile tissue* consists of a layer of loose connective tissue, situated between the mucous membrane and the muscular coat; imbedded in it is a plexus of large veins, and numerous bundles of unstriped muscular fibres, derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

External Organs (fig. 1018)

The **external genital organs of the female** are: the mons Veneris, the labia majora et minora, the clitoris, the bulbus vestibuli, and the glands of Bartholin. The term *vulva* or *pudendum* (pudendum muliebre), as generally applied, includes all these parts.

Fig. 1018.—External genital organs of female. The labia minora have been drawn apart.



The **mons Veneris** is the rounded eminence in front of the pubic symphysis, formed by a collection of fatty tissue beneath the integument. It becomes covered with hair at the time of puberty.

The **labia majora** (labia majora pudendi) are two prominent longitudinal cutaneous folds which extend downwards and backwards from the mons

Veneris and form the lateral boundaries of a fissure or cleft, the *urogenital cleft* (rima pudendi) into which the vagina and urethra open. Each labium has two surfaces, an outer, pigmented and covered with strong, crisp hairs; and an inner, smooth and beset with large sebaceous follicles. Between the two there is a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos of the scrotum, besides vessels, nerves, and glands. The labia are thicker in front, where they form by their meeting the *anterior commissure* (commissura labiorum anterior). Posteriorly they are not really joined, but appear to become lost in the neighbouring integument, terminating close to, and nearly parallel with, each other. Together with the connecting skin between them, they form the *posterior commissure* (commissura labiorum posterior), or posterior boundary of the vulval orifice. The interval between the posterior commissure and the anus, from an inch to an inch and a quarter in length, constitutes the perinæum. The labia majora correspond to the scrotum in the male.

The **labia minora,** or **nymphæ** (labia minora pudendi), are two small cutaneous folds, situated within the labia majora, and extending from the clitoris obliquely downwards, outwards, and backwards for about an inch and a half on each side of the orifice of the vagina, between which and the labia majora they are lost; in the virgin the posterior ends of the labia minora are usually joined across the middle line by a fold of skin, named the *fourchette* (frenulum labiorum pudendi). Anteriorly, each labium minus divides into two portions: the upper division passes above the clitoris to meet its fellow of the opposite side, forming a fold which overhangs the glans clitoridis and is named the *præputium clitoridis*; the lower division passes beneath the clitoris and becomes united to its under surface, forming, with its fellow of the opposite side, the *frenulum clitoridis*. On the internal surfaces of the labia minora are numerous sebaceous follicles.

The **clitoris** is an erectile structure, homologous with the penis. It is situated beneath the anterior commissure, partially hidden between the anterior extremities of the labia minora. It consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous membrane, united together along their inner surfaces by an incomplete fibrous pectiniform septum; these are connected to the rami of the pubis and ischium on either side by a crus; the free extremity, or *glans clitoridis*, is a small rounded tubercle, consisting of spongy erectile tissue, and highly sensitive. The clitoris is provided, like the penis, with a suspensory ligament, and with two small muscles, the Erectores clitoridis, which are inserted into the crura of the clitoris.

The **vestibule.**—The cleft between the labia minora and behind the glans clitoridis is named the *vestibule* (vestibulum vaginæ): in it are seen the urethral and vaginal orifices and the openings of the ducts of Bartholin's glands.

The **urethral orifice** (orificium urethræ externum) is placed about an inch behind the glans clitoridis and immediately in front of that of the vagina; it usually assumes the form of a short, sagittal cleft with slightly raised margins.

The **vaginal orifice** (orificium vaginæ) is a mesial slit below and behind the opening of the urethra; its size varies inversely with the degree of development of the *hymen.*

The **hymen** is a thin fold of mucous membrane situated at the orifice of the vagina; the inner surfaces of the fold are normally in contact with each other, and the vaginal orifice appears as a cleft between them. The hymen varies much in shape. When stretched, its commonest form is that of a ring, generally broadest posteriorly; sometimes it is represented by a semilunar fold, with its concave margin turned towards the pubes. Occasionally it is cribriform, or its free margin forms a membranous fringe. It may be entirely absent, or may form a complete septum across the lower end of the vagina; the latter condition is known as an imperforate hymen. It may persist after copulation, so that it cannot be considered as a test of virginity. When the hymen has been ruptured, small rounded elevations known as the *carunculæ hymeneales* are found as its remains. Between the hymen and the fourchette is a shallow depression, named the *fossa navicularis.*

The **bulbus vestibuli** is the homologue of the bulb and adjoining part of the corpus spongiosum of the male, and consists of two elongated masses

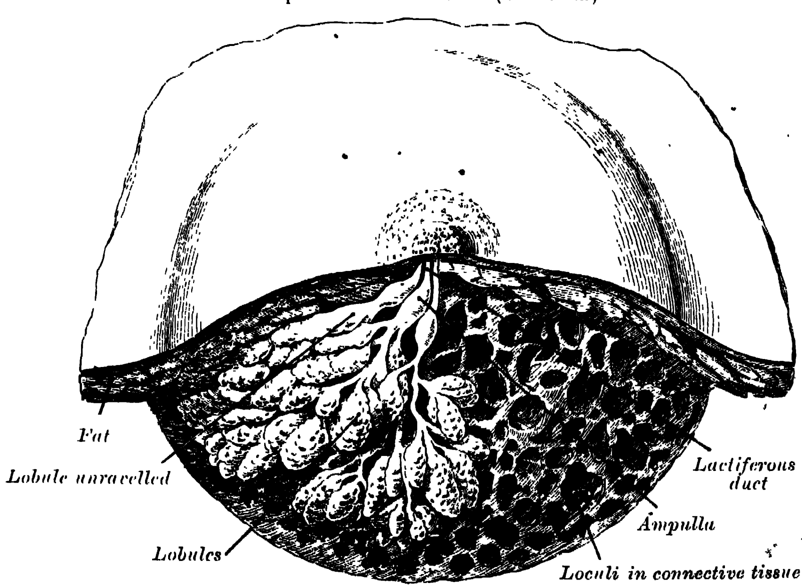
of erectile tissue, placed one on either side of the vaginal orifice and united to each other in front by a narrow median band termed the *pars intermedia*. Each lateral mass measures a little over an inch in length. Their posterior ends are expanded and are in contact with the glands of Bartholin; their anterior ends are tapered and joined to one another by the pars intermedia: their deep surfaces are in contact with the triangular ligament; superficially they are covered by the Bulbo-cavernosus muscle.

The **glands of Bartholin** (glandulæ vestibulares majores) are the homologues of Cowper's glands in the male. They consist of two small, roundish bodies of a reddish-yellow colour, situated one on either side of the vaginal orifice in contact with the posterior end of each lateral mass of the bulbus vestibuli. Each gland opens by means of a duct, about three-quarters of an inch in length, immediately external to the hymen, in the groove between it and the labium minus.

Mammary Glands

The **mammæ**, or breasts, secrete the milk, and are accessory glands of the generative system. They exist in the male as well as in the female; but in the former only in the rudimentary state, unless their growth is excited by peculiar circumstances. In the female they are two large hemispherical eminences lying within the superficial fascia and situated towards the lateral aspect of the pectoral region; they correspond to the intervals between the second and sixth ribs, and extend from the side of the sternum to near the mid-axillary line. Their weight and dimensions differ at different periods of life, and in different individuals. Before puberty they are of small size, but enlarge as the generative organs become more completely developed.

Fig. 1019.—Dissection of the lower half of the female breast during the period of lactation. (Luschka.)



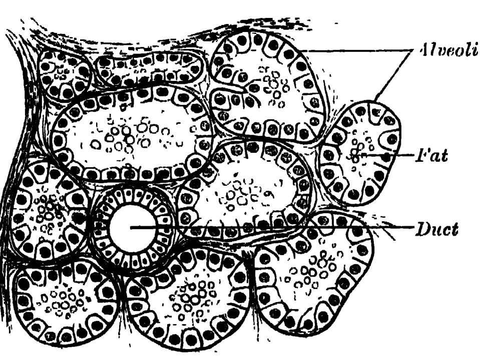
They increase during pregnancy, and especially after delivery, and become atrophied in old age. The left mamma is generally a little larger than the right. The base of each is nearly circular, flattened, or slightly concave, and has its long diameter directed upwards and outwards towards the axilla; it is separated from the fascia covering the Pectoralis major and Serratus magnus muscles by loose connective tissue. The outer surface of the mamma is convex, and presents, just below the centre, a small conical prominence, the nipple.

The **nipple** (papilla mammæ) is a cylindrical or conical eminence, capable of undergoing a sort of erection from mechanical excitement, a change mainly

due to the contraction of its muscular fibres. It is of a pink or brownish hue, its surface wrinkled and provided with papillæ; and it is perforated by from fifteen to twenty orifices, the apertures of the lactiferous ducts. The surface of the nipple is dark-coloured, and surrounded by an *areola* having a coloured tint. In the virgin the areola is of a delicate rosy hue; about the second month after impregnation it enlarges and acquires a darker tinge, which increases as pregnancy advances, becoming in some cases of a dark brown, or even black colour. This colour diminishes as soon as lactation is over, but is never entirely lost throughout life. These changes in the colour of the areola are of importance in forming a conclusion in a case of suspected first pregnancy. Near the base of the nipple, and upon the surface of the areola, are numerous large sebaceous glands (*glands of Montgomery*), which become much enlarged during lactation, and present the appearance of small tubercles beneath the skin. These glands secrete a peculiar fatty substance, which serves as a protection to the integument of the nipple during the act of sucking. The nipple consists of numerous vessels, intermixed with plain muscular fibres, which are principally arranged in a circular manner around the base: some few fibres radiating from base to apex. The nipple and areola are closely attached to the skin.

Structure (figs. 1019, 1020).—The mamma consists of gland-tissue; of fibrous tissue, connecting its lobes; and of fatty tissue in the intervals between the lobes. The gland-tissue, when freed from fibrous tissue and fat, is of a pale reddish colour, firm in texture, flattened from before backwards and thicker in the centre than at the circumference. The anterior surface of the mamma presents numerous irregular processes which project towards the skin and are joined to it by bands of connective tissue. It consists of numerous lobes, and these are composed of lobules, connected together by areolar tissue, blood-vessels, and ducts. The smallest lobules consist of a cluster of rounded alveoli, which open into the smallest branches of the lactiferous ducts; these ducts unite to form larger ducts, and these terminate in a single canal, corresponding with one of the chief subdivisions of the gland. The number of excretory ducts varies from fifteen to twenty; they are termed the *tubuli lactiferi*. They converge towards the areola, beneath which they form dilatations, or *ampullæ*, which serve as reservoirs for the milk, and, at the base of the nipple, become contracted, and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The ducts are composed of areolar tissue containing longitudinal and transverse elastic fibres; muscular fibres are entirely absent; they are lined by columnar epithelium resting on a basement-membrane. The epithelium of the mammary gland differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or suckling, the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge, and the cells undergo rapid multiplication. At the commencement of lactation, the cells in the centre of the alveolus undergo fatty degeneration, and are eliminated in the first milk, as *colostrum corpuscles*. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells, with spherical nuclei, lining the basement-membrane.* The cells, during the state of activity of the gland, are capable of forming, in their interior, oil-globules, which are then ejected into the lumen of the alveolus, and constitute the milk-globules.

Fig. 1020.—Transverse section of portion of mammary gland.



The *fibrous tissue* invests the entire surface of the breast, and sends down septa between its lobes, connecting them together.

The *fatty tissue* covers the surface of the gland, and occupies the interval between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple.

* According to Lacroix and Benda, there is a thin layer of non-striped muscle between the basement-membrane and the secreting cells.

Vessels and Nerves.—The *arteries* supplying the mammæ are derived from the thoracic branches of the axillary, the intercostals, and the internal mammary. The *veins* describe an anastomotic circle round the base of the nipple, called by Haller the *circulus venosus.* From this, large branches transmit the blood to the circumference of the gland, and end in the axillary and internal mammary veins. The *lymphatics* are described on page 790. The *nerves* are derived from the anterior and lateral cutaneous nerves of the thorax.

Applied Anatomy.—The ducts descending from the nipple radiate through the gland, and when an incision is made into the breast the scalpel should be directed radially, from the centre to the periphery, so that it may not pass across the ducts. A milk duct may become obstructed and distended, forming a tumour known as a *galactocele.* *Abscess* frequently occurs about the breast, and most often in women who are lactating, especially those who have cracks or fissures about the nipple. The abscess may lie between the septa, in the breast-tissue itself; or it may lie beneath the skin by the side of the nipple and superficial to the breast; or it may form beneath it, between the breast and the deep fascia. Free incision, radiating from the nipple, is required in such cases.

Cystic formation of many different kinds is commonly seen in the mamma; in some cases it is due to dilatation of the larger ducts or of the lymph spaces throughout the gland; in others the cysts occur in new growths of the mamma, or as the result of obstruction of the smaller ducts by chronic inflammatory processes.

Malignant growths are seen more often in the breast than in any other organ; they are of great variety, but the commonest is the spheroidal-celled cancer, the cells of which are intermingled with a varying amount of fibrous tissue. A hard contracting tumour-mass results, which drags on the fibrous septa between the lobes so that fixation or retraction of the nipple ensues, and sooner or later the malignant infiltration invades the surrounding breast-tissues, the skin, the deep fascia and Pectorals, and even the chest wall and pleura. The lymphatic glands beneath the Pectorals and those situated towards the apex of the axilla become early involved with secondary malignant deposit, and later the supraclavicular glands enlarge. In other cases the mediastinal glands may be involved, when the disease is situated on the inner side of the nipple.

The operation for removal of a breast affected with malignant disease should be an extensive procedure, with the object of extirpating all fascial planes and lymphatic structures that may be infected. The incision commences below, over the upper part of the sheath of the Rectus, encloses the mamma by an ellipse, and is then continued on towards the apex of the axilla. The skin is reflected on both sides of the incision; anteriorly, till the sternum is reached, and posteriorly to the posterior boundary of the axilla. The origin of the sternal portion of the Pectoralis major is then divided and turned backwards. The Pectoralis minor is next seen, and its origin is then divided in a similar manner. The whole of the muscular and fascial planes of the front of the chest are thus separated *en masse,* carrying with them the mamma and the skin covering it. The insertions of the two Pectorals have next to be divided, and finally the axillary lymphatic glands and fat are removed from the axillary vessels in one piece with the mass of tissue already detached. This is done by first freely exposing the whole length of the axillary vein and then, with a blunt instrument, peeling the structures off the vein from above downwards, from the point where they are crossed by the Subclavius muscle to the lower border of the axilla. In this part of the operation many branches of both vein and artery require ligature. The only thing which then remains to be divided is the deep fascia along the posterior axillary wall. The wound is then closed, drainage is provided, and firm pressure is applied with the dressings. It will be noted that the clavicular portion of the Pectoralis major is left intact, as it is of considerable service for the subsequent movements of the arm, the utility of which is but slightly impaired.

THE DUCTLESS GLANDS

There are certain organs which are very similar to secreting glands, but differ from them in one essential particular, viz. they do not possess any ducts by which their secretion is discharged. These organs are known as *ductless glands.* They are capable of *internal secretion*—that is to say, of forming, from materials brought to them in the blood, substances which have a certain influence upon the nutritive and other changes going on in the body. This secretion is carried into the blood-stream, either directly by the veins or indirectly through the medium of the lymphatics.

These glands include the thyroid and the parathyroids, the thymus, the spleen, the suprarenal glands, and the small carotid and coccygeal bodies, which will be described in this section. They also include the lymphatic glands, which have already been described in the section on Angiology; and the pineal gland and pituitary body described in the section on Neurology.

The Thyroid Body (fig. 1021)

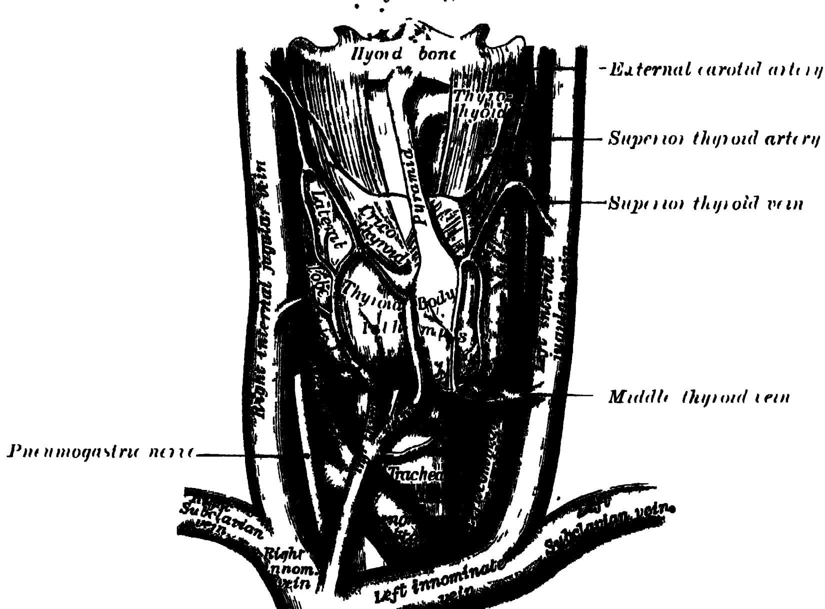
The **thyroid body** is a highly vascular organ, situated at the front and sides of the neck; it consists of two lateral lobes connected across the middle line by a narrow transverse portion, the *isthmus*.

The weight of the thyroid body is somewhat variable, but is usually about one ounce. It is slightly heavier in the female, in whom it becomes enlarged during menstruation and pregnancy.

The lobes are conical in shape, the apex of each being directed upwards and outwards as far as the junction of the middle with the lower third of the thyroid cartilage; the base looks downwards, and is on a level with the fifth or sixth tracheal ring. Each lobe is about two inches in length; its greatest width is about an inch and a quarter, and its thickness about three-quarters of an inch.

The *external* or *superficial surface* is convex, and covered by the skin, the superficial and deep fasciæ, the Sterno-mastoid, the anterior belly of the

Fig. 1021.—The thyroid gland and its relations.



Omo-hyoid, the Sterno-hyoid and Sterno-thyroid muscles, and beneath the last muscle by the pre-tracheal layer of the deep fascia, which forms a capsule for the gland. The *deep* or *internal surface* is moulded over the underlying structures, viz. the thyroid and cricoid cartilages, the trachea, the Inferior constrictor and posterior part of the Crico-thyroid muscles, the œsophagus (particularly on the left side of the neck), the superior and inferior thyroid arteries, and the recurrent laryngeal nerves. The *anterior border* is thin, and inclines obliquely from above downwards and inwards towards the middle line of the neck, while the *posterior border* is thick and overlaps the common carotid artery.

The *isthmus* connects together the lower thirds of the two lateral lobes; it measures about half an inch in breadth, and the same in depth, and usually covers the second and third rings of the trachea. Its situation and size present, however, many variations, and this must be remembered in performing tracheotomy. In the middle line of the neck it is covered by the skin and

fascia, and close to the middle line, on either side, by the Sterno-hyoid. Across its upper border runs a branch of the superior thyroid artery; at its lower border are the inferior thyroid veins. Sometimes the isthmus is altogether wanting.

A third lobe, of conical shape, called the *pyramid*, frequently arises from the upper part of the isthmus, or from the adjacent portion of either lobe, but most commonly the left, and ascends as high as the hyoid bone. It is occasionally quite detached, or may be divided into two or more parts.

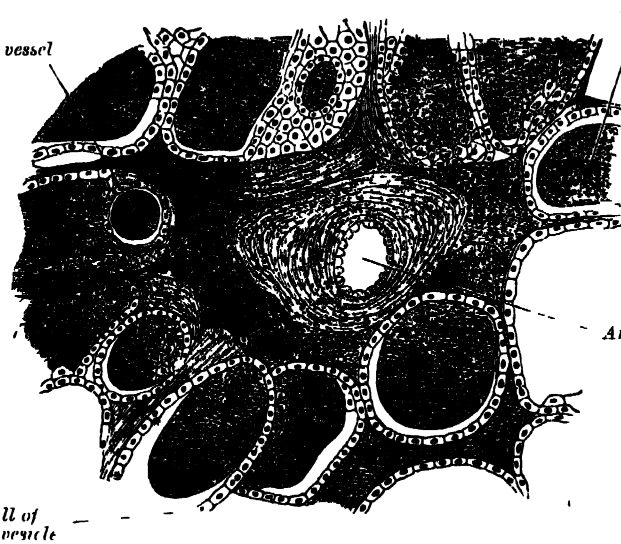
A fibrous or muscular band is sometimes found attached, above, to the body of the hyoid bone, and below to the isthmus of the gland, or its pyramidal process. When muscular, it is termed the *Levator glandulæ thyreoideæ*.

Small detached portions of thyroid tissue are sometimes found in the vicinity of the lateral lobes or above the isthmus; they are called *accessory thyroids*.

Structure.—The thyroid body is invested by a thin capsule of connective tissue, which projects into its substance and imperfectly divides it into masses of irregular form and size. When the organ is cut into, it is of a brownish-red colour, and is seen to be made up of a number of closed vesicles, containing a yellow glairy fluid, and separated from each other by intermediate connective tissue.

According to Baber, the vesicles of the thyroid of the adult animal are generally closed cavities; but in some young animals (e.g. young dogs) the vesicles are more or less tubular and branched. This appearance he supposes to be due to the mode of growth of the gland, and merely indicating that an increase in the number of vesicles is taking place. Each vesicle is composed of a fine basement-membrane, lined by a single layer of cubical epithelium, surrounding a large lumen; between the epithelial cells exists a delicate reticulum. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homo-

FIG. 1022.—Minute structure of thyroid. From a transverse section of the thyroid of a dog. (Semi-diagrammatic.) (Baber.)



geneous, semi-fluid, slightly yellowish, colloid material; red corpuscles are found in it in various stages of disintegration and decolorisation, the yellow tinge being probably due to the hæmoglobin, which is thus set free from the coloured corpuscles. The colloid material contains an iodine compound, *thyroidin*, readily stained by eosin. It passes out between the cubical cells and is absorbed into the blood or lymph.

The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymphatics, which surround a greater or smaller part of the circumference of the vesicle. The lymphatic vessels run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule of the gland.

Vessels and Nerves.—The *arteries* supplying the thyroid are the superior and inferior thyroid, and sometimes an additional branch (thyreoidea media or ima) from the innomi-

nate artery or the arch of the aorta, which ascends upon the front of the trachea. The arteries are remarkable for their large size and frequent anastomoses. The *veins* form a plexus on the surface of the gland and on the front of the trachea; from this plexus the superior, middle, and inferior thyroid veins arise; the superior and middle terminate in the internal jugular, the inferior in the innominate vein. The *lymphatics* are numerous, of large size, and end in the thoracic and right lymphatic ducts. The *nerves* are derived from the middle and inferior cervical ganglia of the sympathetic.

Applied Anatomy.—An enlargement of the thyroid gland is called a goitre. The swelling may take the form of a diffuse hypertrophy of the whole gland, giving rise to the *parenchymatous goitre*, this being mainly due to the hypertrophy of the thyroid follicles themselves; in other cases a *fibroid* form of goitre is produced owing to the increase in the interstitial connective tissue; in others, again, the vascular changes may preponderate, and many large pulsating vessels may be present. Much more commonly, however, the enlargement is due to adenomatous new growth in the substance of the thyroid; these tumours are always innocent, and tend to destroy life only by pressure on the air passages. A single tumour is the rule, but in some instances a very large number may be present. They tend to show marked mucoid degeneration, and so become converted into cyst-adenomata, and finally into what appear to be simple cysts. These tumours may attain an enormous size and may involve practically the whole gland. Malignant tumour-growth also, more rarely, attacks the organ.

When, in spite of treatment, a goitre continues to grow, and especially when there are commencing symptoms of tracheal pressure, operative interference becomes necessary. This is not difficult, if an encapsuled tumour is to be dealt with, provided the anatomical layers covering it are remembered. In such a case it is necessary to make an incision suited to the size and situation of the tumour, and having divided the deep cervical fascia, to retract the Sterno-mastoid or divide it if necessary. The Sterno-hyoid and Sterno-thyroid muscles next require division, or in some cases their fibres may be separated and drawn asunder, and beneath is found the ensheathing capsule derived from the pre-tracheal fascia; this requires division, and exposes the true capsule of the thyroid gland. In the case of an adenoma or cyst, this true capsule then needs incision before the tumour can be effectually shelled out, and this is usually accomplished with very little hæmorrhage, and without any of the main vessels of the gland requiring ligature.

Partial extirpation of the thyroid, viz. the removal of one lateral lobe with division of the isthmus, may be required in cases of parenchymatous goitre, and possibly in early cases of malignant disease. It is a more radical proceeding, and carries with it a much greater risk from hæmorrhage; there is also a danger of wounding the recurrent laryngeal nerve. The whole gland must never be removed, as such a procedure is followed by the development of myxœdema. In hemi-thyroidectomy a free incision is indicated—dividing muscles, if necessary—to expose the true gland capsule, but at the same time avoiding injury to the large vessels which lie beneath it. The superior and inferior pedicles containing the respective thyroid arteries are then isolated and clamped on either side and divided between the clamps. The half gland is then turned over towards the middle line, and the isthmus ligatured and divided. Some venous bleeding is apt to occur from connections with the tracheal veins, and must be stopped. The pedicles are then securely ligatured and the wound closed. In dealing with the inferior thyroid artery, the position of the recurrent laryngeal nerve must be borne in mind, so as not to ligature or divide it. Temporary aphonia not uncommonly follows from bruising of the nerve, and if nothing more serious has occurred soon passes off.

The Parathyroid Glands

The **parathyroid glands** are small brownish-red bodies, situated near the thyroid gland, but differing from it in structure, being composed of masses of cells arranged in a more or less columnar fashion with numerous intervening capillaries. They measure on an average about a quarter of an inch in length, and from a sixth to an eighth of an inch in breadth, and usually present the appearance of flattened oval discs. They are divided, according to their situation, into *superior* and *inferior*. The superior, usually two in number, are the more constant in position, and are situated, one on either side, at the level of the lower border of the cricoid cartilage, behind the junction of the pharynx and œsophagus, and in front of the prevertebral fascia. The inferior, also usually two in number, may be applied to the lower edge of the lateral lobe, or placed at some little distance below the thyroid body, or found in relation to one of the inferior thyroid veins.*

In man, they number four as a rule; fewer than four were found in less

* Consult an article 'Concerning the Parathyroid Glands,' by D. A. Welsh, *Journal of Anatomy and Physiology*, vol xxxii.

than 1 per cent. of over a thousand persons (Pepere *), but more than four in over 33 per cent. of 122 bodies examined by Civalleri. In addition, numerous minute islands of parathyroid tissue may be found scattered in the connective tissue and fat of the neck round the parathyroid glands proper, and quite distinct from them.

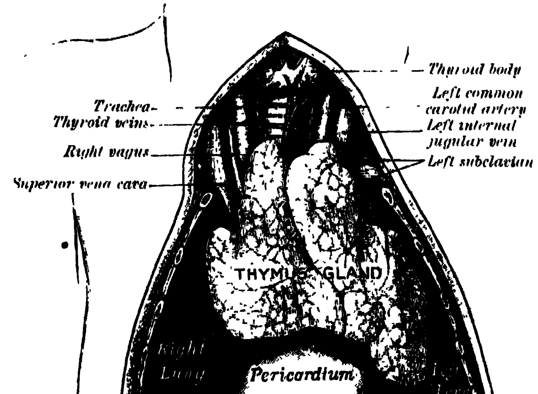
Structure.—Microscopically the parathyroids show great variety in structure. Masses of gland cells, gland cells in networks, columns, or alveoli, and in follicles containing a colloid secretion, all occur normally. In addition, the amount and disposition of the fat, blood-vessels, and fibrous tissue all vary widely, not only in different parathyroids, but even in different parts of the same parathyroid gland.

Applied Anatomy.—No doubt the parathyroid glands produce an internal secretion essential to the well-being of the human economy; but it is still a matter of dispute what symptoms of disease are produced by their removal and suppression of their secretion. Pepere believes that they show signs of exceptional activity during pregnancy, and that parathyroid insufficiency is a main factor in the production of tetany in infants and adults, of eclampsia, and of certain sorts of fits.

The Thymus Gland (fig. 1023)

The **thymus gland** is a temporary organ, attaining its full size at the end of the second year, when it ceases to grow, and gradually dwindles, until at puberty it has almost disappeared. If examined when its growth is most active, it will be found to consist of two lateral lobes placed in close contact along the middle line, situated partly in the thorax, partly in the neck, and extending from the fourth costal cartilage upwards, as high as the lower border of the thyroid gland. It is covered by the sternum, and by the origins of the Sterno-hyoid and Sterno-thyroid muscles. Below, it rests upon the

Fig. 1023.—The thymus gland of a full-time fœtus, exposed *in situ*.



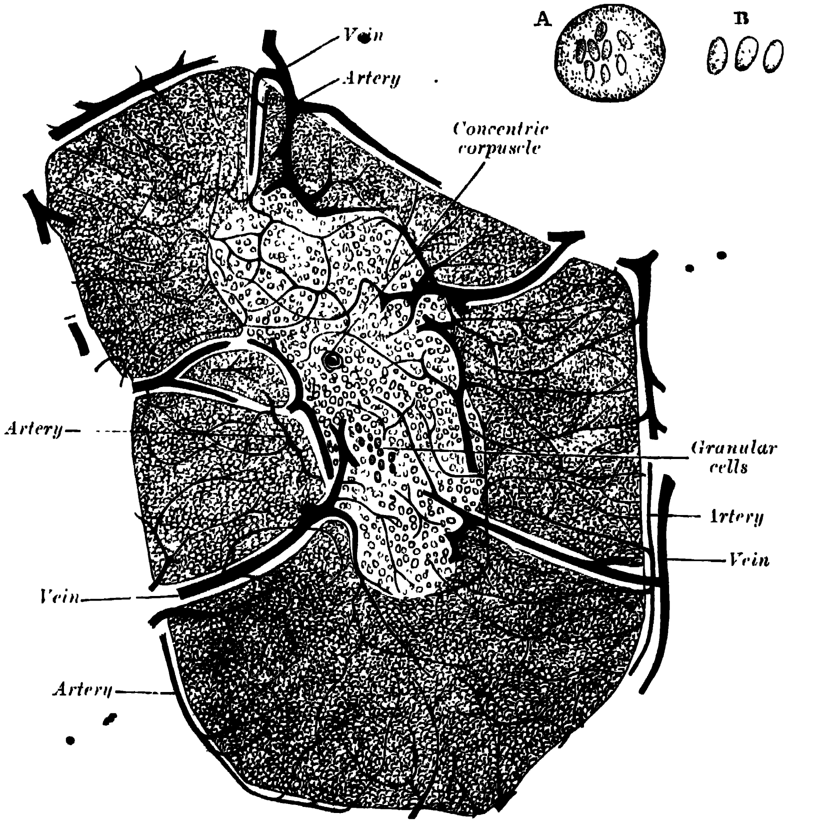
pericardium, being separated from the arch of the aorta and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sterno-hyoid and Sterno-thyroid muscles. The two lobes generally differ in size; they are occasionally united, so as to form a single mass; and sometimes separated by an intermediate lobe. The thymus is of a pinkish-grey colour, soft, and lobulated on its surfaces. It is about two inches in length, one and a half in breadth below, and about three or four lines in thickness. At birth it weighs about half an ounce.

Structure.—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue; the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from that of a pin's head to that of a small pea, and are made up of a number of small nodules or follicles, which are irregular in shape and are more or less fused together, especially towards the interior of the gland. Each follicle consists of a medullary and a cortical portion, and these differ in many essential

* Consult *Le Ghiandole paratiroidee*, by A. Pepere, Turin, 1906.

particulars from each other. The *cortical portion* is mainly composed of lymphoid cells, supported by a delicate reticulum. In addition to this reticulum, of which only traces are found in the medullary portion, there is also a network of finely branched cells, which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the *medullary portion* there are but few lymphoid cells, but there are, especially towards the centre, granular cells and concentric corpuscles. The granular cells are rounded or flask-shaped masses, attached (often by fibrillated extremities) to blood-vessels and to newly formed connective tissue. The concentric corpuscles are composed of a central mass, consisting of one or more granular cells, and of a capsule which is formed of epithelioid cells; these latter are continuous with the branched cells forming the network mentioned above.

FIG. 1024.—Minute structure of thymus gland. Follicle of injected thymus from calf, four days old, slightly diagrammatic, magnified about 50 diameters. The large vessels are disposed in two rings, one of which surrounds the follicle, the other lies just within the margin of the medulla. (Watney.)



A and B. From thymus of camel, examined without addition of any reagent. Magnified about 400 diameters. A. Large colourless cell, containing small oval masses of hæmoglobin. Similar cells are found in the lymph-glands, spleen, and medulla of bone. B. Coloured blood-corpuscles.

Each follicle is surrounded by a capillary plexus, from which vessels pass into the interior, and radiate from the periphery towards the centre, forming a second zone just within the margin of the medullary portion. In the centre of the medulla there are very few vessels, and they are of minute size.

Watney has made the important observation that hæmoglobin is found in the thymus, either in cysts or in cells situated near to, or forming part of, the concentric corpuscles. This hæmoglobin occurs as granules or as circular masses exactly resembling coloured blood-corpuscles. He has also discovered, in the lymph issuing from the thymus, similar cells to those found in the gland, and, like them, containing hæmoglobin in the form of either granules or masses. From these facts he arrives at the conclusion that the thymus is one source of the coloured blood-corpuscles.

Vessels and Nerves.—The *arteries* supplying the thymus are derived from the internal mammary, and from the superior and inferior thyroid. The *veins* terminate in the left

innominate vein, and in the thyroid veins. The *lymphatics* are described on page 793. The *nerves* are exceedingly minute; they are derived from the pneumogastric and sympathetic. Branches from the descendens hypoglossi and phrenic reach the investing capsule, but do not penetrate into the substance of the gland.

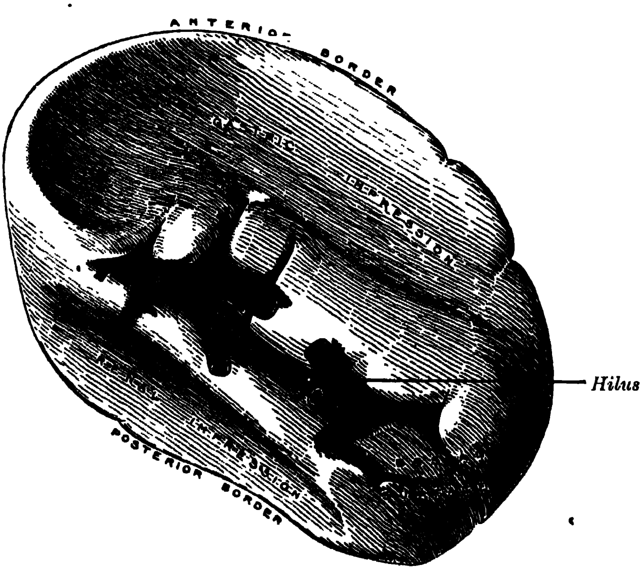
Applied Anatomy.—Sudden death—'thymus death'—with heart-failure, and with or without acute respiratory embarrassment, has been recorded in a number of infants and children in whom the thymus gland was considerably enlarged and the lymphatic tissues throughout the body showed general hypertrophy, but who showed no other evidence of disease. Such deaths have often occurred during the administration of anæsthetics, particularly chloroform. How far the enlarged thymus was responsible for the death of these patients, and, if it was responsible, how far its action was mechanical, are points that have been much disputed. Short of producing this sudden death, it appears that thymic enlargement may cause attacks of respiratory stridor, or noisy and difficult breathing, and spasmodic attacks of asthma—'thymic asthma'—which may be frequently repeated and may even result in death. Primary tumours of the thymus are rare forms of mediastinal new growth, and are usually dermoids or lymphosarcomas.

The Spleen

The **spleen** (lien) is situated principally in the left hypochondriac region, but its upper and inner extremity extends into the epigastric region; it lies between the fundus of the stomach and the Diaphragm. It is the largest of the ductless glands, and is of an oblong, flattened form, soft, of very friable consistence, highly vascular, and of a dark purplish colour.

Relations.—The *external* or *diaphragmatic surface* (facies diaphragmatica) is convex, smooth, and is directed upwards, backwards, and to the left, except at its upper end, where it is directed slightly inwards. It is in relation with the under surface of the Diaphragm, which separates it from the ninth, tenth,

Fig. 1025.—The spleen, showing its gastric and renal surfaces.



and eleventh ribs of the left side, and the intervening lower border of the left lung and pleura.

The *internal surface* is divided by a ridge into an anterior or gastric, and a posterior or renal portion.

The *gastric surface* (facies gastrica), which is directed forwards and inwards, is broad and concave, and is in contact with the posterior wall of the fundus of the stomach; and below this with the tail of the pancreas. It presents near its inner border a long fissure, termed the hilus. This is pierced by several irregular apertures, for the entrance and exit of vessels and nerves.

The *renal surface* (facies renalis) is directed inwards and downwards. It is somewhat flattened, is considerably narrower than the gastric surface, and

is in relation with the upper part of the outer surface of the left kidney and occasionally with the left suprarenal gland.

The *upper end* is directed inwards, towards the vertebral column, where it lies on a level with the eleventh thoracic vertebra. The *lower end*, sometimes termed the *basal surface*, is flat, triangular in shape, and rests upon the splenic flexure of the colon and the phreno-colic ligament, and is generally in contact with the tail of the pancreas. The *anterior* border is free, sharp, and thin, and is often notched, especially below; it separates the diaphragmatic from the gastric surface. The *posterior* border, more rounded and blunter than the anterior, separates the renal from the diaphragmatic surface; it corresponds to the lower border of the eleventh rib and lies between the Diaphragm and left kidney. The *internal* border or intermediate margin is the ridge which separates the renal and gastric surfaces. The *inferior* border separates the diaphragmatic from the basal surface.

The spleen is almost entirely surrounded by peritoneum, which is firmly adherent to its capsule. It is held in position by two folds of this membrane. One, the *lieno-renal ligament*, is derived from the layers of peritoneum forming the greater and lesser sacs, where they come into contact between the left kidney and the spleen; the splenic vessels pass between its two layers (fig. 926). The other fold, the *gastro-splenic omentum*, is also formed of two layers, derived from the greater and lesser sacs respectively, where they meet between the spleen and stomach (fig. 926); the vasa brevia and left gastro-epiploic branches of the splenic artery run between its two layers. The lower end or basal surface of the spleen is supported by the phreno-colic ligament (see page 1129).

The size and weight of the spleen are liable to very extreme variations at different periods of life, in different individuals, and in the same individual under different conditions. *In the adult*, it is usually about five inches in length, three inches in breadth, and an inch or an inch and a half in thickness, and weighs about seven ounces. *At birth*, its weight, in proportion to the entire body, is almost equal to what is observed in the adult, being as 1 to 350: while in the adult it varies from 1 to 320 and 400. *In old age*, the organ not only diminishes in weight, but decreases considerably in proportion to the entire body, being as 1 to 700. The size of the spleen is increased during and after digestion, and varies according to the state of nutrition of the body, being large in highly fed, and small in starved animals. In malarial fever it becomes much enlarged, weighing occasionally even from eighteen to twenty pounds.

Frequently in the neighbourhood of the spleen, and especially in the gastro-splenic and great omenta, small nodules of splenic tissue may be found, either isolated or connected to the spleen by thin bands of splenic tissue. They are known as *supernumerary* or *accessory spleens*. They vary in size from that of a pea to that of a plum.

Structure.—The spleen is invested by two coats: an external serous and an internal fibro-elastic coat.

The *external* or *serous coat* is derived from the peritoneum; it is thin, smooth, and in the human subject intimately adherent to the fibro-elastic coat. It invests the entire organ, except at the hilus and along the lines of reflection of the lieno-renal ligament and gastro-splenic omentum.

The *fibro-elastic coat* invests the organ, and at the hilus is reflected inwards upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, *trabeculæ* (fig. 1026), are given off in all directions; these uniting, constitute the framework of the spleen. The spleen therefore consists of a number of small spaces or *areolæ*, formed by the trabeculæ; in these areolæ is contained the *splenic pulp*.

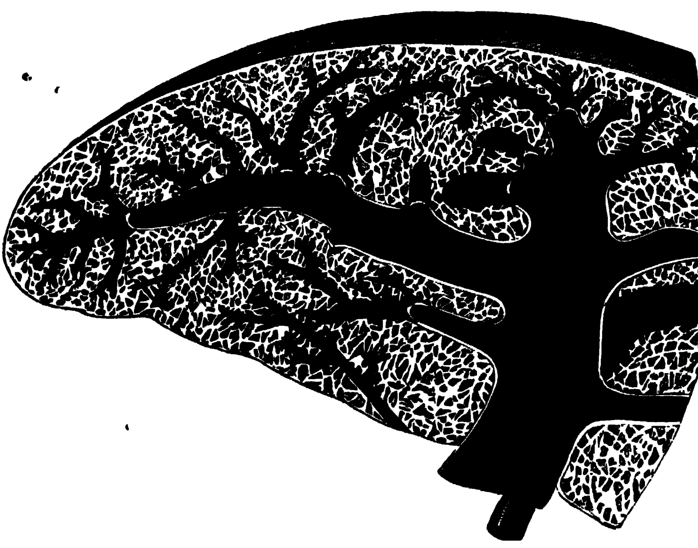
The fibro-elastic coat, the sheaths of the vessels, and the trabeculæ, are composed of white, and yellow elastic, fibrous tissues, the latter predominating. It is owing to the presence of the elastic tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents of this tunic, there is found in man a small amount of non-striped muscular fibre; and in some mammalia (e.g. dog, pig, and cat) a large amount, so that the trabeculæ appear to consist chiefly of muscular tissue.

The *splenic pulp* is a soft mass of a dark reddish-brown colour, resembling grumous blood; it consists of a number of branching cells and of an intercellular substance. The cells are connective-tissue corpuscles, and are termed the *sustentacular* or *supporting cells of the pulp*. The processes of these cells communicate with each other, thus forming a

delicate reticulated tissue in the interior of the areolæ, so that each areola may be considered to be divided into a number of smaller spaces by the junction of the processes of the branching corpuscles. These secondary spaces are full of blood, in which, however, the white corpuscles are found to be in larger proportion than they are in ordinary blood. Large rounded cells, termed *splenic cells,* are also seen; these are capable of amœboid movement, and often contain pigment and red blood-corpuscles in their interior. The sustentacular cells are either small uni-nucleated, or large multi-nucleated cells; they do not stain deeply with carmine, and in this respect differ from the cells of the Malpighian bodies, but like these cells they exhibit amœboid movements. In many of them may be seen deep red or reddish-yellow granules of various sizes, also blood-corpuscles in all stages of disintegration. Klein has pointed out that sometimes these cells, in the young spleen, contain proliferating nuclei; that is to say, the nucleus is of large size, and presents a number of knob-like projections, as if small nuclei were budding from it by a process of gemmation. This observation is of importance, as it may explain one possible source of the colourless blood-corpuscles.

Blood-vessels of the spleen.—The splenic artery is remarkable for its large size in proportion to the size of the organ, and also for its tortuous course. It divides into six or more branches, which enter the hilus of the spleen and ramify throughout its substance (fig. 1027), receiving sheaths from an involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

FIG. 1026.—Transverse section of the spleen, showing the trabecular tissue and the splenic vein and its tributaries.



Each branch runs in the transverse axis of the organ, from within outwards, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells. Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.

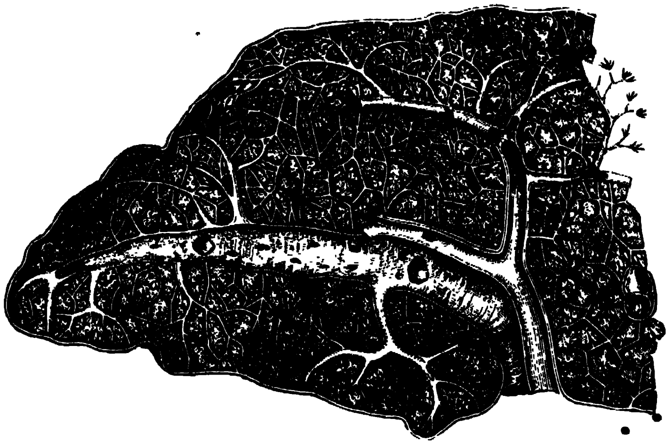
The *arterioles*, supported by the minute trabeculæ, traverse the pulp in all directions in bundles of straight vessels. Their external coats, on leaving the trabecular sheaths, consist of ordinary connective tissue, but they gradually undergo a transformation, become much thickened, and converted into adenoid material.* This change is effected by the conversion of the connective tissue into adenoid tissue; the bundles of connective tissue becoming looser and their fibrils more delicate, and containing in their interstices an abundance of lymph-corpuscles (W. Müller).

The altered coat of the arterioles, consisting of adenoid tissue, presents here and there thickenings of a spheroidal shape, the *Malpighian bodies of the spleen.* These bodies vary

* According to Klein, it is the sheath of the small vessel which undergoes this transformation, and forms a 'solid mass of adenoid tissue which surrounds the vessel like a cylindrical sheath.'—*Atlas of Histology*, p. 424.

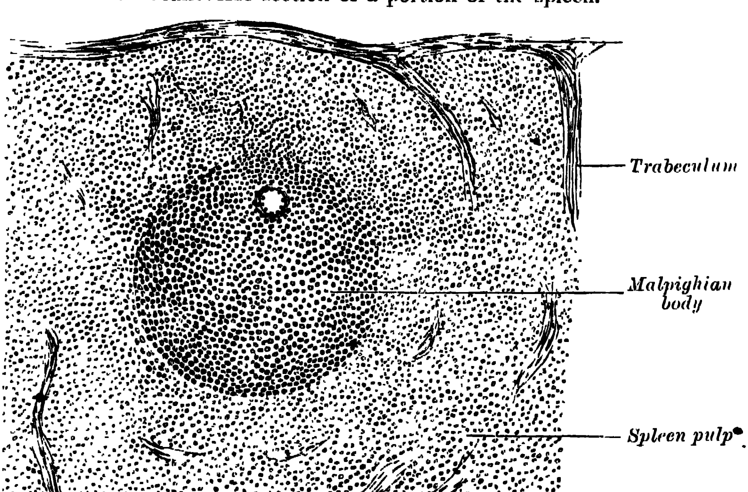
in size from about $\frac{1}{100}$ of an inch to $\frac{1}{25}$ of an inch in diameter. They are merely local expansions or hyperplasiæ of the adenoid tissue of which the external coat of the smaller arteries of the spleen is formed. They are most frequently found surrounding the arteriole, which thus seems to tunnel them, but occasionally they grow from one side of the vessel only, and present the appearance of a sessile bud growing from the arterial wall. Klein, however, denies this, and says it is incorrect to describe the Malpighian bodies as isolated

FIG. 1027.—Transverse section of the human spleen, showing the distribution of the splenic artery and its branches.



masses of adenoid tissue, that they are always formed around an artery, though there is generally a greater amount on one side than on the other, and that, therefore, in transverse sections, the artery, in the majority of cases, is found in an eccentric position. These bodies are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute dots of a semi-opaque whitish colour in the dark substance of the pulp. In

FIG. 1028.—Transverse section of a portion of the spleen.



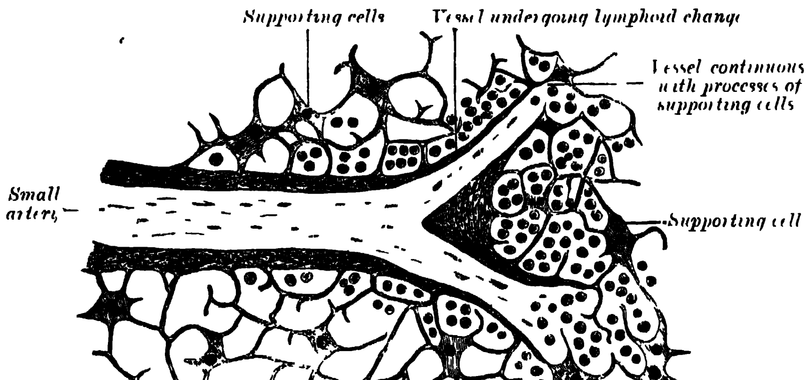
minute structure they resemble the adenoid tissue of lymphatic glands, consisting of a delicate reticulum, in the meshes of which lie ordinary lymphoid cells (fig. 1028).

The reticulum of the tissue is made up of extremely fine fibrils, and is comparatively open in the centre of the corpuscle, becoming closer at its periphery. The cells which it encloses, like the supporting cells of the pulp, are possessed of amœboid movements, but when treated with carmine become deeply stained, and can be easily distinguished from those of the pulp.

The arterioles terminate in capillaries, which traverse the pulp in all directions; their walls become much attenuated, lose their tubular character, and the cells of the adenoid tissue of which they are composed become altered, presenting a branched appearance, and acquiring processes which are directly connected with the processes of the sustentacular cells of the pulp (fig. 1029). In this manner the capillary vessels terminate, and the blood flowing through them finds its way into the interstices of the reticulated tissue formed by the branched connective-tissue corpuscles of the splenic pulp. Thus the blood passing through the spleen is brought into intimate relation with the elements of the pulp, and no doubt undergoes important changes.

After these changes have taken place the blood is collected from the interstices of the tissue by the rootlets of the veins, which commence much in the same way as the arteries terminate. Where a vein is about to commence, the connective-tissue corpuscles of the pulp arrange themselves in rows, in such a way as to form an elongated space or sinus. They become changed in shape, being elongated and spindle-shaped, and overlap each other at their extremities. They thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these cells are seen delicate transverse lines or markings, which are due to minute elastic fibrillæ arranged in a circular manner around the sinus. Thus the channel obtains an external investment, and gradually becomes converted into a small vein, which after a time attains a coat of ordinary connective tissue, lined by a layer of fusiform epithelial cells which are continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones; these do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form six or more branches, which emerge from the hilus, and, uniting, constitute the splenic vein, the largest radicle of the portal vein.

FIG. 1029.—Section of the spleen, showing the termination of the small blood-vessels.



The veins are remarkable for their numerous anastomoses, while the arteries hardly anastomose at all.

The lymphatics are described on page 787.

The *nerves* are derived from branches of the right and left semilunar ganglia, and from the right pneumogastric nerve.

Surface Marking.—The spleen is situated under cover of the ribs of the left side, being separated from them by the Diaphragm, and above by a small portion of the lower margin of the left lung and pleura. Its position corresponds to the ninth, tenth, and eleventh ribs. It is placed very obliquely. 'It is oblique in two directions, viz. from above downwards and outwards, and also from above downwards and forwards' (Cunningham). 'Its highest and lowest points are on a level respectively with the ninth dorsal and first lumbar spines; its inner end is distant about an inch and a half from the median plane of the body, and its outer end about reaches the mid-axillary line' (Quain).

Applied Anatomy.—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be ruptured by direct or indirect violence; torn by a broken rib; or injured by a punctured or gunshot wound. When the organ is enlarged, the chance of rupture is increased. The great risk is hæmorrhage, owing to the vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due, in a great measure, to the contractile power of the capsule, which narrows the wound and prevents the escape of blood. In cases where the diagnosis is clear, and the symptoms indicate danger to life, laparotomy must be performed, and if the hæmorrhage cannot be stayed by ordinary surgical methods, the spleen must be removed.

The spleen may become enormously enlarged in certain diseased conditions, such as ague, leukæmia, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma, as a part of a general blood-disease. In these cases the tumour may fill a considerable part of the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine new growth.

The spleen is sometimes the seat of cystic tumours, especially hydatids, and of abscess. These cases require treatment by incision and drainage; and in abscess great care must be taken, if there are no adhesions between the spleen and abdominal wall, to prevent the escape of any of the pus into the peritoneal cavity. If possible the operation should be performed in two stages. Sarcoma and carcinoma are occasionally found in the spleen, but very rarely as a primary disease.

Extirpation of the spleen has been performed for wounds or injuries, in floating spleen, in simple hypertrophy, and in leukæmic enlargement; but in the last condition the operation is now regarded as unjustifiable, as every case in which it has been performed has terminated fatally. The incision is best made in the left semilunar line; the spleen is isolated from its surroundings, and the pedicle transfixed and ligatured in two portions, before the tumour is turned out of the abdominal cavity, if possible, so as to avoid any traction on the pedicle, which may cause tearing of the splenic vein. Care must be taken in applying the ligature not to include the tail of the pancreas, and in lifting out the organ to avoid rupturing the capsule.

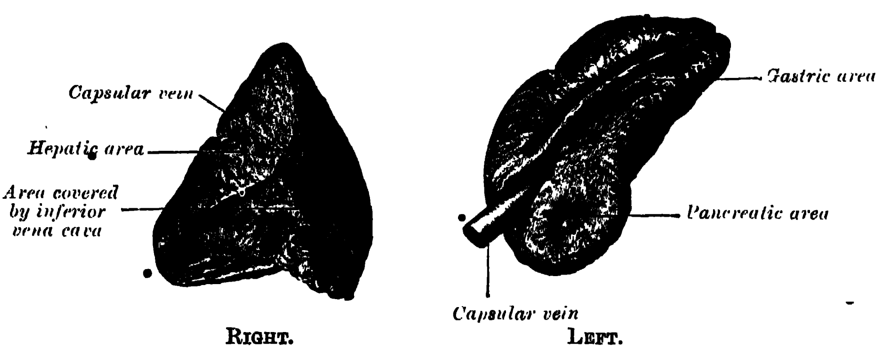
Suprarenal Glands

The **suprarenal glands** (glandulæ suprarenales) are two small flattened bodies of a yellowish colour, situated at the back part of the abdomen, behind the peritoneum, and immediately above and in front of the upper end of each kidney; hence their name. The right one is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left is more semilunar, usually larger and placed at a higher level than the right. They vary in size in different individuals, being sometimes so small as to be scarcely detected: their usual size is from an inch and a quarter to nearly two inches in length, rather less in width, and from two to three lines in thickness. Their average weight is from one to one and a half drachms each.

Relations.—The relations of the suprarenal glands differ on the two sides of the body.

The *right suprarenal* is situated behind the inferior vena cava and right lobe of the liver, and in front of the Diaphragm and upper end of the

Fig. 1030.—Suprarenal glands viewed from the front.



right kidney. It is roughly triangular in shape; its base, directed downwards, is in contact with the inner and anterior aspects of the upper end of the right kidney. It presents two surfaces for examination, an anterior and a posterior. The *anterior surface* looks forwards and outwards, and has two areas: an inner, narrow and non-peritoneal, which lies behind the inferior vena cava; and an outer, somewhat triangular, in contact with the liver. The upper part of this surface is devoid of peritoneum, and is in relation with the bare area of the liver near its lower and inner angle, while its inferior portion is covered by peritoneum, reflected on to it from the inferior layer of the coronary ligament. A little below the apex, and near the anterior border of the gland,

is a short furrow termed the hilus, from which the suprarenal vein emerges to join the inferior vena cava. The *posterior surface* is divided into upper and lower parts by a curved ridge: the upper, slightly convex, rests upon the Diaphragm; the lower, concave, is in contact with the upper end and the adjacent part of the anterior surface of the kidney.

The *left suprarenal*, slightly larger than the right, is crescentic in shape, its concavity being adapted to the inner border of the upper part of the left kidney. It presents an inner border which is convex, and an outer which is concave; its upper border is narrow, and its lower rounded. Its *anterior surface* has two areas: an upper one, covered by the peritoneum forming the lesser sac, which separates it from the cardiac end of the stomach and sometimes from the superior extremity of the spleen; and a lower one, which is in

FIG. 1031.—Suprarenal glands viewed from behind.

contact with the pancreas and splenic artery, and is therefore not covered by the peritoneum. On the anterior surface, near its lower end, is a furrow or hilus, directed downwards and forwards, from which the suprarenal vein emerges. Its *posterior surface* presents a vertical ridge, which divides it into two areas; the outer area rests on the kidney, the inner and smaller, on the left crus of the Diaphragm.

The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous capsule, which is difficult to remove on account of the numerous fibrous processes and vessels entering the organ through the furrows on its anterior surface and base.

Small accessory suprarenals are often to be found in the connective tissue round the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

Structure.—On section, the suprarenal gland is seen to consist of two portions: an external or cortical, and an internal or medullary. The former constitutes the chief part of the organ and is of a deep yellow colour; the medullary substance is soft, pulpy, and of a dark red or brown colour.

The *cortical portion* consists of a fine connective-tissue network, in which is imbedded the glandular epithelium. The epithelial cells are polyhedral in shape and possess rounded nuclei; many of the cells contain coarse granules, others fat globules. Owing to differences in the arrangement of the cells three distinct zones can be made out: (1) the *zona glomerulosa*, situated beneath the capsule, consists of cells arranged in rounded groups, with here and there indications of an alveolar structure; the cells of this zone are very granular and stain deeply. (2) The *zona fasciculata*, continuous with the zona glomerulosa, is composed of quadrilateral groups of cells arranged in a radial manner; these cells contain finer granules and in many instances fat globules. (3) The *zona reticularis*, in contact with the medulla, consists of cylindrical masses of cells irregularly arranged; these cells often contain pigment granules which give this zone a darker appearance than the rest of the cortex.

The *medullary portion* is extremely vascular, and is composed of a loose meshwork of connective tissue surrounding a large plexus of veins and containing non-striped muscular fibres. In addition to the veins, multi-nucleated masses of protoplasm are scattered throughout the medulla as well as many irregular-shaped cells containing pigment. The cell-protoplasm has an especial affinity for chromic salts, which stain it a brown colour. Such cells are therefore termed *chromaffin cells*. This portion of the gland is richly supplied with non-medullated nerve-fibres, and here and there sympathetic ganglia are found.

Vessels and Nerves.—The *arteries* supplying the suprarenal glands are numerous and of comparatively large size; they are derived from the aorta, the inferior phrenic, and the renal. They subdivide into minute branches previous to entering the cortical part of the gland, where they break up into capillaries which end in the venous plexus of the medullary portion.

The *suprarenal vein* returns the blood from the medullary venous plexus and receives several branches from the cortical substance; it emerges from the hilus of the gland and on the right side opens into the inferior vena cava, on the left into the renal vein.

The *lymphatics* terminate in the lumbar glands.

The *nerves* are exceedingly numerous, and are derived from the solar and renal plexuses, and, according to Bergmann, from the phrenic and pneumogastric nerves. They enter the lower and inner part of the capsule, traverse the cortex, and terminate around the cells of the medulla. They have numerous small ganglia developed upon them, from which circumstance the organ has been conjectured to have some function in connection with the sympathetic nervous system.

Applied Anatomy.—The suprarenal *cortex* is derived from the cœlomic epithelium of the Wolffian ridge, and is connected with the sexual glands; it is related to growth and development in some way, and is often found to be hypertrophied in patients with chronic kidney disease and high blood-pressure. The *medulla*, on the other hand, is neuro-ectodermal in origin, and closely connected with the sympathetic nervous system. It supplies the body with an internal secretion called *adrenalin*, that tends to raise the blood-pressure by stimulating the vaso-constrictor fibres of the sympathetic. When the suprarenal medulla is destroyed by tuberculosis, to which the glands are prone, or by the pressure of a new growth, the secretion of adrenalin becomes inadequate, and Addison's disease develops. Patients with Addison's disease become pigmented in various parts of the body, possibly from irritation of the sympathetic, and complain of great weakness, lack of energy, nausea, and severe attacks of vomiting. Their blood-pressure is low, the whole nervous system is depressed, and death follows after a period of months or years, usually from asthenia. Tumours derived from the suprarenal itself, or from misplaced suprarenal 'rests' occurring in such organs as the kidney or liver, may be either benign or malignant, and are classed together under the name 'hypernephroma.' In children the malignant hypernephroma is often associated with obesity and precocity. The benign hypernephroma, or suprarenal adenoma, appears to produce no symptoms except those due to its slow enlargement.

The **carotid bodies**, two in number, are situated one on either side of the neck, behind the common carotid artery at its point of bifurcation into the external and internal carotid trunks. They are reddish-brown in colour and oval in shape, the long diameter measuring about one-fifth of an inch. Each is invested by a fibrous capsule and consists largely of spherical or irregular masses of cells—the masses being more or less isolated from one another by septa which extend inwards from the deep surface of the capsule. The cells are polyhedral in shape, and each contains a large nucleus imbedded in finely granular protoplasm which is stained yellow by chromic salts. Numerous nerve-fibres, derived from the sympathetic plexus on the carotid artery, are distributed throughout the organ, and a network of large capillaries ramifies amongst the cells.

The **coccygeal body** or *gland of Luschka* is placed in front of, or immediately below, the tip of the coccyx. It is about the size of a millet-seed and is irregularly oval in shape; several smaller nodules are found around or near the main mass. It consists of irregular masses of round or polyhedral cells,

the cells of each mass being grouped around a dilated capillary vessel. Each cell contains a large round or oval nucleus, the protoplasm surrounding which is clear and is not stained by chromic salts.*

Besides the ductless glands mentioned, reference may be made to a pair of small bodies, the **aortic bodies of Zuckerkandl**. These are found in the embryo and persist until shortly after birth; they lie one on either side of the abdominal aorta close to the origin of the superior mesenteric artery. They consist essentially of masses of polygonal or cuboidal, chromaffin, cells imbedded in a wide-meshed capillary plexus.
